The present invention provides a method of producing a planar lipid bilayer on a solid support. With this method, a solution of lipid vesicles is first deposited on the solid support. Next, the lipid vesicles are destabilized by adding an amphipathic peptide solution to the lipid vesicle solution. This destabilization leads to production of a planar lipid bilayer on the solid support. The present invention also provides a supported planar lipid bilayer, where the planar lipid bilayer is made of naturally occurring lipids and the solid support is made of unmodified gold or titanium oxide. Preferably, the supported planar lipid bilayer is continuous. The planar lipid bilayer may be made of any naturally occurring lipid or mixture of lipids, including, but not limited to phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, cardiolipin, cholesterol, and sphingomyelin.

CROSS REFERENCE TO RELATED APPLICATIONS

This application is a national stage filing under 35 U.S.C. §371 of International Patent Application Ser. No. PCT/US2006/012085, which was filed on Mar. 29, 2006 and which was published in English under PCT Article 21(2) as WO 2006/110350 on Oct. 19, 2006, which International Patent Application claims benefit of priority of U.S. Provisional Patent Application Ser. No. 60/666,647, filed Mar. 29, 2005, which applications are incorporated herein by reference in their entirety.

FEDERALLY-SPONSORED RESEARCH OR DEVELOPMENT

This invention was made with Government support under contracts NAG-8-1843 awarded by the NASA Marshall Space Flight Center and 0213618 awarded by the National Science Foundation. The Government has certain rights in this invention.

FIELD OF THE INVENTION

The present invention relates generally to lipid membranes. More particularly, the present invention relates to methods of fabricating lipid bilayer membranes on solid supports.

BACKGROUND

Supported lipid bilayers formed by the fusion of small unilamellar vesicles onto silicon oxide or organic film-modified surfaces enable the biofunctionalization of inorganic solids, such as semiconductors, gold-covered surfaces, and optoelectronic and lab-on-a-chip devices. They have proven valuable in the study of the characteristics and behavior of membrane-bound proteins, membrane-mediated cellular processes, protein-lipid interactions, and biological signal transduction. Because of the complexity of biomembranes, there is a clear need to develop model membrane systems, where one or a few membrane components can be isolated and studied. In addition, a wide range of available surface-sensitive techniques can be used to study natural biological systems effectively by supporting model membranes on a solid surface. Applications of supported membranes on solid surfaces potentially include biosensors, programmed drug delivery, the acceleration and improvement of medical implant acceptance, and the production of catalytic interfaces.

In order to mimic natural biological systems, researchers have employed vesicle fusion methods to form supported bilayers on substrates such as glass, mica, self-assembled monolayers, and quartz. However, it has proven problematic to create planar lipid bilayers on preferred solid substrates, such as gold and TiO₂. For example, scientists have attempted to modify gold surfaces using self-assembled monolayers (SAMs), which may require special synthesis, but the structure of the SAMs that are formed may not be well-defined. Accordingly, there is a need in the art to develop new methods of forming supported bilayers on preferred substrates.

SUMMARY OF THE INVENTION

The present invention provides a method of producing a planar lipid bilayer on a solid support. With this method, a

2

solution of lipid vesicles is first deposited on the solid support. Next, the lipid vesicles are destabilized by adding an amphipathic peptide solution to the lipid vesicle solution. This destabilization leads to production of a planar lipid bilayer on the solid support. Preferably, the amphipathic peptide is an alpha-helical peptide. More preferably, the alpha-helical peptide is a polypeptide having the entirety or a portion of the sequence SEQ ID NO: 1.

The present invention also provides a supported planar lipid bilayer, where the planar lipid bilayer is made of naturally occurring lipids and the solid support is made of unmodified gold or titanium oxide. Preferably, the supported planar lipid bilayer is continuous. The planar lipid bilayer may be made of any naturally occurring lipid or mixture of lipids, including but not limited to phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, cardiolipin, cholesterol, and sphingomyelin.

BRIEF DESCRIPTION OF THE FIGURES

The present invention together with its objectives and advantages will be understood by reading the following description in conjunction with the drawings, in which:

FIG. 1 shows a method of producing a planar lipid bilayer according to the present invention.

FIG. 2 shows quartz crystal microbalance-dissipation (QCM-D) analysis of planar lipid bilayer formation on a gold substrate according to the present invention.

FIG. 3 shows QCM-D analysis of planar lipid bilayer formation on a TiO₂ substrate according to the present invention.

FIG. 4 shows atomic force microscopy (AFM) analysis of planar lipid bilayer formation on a TiO₂ substrate according to the present invention.

DETAILED DESCRIPTION OF THE INVENTION

FIG. 1 illustrates a schematic of a method according to the present invention. FIG. 1A shows lipid vesicles **110** that have been deposited onto solid substrate **120**. The vesicles have adsorbed to solid substrate **120**. A large amount of water, indicated by circles **130**, is trapped within the intact vesicles as well as between vesicles adsorbed on the surface of solid substrate **120**. After addition of an amphipathic peptide (AP) solution (FIG. 1B), the vesicles are destabilized and ruptured, allowing the ruptured vesicles to fuse and form planar bilayer **112**. When planar bilayer **112** forms, water **130** trapped within vesicles **112** is dispersed to form water layer **132**.

The amphipathic peptide is preferably an alpha-helical peptide. More preferably, the amphipathic peptide is the AH peptide of the HCV nonstructural protein NS5A. This peptide is conserved across HCV isolates and has the sequence SEQ ID NO: 1. Either the entire peptide, amino acids 1-16 of the peptide (AH_S1), or amino acids 17-31 of the peptide (AH_S2) may be used to destabilize the lipid vesicles. Alternatively, the peptide may not have the exact sequence of SEQ ID NO: 1, as long as its amphipathic alpha-helical nature is preserved. For example, as shown by circular dichroism, the peptide may have a sequence that is at least about 80% identical to SEQ ID NO: 1, while still maintaining alpha-helicity. Preferably, the concentration of amphipathic peptide in the peptide solution is between about 0.05 µg/ml to 0.5 µg/ml. The amphipathic peptide may be contained in a variety of solvents, including biological buffers (such as Tris buffer, PBS buffer, and HEPES Buffer) and dimethylsulfoxide (DMSO).

Lipid vesicles suitable for the present invention are preferably between about 25 nm and about 80 nm in diameter. The

3

vesicles may be prepared using any method known in the art, including but not limited to extrusion methods. The vesicles are preferably at a concentration of about 0.05 mg/ml to about 5 mg/ml in a biological buffer, such as Tris, PBS, and HEPES buffer, with NaCl concentration of about 100 mM to about 250 mM. Any lipid or mixture of lipids may be used to form the lipid vesicles, including but not limited to phospholipids. Preferred lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, cardiolipin, cholesterol, and sphingomyelin.

Any solid support may be used according to the present invention. Example materials include, but are not limited to silicon-containing materials, gold, platinum, and titanium oxide.

The present invention also provides supported planar lipid bilayers produced using the method of the present invention. Preferably, the lipid bilayer is composed of naturally occurring lipids and the solid support is made of unmodified gold or titanium oxide. Any naturally occurring lipid may be used for the bilayer, such as phospholipids. Preferred lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, cardiolipin, cholesterol, and sphingomyelin. Preferably, planar lipid bilayers according to the present invention are continuous, i.e. there are no gaps in the layer.

EXAMPLES

Formation of a Planar Lipid Bilayer on a Solid Substrate

Bilayer formation from intact vesicles was characterized using a quartz crystal microbalance-dissipation (QCM-D) instrument. To interpret the QCM-D results, a linear relationship between Δf and adsorbed mass (Δm) derived from the classical Sauerbrey equation was employed:

$$\Delta m = -\frac{C}{n} \Delta f \quad \text{Equation (1)}$$

where C is the mass-sensitivity constant with value $17.7 \text{ ng cm}^{-2} \text{ Hz}^{-1}$ for the QCM-D crystal at 5 MHz, and n is the overtone number ($n=1$ for the fundamental and 3, 5, 7 for the overtones). The QCM-D has been used in numerous studies of the vesicle fusion process, where the dissipation is used to distinguish between rigid lipid bilayers and monolayers and soft deformable vesicles (see, e.g., Keller and Kasemo, "Surface specific kinetics of lipid vesicle adsorption measured with a quartz crystal microbalance", *Biophys J.* 1998 Sep; 75(3):1397-1402).

In order to investigate the ability of AH peptides to rupture vesicles, we tested unilamellar vesicles of 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC) extruded through 30 nm polycarbonate etch-tracked (PEC) membranes on a gold surface in the absence of the AH peptide, then applied the peptide to form a bilayer. When vesicles adsorb, a large amount of trapped water exists within the intact vesicles as well as between vesicles adsorbed on the surface. This trapped water is able to dissipate a large amount of energy, unlike the water that rests on top of a bilayer. This change in energy dissipation can in turn be used to track the transition between an intact vesicle and a bilayer.

In FIG. 2, $\Delta f(t)$ (triangles) and $\Delta D(t)$ (circles) show change in frequency and change in dissipation. FIG. 2A shows vesicle adsorption on an oxidized gold surface. After 10 min (arrow 1) of stabilizing the frequency signal, the POPC vesicle solution (0.1 mg/ml, $\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) was

4

injected into a liquid cell. After 50 and 55 min (arrows 2 and 3), the same buffer that was used to dilute the vesicles (10 mM Tris (pH 7.5), 150 mM NaCl solution with 1 mM EDTA in 18.2 M Ω -cm MilliQ water (MilliPore, Oreg., USA) was used to wash the substrate twice and the stability of the intact vesicles on the gold surface was observed. As shown in FIG. 2B, at 60 min (arrow 4), an amphipathic α -helix peptide (AH peptide) solution was added (0.05 $\mu\text{g/ml}$) to the intact vesicles ($\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) on the gold surface. The peptide destabilized and ruptured the vesicles, making a complete bilayer. This is reflected in a decrease of frequency of 25.5 Hz ± 0.5 , with a maximum decrease of dissipation of as much as 0.08×10^{-6} observed. After 120 and 140 min (arrows 5 and 6), the vesicle buffer was used to wash the substrate twice and the stability of the bilayers on the gold surface was observed. According to the Sauerbrey equation, from which the bilayer thickness can be calculated, these QCM-D parameters indicate the transition of the vesicles to a thin and rigid bilayer film.

In FIG. 2C, the effect of a non-amphipathic non-helical peptide (NH peptide) was examined. Unlike the AH peptide, the NH peptide has three charged amino acids spaced at intervals along the predicted N-terminal helix such that no sustained hydrophobic patch remains. The NH peptide has an Asp rather than a Val at residue 8, a Glu instead of an Ile at residue 12, and an Asp instead of a Phe at residue 19 of SEQ ID NO:1. In FIG. 2C, after 10 min (arrow 1) of stabilizing the frequency signal, the POPC vesicle solution (0.1 mg/ml, $\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) was applied to the liquid cell. After 60 and 70 min (arrows 2 and 3), the vesicle buffer was used to wash the substrate twice and the stability of the intact vesicles on the gold surface was observed. At 85 min (arrow 4), the NH peptide solution was added (0.05 $\mu\text{g/ml}$) to the intact vesicles on the gold surface. The NH peptide does not show any evidence of having destabilized and ruptured the vesicles. After 160 min (arrow 5), the vesicle buffer was used to wash the substrate twice and the stability of the intact vesicles on the gold surface was observed.

Formation of a Planar Lipid Bilayer on a TiO₂ Substrate

In order to investigate the ability of AH peptides to rupture vesicles on a TiO₂ surface, we tested unilamellar vesicles of POPC extruded through 30 nm PEC membranes on a TiO₂ surface in the absence of the AH peptide, then applied the peptide to form a bilayer (FIG. 3). In FIG. 3, $\Delta f(t)$ (triangles) and $\Delta D(t)$ (circles) show change in frequency and change in dissipation. FIG. 3A shows vesicle adsorption on a TiO₂ surface. After 10 min (arrow 1) of stabilizing the frequency signal, the POPC vesicle solution (0.1 mg/ml, $\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) was injected into the liquid cell. After 60 and 65 min (arrows 2 and 3), the same buffer that was used to dilute the vesicles (10 mM Tris (pH 7.5); 150 mM NaCl solution with 1 mM EDTA in 18.2 M Ω -cm MilliQ water (MilliPore, Oreg., USA) was used to wash the substrate twice and the stability of the intact vesicles on the TiO₂ surface was observed. As shown in FIG. 3B, at 70 min (arrow 4), the AH peptide solution was added (0.05 $\mu\text{g/ml}$) to the intact vesicles ($\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) on the TiO₂ surface (FIG. 2B). The peptide destabilized and ruptured the vesicles, making a complete bilayer. After 270 min (arrow 5), the vesicle buffer was used to wash the substrate twice and the stability of the bilayers on the TiO₂ surface was observed.

In FIG. 3C, the effect of the NH peptide was examined. In FIG. 3C, after 10 min (arrow 1) of stabilizing the frequency signal, the POPC vesicle solution (0.1 mg/ml, $\phi_{30nm \text{ PEC}}=59 \text{ nm} \pm 0.2 \text{ nm}$) was applied to the liquid cell. After 40 and 50 min (arrows 2 and 3), the vesicle buffer was used to wash the substrate twice and the stability of the intact vesicles on the

5

TiO₂ surface was observed. At 60 min (arrow 4), the NH peptide solution was added (0.05 µg/ml) to the intact vesicles on the TiO₂ surface. The NH peptide does not show any evidence of having destabilized and ruptured the vesicles. After 270 min (arrow 5), the vesicle buffer was used to wash the substrate twice and the stability of the intact vesicles on the TiO₂ surface was observed.

6

the AH peptides ruptured vesicles to form bilayers ($P \leq 0.001$). These results correlate with QCM-D kinetic data.

As one of ordinary skill in the art will appreciate, various changes, substitutions, and alterations could be made or otherwise implemented without departing from the principles of the present invention. Accordingly, the scope of the invention should be determined by the following claims and their legal equivalents.

AFM Analysis of Lipid Bilayer Formation According to the Present Invention

AFM was utilized in order to confirm and directly display rupture of vesicles and bilayer formation by the destabilizing agent the AH peptide. FIG. 4 shows the results of this analysis. For each column, the top image shows a top view in 2-D, the middle image shows a top view in 3-D, and the graph shows measurements taken along the black line shown in the top image. The images are presented in Height mode. Scans were taken in the direction indicated by the white arrow on FIG. 4A, top image.

In FIG. 4A, AFM was conducted on a bare TiO₂ surface in Tris buffer (150 mM NaCl, 10 mM Tris [pH 7.5], 1 mM EDTA) as a control. The bare TiO₂ surface showed an average root mean square roughness (Rq) of 1.63 ± 0.12 nm (\pm S.E. n=15). 59 nm \pm 0.2 nm diameter POPC vesicles (0.1 mg/ml) were carefully added through the injection system, incubated for 30 minutes, and thoroughly rinsed three times with Tris buffer. Intact vesicles, such as vesicle 410, were clearly identified by AFM and the average Rq increased to 2.70 ± 0.15 nm (\pm S.E. n=15), as shown in FIG. 4B. A grain analysis was applied in order to identify and count the vesicles. In order to minimize the effects of particles other than vesicles, only diameters between 50 to 100 nm hyperbolar-shaped objects were counted. The AFM images, as shown in FIG. 4B, and grain analysis were used to identify the sizes of thirteen vesicles. The vesicles had an average diameter of 74.57 ± 4.07 nm (\pm S.E. n=13) and average volume of $3.32 \times 10^{-5} \mu\text{m}^3 \pm 6.16 \times 10^{-6} \mu\text{m}^3$ (\pm S.E. n=13). Cross-sectional analysis displays the height of the vesicles to be approximately 15 nm.

The AFM images in FIG. 4C show the effect of the AH peptide on the vesicles as a destabilizing agent, which was examined by injecting the peptide (0.05 µg/ml) and incubating the solution for 2 hours prior to scanning the images. These images clearly confirm the QCM-D data, indicating that vesicles were ruptured as a result of the treatment by AH peptide at 0.05 µg/ml concentration after 120 minutes. The average Rq of 1.67 ± 0.12 nm (\pm S.E. n=15) indicated the roughness became similar to the bare TiO₂ surface. Grain analysis identified no vesicle-like structures, indicating that

What is claimed is:

1. A supported planar lipid bilayer comprising:

- a) a planar lipid bilayer comprising naturally occurring lipids; and
 - b) a solid support comprising unmodified gold or titanium oxide;
- wherein said lipid bilayer is supported by said solid support.

2. The supported planar lipid bilayer as set forth in claim 1, wherein said lipids are phospholipids.

3. The supported planar lipid bilayer as set forth in claim 1, wherein said lipids are selected from the group consisting of phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, cardiolipin, cholesterol, and sphingomyelin.

4. The supported planar lipid bilayer as set forth in claim 1, wherein said planar lipid bilayer is continuous.
