Abstract

The success of current spaceborne Synthetic Aperture Radar (SAR) is boosting the performance requirement of next generation systems. In order to cope with the evolution of SAR the design of the new systems will need to meet higher requirements for spacial and radiometric resolutions together with an increased availability. This tendency is recognized nearly independently of the application area and manifests itself through several study programs initiated by space agencies aiming at the design of future SAR systems. In this context the use of large reflectors combined with digital feed arrays for SAR has not always received adequate attention. This paper suggests an X-band spaceborne SAR system utilizing a deployable reflector together with a digital feed array, analyzes its performance and highlights its advantages compared to other systems based on direct radiating arrays.

1 Introduction

A review of several ongoing studies for the conception of next generation SAR systems, reveals the shared characteristic of being multi-channel systems utilizing digital beamforming (DBF) techniques [1, 2, 3]. The common purpose of using multi-channel systems is to simultaneously obtain high spatial resolution and wide swath.

For DESDynI/Tandem-L a reflector-based SAR system was first suggested, which was later extended to a hybrid architecture through a digital feed [4]. With this system it would be possible to image a swath width of 300 − 400 km [3]. Such a hybrid architecture has the potential to combine both the flexibility and the capabilities of DBF with the high antenna gain provided by a large reflector aperture. To lower the stowed satellite volume and weight, and therefore the launch costs, the reflector could be deployable. Unfurlable reflector antennas are a mature technology with extensive flight heritage in space telecommunications and satellites with lightweight mesh reflectors spanning diameters of > 20 m are deployed in space [5].

From the above it seems reasonable to consider reflector-based SAR systems for future, or at least to perform comprehensive trade analyses of reflector versus direct radiating array antennas. In [6] a planar and a reflector system were designed to a common set of performance parameters; the comparison revealed that the reflector system can be realized with a simpler hardware and shows a performance advantage of several dBs in terms of ambiguity and signal-to-noise ratio.

The paper addresses this issue by suggesting a SAR system utilizing a reflector in conjunction with a digital feed array. Keeping future follow-up systems for the German TerraSAR-X and TanDEM-X SAR satellites in mind, the reflector system will be designed for X-band @ 9.65 GHz operation with performance requirement possibly exceeding those of HRWS [1]. In this paper emphasis will be given to the various operation modes and the performance; the antenna design is detailed in [7] while [8] elaborates on the performance improvement using dedicated DBF techniques and [9] addresses the issue of imaging gap removal by varying the pulse repetition frequency (PRF).

2 Architecture and Operation

In 1981 Blyth [10] suggested a basic approach for analog beam-steering such that the receive beam moves over the swath in accordance with the direction of reflection. About twenty years later, his idea finds a more detailed description and justification in two independent and almost contemporary works [11, 12]. Digital beamforming techniques in elevation and azimuth for a reflector are presented for the first time in [4].

In the following the digital beamforming technique and the corresponding system architecture is addressed. For clarity this will be given separately for the elevation and azimuth directions.

2.1 Digital Beamforming in Elevation

The SCan-On-REceive (SCORE) mode of operation, which is also suggested here, is primarily based on generating a wide transmit beam that illuminates the complete swath and a narrow, high gain receive beam that follows the pulse echo on the ground. SCORE results in an increased signal-to-noise ratio compensating the low gain of the transmit antenna and suppressing range ambiguities.

The system (in elevation) consists of a parabolic reflector and a feed array of $N_{el}$ antenna elements fed through transmit/receive modules, where an analog-to-digital converter (ADC) is placed after each T/R-module as shown in Fig. 1.
3 System Design and Requirements

The system is not designed for a specific set of user requirements which causes some difficulty in quantifying the SAR performance requirements. To overcome this difficulty we state the requirements based on state-of-the-art SAR systems. The later analysis will then give more insight into the actual performance and the possible compromises. The requirements are a resolution of \( D/2 \), an ambiguity-to-signal ratio of \(-20\, dB\), and a noise-equivalent sigma zero of \(-20\, dB\) per unit power. We assume an available average power of 2 kW which matches the value for the HRWS system [1].

3.1 Orbit Selection

The orbit selection is closely related to the intended application area and plays a crucial role for the reflector and feed design. Increasing the orbit height allows the reduction of the incidence angle range for the same swath width. It is noted that for direct radiating arrays increasing the orbit height is disadvantageous because of the degraded SNR or increased antenna size; in the case of a reflector system, effective antenna areas in the order of \( 15 \sim 40\, m^2 \) can be realized, which makes higher orbits an attractive option since it releases the elevation scanning requirements. For the mixed scientific and commercial application considered here the access range should be such that any arbitrary region on the Earth can be imaged at least once during the repeat cycle, however, global coverage within one repeat cycle is even preferable. The table below shows the access range and repeat cycle time for valid orbit configurations for orbit heights in the order of 750 km. Global coverage within one repeat cycle is possible if the contiguous imaged swath of a single pass is equal to the access range given in the table. The reflector and feed system is designed to image any sub-swath within the access range for all of the repeat cycles. The instantaneous imaged swath will be 310 km thus allowing a global coverage within \( \geq 9\) days.

3.2 Reflector and Digital Feed

The antenna and feed design is elaborated in [7]. Here the description is restricted to reporting the values of the system used for the performance analysis. A circular rim reflector of diameter \( D = 6\, m \), focal length \( F = 6.2\, m \), and vertical (elevation) feed offset of 0.82 m is designed. The feed array consists of 4 x 36 digital channels in azimuth and elevation, respectively. Each channel (connected to an ADC) may consist of one or more radiators.
4 Modes of Operation

The digital feed allows operation in various modes which basically differ in the number of imaged sub-swathes and the way they are combined into one larger swath. These modes can be divided into four categories and shown in the timing diagram of Fig. 2.

Single Stripmap This mode is well known from conventional SAR, where any sub-swath within the access range is imaged with a single burst and constant PRF. As mentioned in section 2.2 the azimuth processing needs to be adapted to the fact that each channel samples a narrow Doppler spectrum which are combined during processing.

Multi Stripmap Here multiple sub-swathes of the same PRF are imaged simultaneously allowing an increase of the total swath up to the access range. However, the imaged swath contains gaps caused by the transmit instances. The gaps width can be reduced by reducing the pulse duty cycle. This mode takes advantage of DBF, since several SCORE beams are generated each one following the receive echo within one sub-swath.

ScanSAR In this mode multiple bursts are used increase the swath width. For the system shown here, a total of six to seven bursts would be required to cover the complete access range. An alternative would be to use ScanSAR to fill the gaps of the Multi-Stripmap mode; this would allow operation with only two bursts to image the complete access range. In any case the ScanSAR requires an adaption of the azimuth processing.

PRF Variation Multiple sub-swathes are imaged at the same time but in addition the PRF is varied from pulse to pulse. By this the gaps of the Multi-Stripmap mode can be avoided. This mode offers a highly attractive way to image an ultra wide swath, but requires innovative processing approaches [9].

5 SAR Performance

In the following the performance of the Multi-Stripmap mode is shown, since it is the most attractive one. The performance of the Single-Stripmap is identical to that of any single sub-swath. For the impact of the PRF-Variation we refer to the separate investigation in [9].

The range performance given in terms of the range-ambiguity-to-signal ratio (RASR) is shown in Fig. 3. The RASR is below $-40$ dB which is possible because of the narrow low sidelobe SCORE Rx patterns shown exemplarily in Fig. 3(b).

The azimuth performance is given in terms of the azimuth-ambiguity-to-signal ratio (AASR) shown in Fig. 4. The AASR suffers from the degradation of the azimuth patterns at the near-range boundary of the access range. This is basically an antenna and feed dimensioning issue which involves a compromise between the allowable maximum size and the performance. Here the AASR computed for a single azimuth channel is representative for the overall AASR as explained in section 2.2.

Figure 2: The timing diagram for different operation modes for a 745 km orbit and a pulse duty cycle of 10 %

Figure 3: Elevation ambiguity performance of reflector system.

Figure 4: Azimuth ambiguity performance of reflector system.

\footnote{The echo signals from all the imaged sub-swathes arrive simultaneously, something that typically causes range ambiguities in a conventional SAR, here the narrow Rx SCORE pattern with low sidelobe level allows adequate range ambiguity suppression.}
The noise-equivalent sigma-zero for a total average transmit power of 2 kW, a 2-way system loss of 3 dB, and a system noise temperature of 460 K is shown in Fig. 5(a).

One characteristic of the reflector system with a transmit feed connected to T/R-modules (TRM) is that the power density on the ground does not decrease when illuminating a wider swath. As such the NESZ shown in Fig. 5(a) is valid independently of the number of imaged sub-swathes, however the average power consumption increases with the number of imaged sub-swathes. In Fig. 5(b) the pulse extension loss (PEL) is shown. This performance parameter describes the loss due to the non-vanishing pulse extension on the ground which is attenuated by the narrow RX SCORE antenna pattern. For the 10 % duty cycle this loss is below 2 dB.

6 Conclusion

Spaceborne SAR systems utilizing reflector antennas offer the possibility to improve the SAR performance with respect to next generation SAR systems. This performance improvement manifests itself through an increased swath width and a higher signal-to-noise ratio. The digital feed of a reflector system uses a smaller number of T/R-modules and by this require a higher average power per T/R-modules the same total power. Further the imaging modes shows a high potential for systems operating at low pulse duty cycle which require a higher peak power. The power requirements are not fulfilled with current T/R-modules at X-band and thus require future technology development; here GaN technology seems to be a promising candidate. On-going research on advanced digital beam-forming techniques for reflector systems show a high potential and should be continued.
