#### Abstract

The entomopathogenic fungus Metarhizium anisopliae isolate IP 46, originating from a soil sample collected in 2001 in the Cerrado of Central Brazil, was tested for its ability to reduce the survival of adult male and female Anopheles gambiae s.s. and An. arabiensis mosquitoes. A 6-h exposure to the fungus coated on test paper at a concentration of  $3.3 \times 10^6$  conidia cm<sup>-2</sup> reduced the daily survival of both mosquito species (HR = 3.14, p < 0.001), with higher risk of dying in An. gambiae s.s relative to An. arabiensis (HR = 1.38, p < 0.001). Fungal sporulation was observed in >95% of mosquito cadavers in the treatment groups. The results indicate that M. anisopliae IP 46 has the potential to be a bio-control agent for African malaria vector species, and is a suitable candidate for further research and development.

#### Findings

*Metarhizium anisopliae* IP 46 has shown ovicidal effects against the eggs of *Aedes* spp in Brazil [1-3]. However, its pathogenicity against adult malaria vectors has never been explored. As such, we examined the effect of this strain against laboratory-reared adult *Anopheles gambiae sensu stricto* and *An. arabiensis*, with the aim to include IP 46 in the spectrum of fungal candidates available for use as biocontrol agents.

The fungus was imported as conidia from the Institute of Tropical Pathology and Public Health, Federal University of Goiás, Goiânia, Brazil (Tropical Pesticides Research Institute Import Permit No. 2471). Before conducting bioassays, the IP 46 isolate was host-passaged through laboratory-reared *An. gambiae* s.s. adults in order to maintain its virulence. Conidia were harvested from cultures grown on autoclaved rice substrate (200 g per bag) in nylon bags at 25°C and 12 h photophase, after 15 d incubation. They were then dried in silica gel at 4°C for 4 d. Preparation of stock- and working-solution concentrations formulated in Enerpar oil (Enerpar M002<sup>®</sup>, BP South Africa Ltd) followed standard protocols [4]. Before each experiment, conidia viability (>95% germination on Sabouraud Dextrose Agar) was confirmed. 1200 µl of the working-solution was applied evenly to 15 × 25 cm proof-

ing paper using a metal bar (0.31 mm diameter; paper and applicator bar from RK Print Coat Instruments, London), giving a uniform concentration of  $3.3 \times 10^6$  conidia cm<sup>-2</sup>. The treated paper was left to dry for 12 h at  $26 \pm 1^\circ$ C and  $80 \pm 5\%$  RH, and then used to line the inside of plastic exposure tubes (8.2 cm diameter × 12.5 cm height). Untreated control replicates used paper treated with Enerpar oil only.

A total of 30-40 unfed 3-7 d old adult An. gambiae s.s. (colony established in 1996, Njage village, Tanzania) or An. arabiensis (colony established in 2007, Sagamaganga village, Tanzania) were introduced to the exposure tubes. Four separate bioassays were run (both sexes for each species) and three replicates were carried out for each bioassay. Mosquitoes were held in the tubes for 6 h, after which they were transferred to 9 cm<sup>3</sup> holding cages at 26 ± 1°C and 90 ± 5% RH, and provided with 9% glucose/ water (w/v) solution. The survival and fungus infection status of mosquitoes were monitored daily for up to 28 d, following procedures described elsewhere [4]. Mosquito survival was analysed by Kaplan-Meier pair-wise comparison and Cox regression analysis, using SPSS version 16. Cox regression generated hazard ratios (HR) indicating the daily risk of dying for a mosquito in each bioassay group.

Metarhizium anisopliae IP 46 was capable of infecting males and females of both mosquito species: >95% of An. gambiae s.s. and An. arabiensis cadavers showed fungus sporulation after incubation for 5-6 d. The fungus significantly reduced the survival of all exposed mosquitoes compared to controls (*p* < 0.001, Table 1, Fig. 1); >90% of mosquitoes in the exposure groups had died by day 14 while >25% of control mosquitoes were still alive by this time. All of the control mosquitoes in all bioassays had died by day 28. For An. gambiae s.s. the daily risk of dying was over three-fold greater in exposed females (HR = 3.18, p < 0.001) and males (HR = 3.81, p < 0.001) relative to their controls. A similar trend was observed in exposed females (HR = 2.28, *p* < 0.001) and males (HR = 3.31, *p* < 0.001) of An. arabiensis. The daily risk for males was higher than for females in both species (An. gambiae s.s. HR = 1.11, p = 0.001 and An. arabiensis HR = 1.13, p =

0.004). Overall, daily risk of dying was higher for exposed *An. gambiae* than *An. arabiensis* (HR = 1.38, p < 0.001). The controls for *An. gambiae* survived relatively longer (males MST = 14 d; females MST = 16 d) than those of *An. arabiensis* (male MST = 12 d; female MST = 12 d, Table 1), but this difference was accounted for by Cox regression model which compares relative risks rather than fixed survival time values.

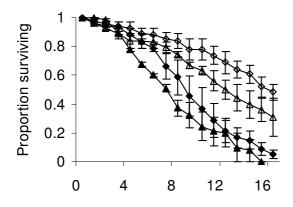

For effective malaria control, entomopathogenic fungi do not need to kill vector mosquitoes instantly [5]. If mosquitoes are able to reproduce and pass genes to the next generation before they are killed by an insecticide the selection pressure for the development of resistance is significantly reduced [6,7]. Here we have shown that the isolate M. anisopliae IP 46 kills females of An. gambiae s.s. and An. arabiensis on average 8-9 d after exposure. By day 14 the majority (>90%) of exposed mosquitoes had been killed. Given that the Plasmodium parasite requires approximately 9 to 14 d to infect the mosquito salivary glands, the risk of malaria transmission by fungusinfected mosquitoes is minimal [8]. Similar rates of mortality have been recorded for other entomopathogenic fungi against mosquitoes [4,9-11]. Perhaps most importantly, M. anisopliae IP 46 was effective against both An. arabiensis and An. gambiae s.s. suggesting that it could be used to target both indoor and outdoor resting anophelines. This is the first study demonstrating the susceptibility of adult An. arabiensis to Metarhizium anisopliae.

Ultimately the success of entomopathogenic fungi against malaria-carrying mosquitoes in any situation may depend on the choice of fungal isolate. This is because of the interisolate variation in virulence, spore production and persistence in relation to their ability to withstand sub-optimal environmental conditions [12-16]. The long-standing barriers that have prevented the widespread uptake of biological control agents include low virulence and shortterm residual activity. In order to overcome such barriers it is necessary to screen an array of fungal strains to identify those with the greatest potential for development. We found that the isolate *M. anisopliae* IP 46 is able to reduce the survival of adult anophelines within the same time frame as other strains, *M. anisopliae* ICIPE-30 and *B. bassi*-

Table I: Pair-wise Kaplan-Meier median survival times (MST) for adult Anopheles gambiae s.s. and An. arabiensis exposed to oilformulated M. anisopliae IP 46 (treatment) or oil only (control).

Species	Sex	MST ± I S.E.		$\chi^2$ value	p value
		Control	Treatment		
An. gambiae s.s.	Female	16 ± 0.51	9 ± 0.23	94.58	<0.001
	Male	14 ± 0.76	8 ± 0.30	133.07	<0.001
An. arabiensis	Female	12 ± 0.79	8 ± 0.38	63.04	<0.001
	Male	12 ± 0.45	6 ± 0.3	3. 3	<0.001
