### ▶ Determining Temperature Differential to Prevent Hardware Cross-Contamination in a Vacuum Chamber

*Goddard Space Flight Center, Greenbelt, Maryland*

When contamination-sensitive hardware must be tested in a thermal vacuum chamber, cross-contamination from other hardware present in the chamber, or residue from previous tests, becomes a concern. Typical mitigation strategies involve maintaining the temperature of the critical item above that of other hardware elements at the end of the test.

A formula for relating the pumping speed of a chamber, the surface area of contamination sources, and the temperatures of the chamber, source, and con-

tamination-sensitive items has been developed. The formula allows the determination of a temperature threshold about which contamination will not condense on the sensitive items. It defines a parameter alpha that is the fraction given by (contaminant source area)/[chamber pumping speed  $\times$  (time under vacuum)<sup>0.5</sup>]. If this parameter is less than  $10^{-6}$ , cross-contamination from common spacecraft material will not occur when the sensitive hardware is at the same temperature as the source of contamination (The chamber is isothermal within 5

°C.).

Knowing when it becomes safe to have the hardware isothermal permits faster and easier thermal transitions when compared with maintaining an arbitrary temperature differential between parts. Furthermore, the standard temperature differential may not be adequate under some conditions ( $\alpha > 10^{-4}$ ).

### ▶ SequenceL: Automated Parallel Algorithms Derived from CSP-NT Computational Laws

**Chip manufacturers and developers of parallel and/or safety-critical software could benefit from this innovation.**

*Goddard Space Flight Center, Greenbelt, Maryland*

With the introduction of new parallel architectures like the cell and multicore chips from IBM, Intel, AMD, and ARM, as well as the petascale processing available for high-end computing, a larger number of programmers will need to write parallel codes. Adding the parallel control structure to the sequence, selection, and iterative control constructs increases the complexity of code development, which often results in increased development costs and decreased reliability.

SequenceL is a high-level programming language — that is, a programming language that is closer to a human's way of thinking than to a machine's. Historically, high-level languages have resulted in decreased development costs and increased reliability, at the expense of performance. In recent applications at JSC and in industry, SequenceL has demonstrated the usual advantages of high-level programming in terms of low cost and high reliability.

SequenceL programs, however, have run at speeds typically comparable with, and in many cases faster than, their counterparts written in C and C++ when run on single-core processors. Moreover, SequenceL is able to generate parallel executables automatically for multicore hardware, gaining parallel speedups without any extra effort from the programmer beyond what is required to write the sequential/single-core code.

A SequenceL-to-C++ translator has been developed that automatically renders readable multithreaded C++ from a combination of a SequenceL program and sample data input. The SequenceL language is based on two fundamental computational laws, Consume-Simplify- Produce (CSP) and Normalize-Transpose (NT), which enable it to automate the creation of parallel algorithms from high-level code that has no annotations of parallelism whatsoever. In our anecdotal experience, SequenceL development has been in every case less costly

than development of the same algorithm in sequential (that is, single-core, single process) C or C++, and an order of magnitude less costly than development of comparable parallel code. Moreover, SequenceL not only automatically parallelizes the code, but since it is based on CSP-NT, it is provably race free, thus eliminating the largest quality challenge the parallelized software developer faces.

Compiling functional code to C++ is not new. Compiling functional code to readable C++ that runs in parallel is much more of a challenge, and that was the majority of this effort. For current purposes in this effort, readability of the generated code is crucial, in case the human programmer wishes to add annotations, or to inspect the code for verification purposes. Moreover, by compiling to C++ it is assured that SequenceL can be used in any application where C++ could be used.

SequenceL has been found to discover all potential parallelisms automat-

ically in relatively complex algorithms (involving multiple threads), and thus shows the potential to relieve more of the programmer's cognitive load as the problem grows in complexity. Sequen-

ceL's runtime environment then selects which parallelisms to actually exploit, with the aim of maximum overall speed when considering communication costs between processes.

## ➤ Remote Data Exploration with the Interactive Data Language (IDL)

*Goddard Space Flight Center, Greenbelt, Maryland*

A difficulty for many NASA researchers is that often the data to analyze is located remotely from the scientist and the data is too large to transfer for local analysis. Researchers have developed the Data Access Protocol (DAP) for accessing remote data. Presently one can use DAP from within IDL, but the IDL-DAP interface is both limited and cumbersome. A more powerful and user-friendly interface to DAP for IDL has been developed.

Users are able to browse remote data sets graphically, select partial data to retrieve, import that data and make customized plots, and have an interactive

IDL command line session simultaneous with the remote visualization. All of these IDL-DAP tools are usable easily and seamlessly for any IDL user.

IDL and DAP are both widely used in science, but were not easily used together. The IDL DAP bindings were incomplete and had numerous bugs that prevented their serious use. For example, the existing bindings did not read DAP Grid data, which is the organization of nearly all NASA datasets currently served via DAP.

This project uniquely provides a fully featured, user-friendly interface to DAP

from IDL, both from the command line and a GUI application. The DAP Explorer GUI application makes browsing a dataset more user-friendly, while also providing the capability to run user-defined functions on specified data. Methods for running remote functions on the DAP server were investigated, and a technique for accomplishing this task was decided upon.

## ➤ Mixture-Tuned, Clutter Matched Filter for Remote Detection of Subpixel Spectral Signals

*NASA's Jet Propulsion Laboratory, Pasadena, California*

Mapping localized spectral features in large images demands sensitive and robust detection algorithms. Two aspects of large images that can harm matched-filter detection performance are addressed simultaneously. First, multimodal backgrounds may thwart the typical Gaussian model. Second, outlier features can trigger false detections from large projections onto the target vector.

Two state-of-the-art approaches are combined that independently address outlier false positives and multimodal backgrounds. The background clustering of Funk et al. models multimodal backgrounds, and the mixture tuned matched filter (MT-MF) of Boardman

et al. addresses outliers. Combining the two methods captures significant additional performance benefits. The resulting mixture tuned clutter matched filter (MT-CMF) shows effective performance on simulated and airborne datasets.

The classical MNF transform was applied, followed by k-means clustering. Then, each cluster's mean, covariance, and the corresponding eigenvalues were estimated. This yields a cluster-specific matched filter estimate as well as a cluster-specific feasibility score to flag outlier false positives.

The technology described is a proof of concept that may be employed in fu-

ture target detection and mapping applications for remote imaging spectrometers. It is of most direct relevance to JPL proposals for airborne and orbital hyperspectral instruments. Applications include subpixel target detection in hyperspectral scenes for military surveillance. Earth science applications include mineralogical mapping, species discrimination for ecosystem health monitoring, and land use classification.
