Abstract. The majority of studies on security in resource limited wireless sensor networks (WSN) focus on finding an efficient balance among energy consumption, computational speed and memory usage. Besides these resources, *time* is a relatively immature aspect that can be considered in system design and performance evaluations. In a recent study by Castelluccia and Spognardi[5], the time dimension is used to lower the ratio of compromised links, thus, improving resiliency in key distribution in WSNs. This is achieved by making the old and possibly compromised keys useful only for a limited amount of time. In this way, the effect of compromised keys diminish in time, so the WSN *selfheals*. In this study we further manipulate the time dimension and propose a deployment model that speeds up the resilience improvement process with a tradeoff between connectivity and resiliency. In our method, *self healing* speeds up by introducing nodes that belong to future generations in the time scale. In this way, the duration that the adversary can make use of compromised keys become smaller.

1 Introduction

The significance of wireless sensor networks (WSNs) is that the cheapest possible node model is targeted due to nature of the network; such as being in a hostile environment, unattended, and due to the geographic constraints which prevent reusability of a sensor node. Moreover, the application fields of WSNs, like battlefield surveillance and habitat monitoring need security precautions in order to work as intended [1].

For secure communication in WSNs, the symmetric encryption is preferred for the sake of energy consumption and faster processing. For this purpose, the distribution of symmetric keys is obligatory and its difficulty is the main problem of secure communication in WSNs. Thinking of the very intuitive but inefficient scheme where all possible pairwise keys in the network are kept in the memory of each node, the connectivity is at its utmost. However, the extra memory that is wasted for unused keys, is too expensive for a tiny sensor node.

On the other hand, using a single key in the whole network will be the most desired choice for memory. However, all the links will be compromised if the key is captured by adversary.

** Albert Levi is supported by TÜBİTAK under grant 104E071.

Therefore, a viable solution would look for an equilibrium in resource consumption in order to deal with the strict constraints. In this sense, Eschenauer and Gligor[9] devise a mechanism in which all nodes are given a random amount of keys from the key pool. This scheme results in reasonable levels of connectivity and resiliency. Eschenauer and Gligor[9] will be referred as *basic scheme* in the following sections.

Besides the advantage of randomness, the time dimension is a reality for any network and should be considered in the design. Castelluccia and Spognardi proposed RoK (A Robust Key Pre-distribution Protocol for Multi-Phase WSNs) [5], that takes time dimension into account. In RoK [5], the network lifetime is divided into phases. At the end of each phase, all the keys of nodes are updated. Thus, new links are established with updated keys that are out of the reach of adversary before compromising nodes with new keys.

In this study, we improve the resiliency of RoK by further exploiting the time dimension. Our contribution is to use keys that are assigned to future uses, earlier than their times. As a result, we end up with improved resiliency measures. We propose two models called Constant Offset Future Random Generations (COFRG) and Growing Offset Future Random Generations (GOFRG). At each deployment phase, both of them choose a time interval in future. Some of the keys from this time interval are chosen randomly and used in the current time. In COFRG, the time interval is a fixed offset from current time. However, in GOFRG this interval has growing offsets with respect to present. In this way, at each deployment of GOFRG, a high fraction of deployed keys become new to adversary. This is valid for COFRG too, but the fraction of new keys at each deployment of COFRG becomes lower after the initial stages of the network. Therefore, the contribution of GOFRG to resiliency is better as compared to COFRG. On the other hand, connectivity decreases in both models due to higher number of nodes that belong to future generations in comparison to RoK.

The rest of the paper includes the background information on multiphase keying in Sect. 2. Section 3 compares the general characteristics of multiphase keying and the basic scheme. In Sect. 4 the proposed schemes are presented. The advantages versus the drawbacks of the schemes are discussed in Sect. 5. Related works are described in Sect. 6. Finally Sect. 7 summarizes the conclusions.

2 Previous Work in Multiphase Keying: RoK Approach

In *Multiphase Keying* models, the network life is divided into phases of equal time intervals. All the keys in the key pool and in the key rings of nodes are updated with each phase, such that the adversary fails to derive the keys of future phases from previously captured keys. At the same time, deriving keys of previous phases from current phase keys is prevented. However for the sake of connectivity among nodes that are active in neighboring phases, this prevention mechanism is activated gradually, as explained below. All the schemes that are discussed in this paper, namely RoK, COFRG and GOFRG are different variations of the *multiphase* approach.

Each *phase* is called a *generation* which consists of 10 *rounds*, where one *round* is the smallest unit of time. The reason for this time segmentation is that the attack scenarios are based on *rounds*.

In RoK [5] all the keys are identified with the generation in which they are used. So that, by the end of each generation all the valid keys are updated. However, in order to compromise the maximum number of links, an attacker may prefer to update the key ring of each captured node forever. To prevent this, a security mechanism should be able to guarantee that the key ring of any node is bound to a given amount of time. After exceeding this time, a node should no more establish a secure communication between new deployed nodes. The update function should be chosen such that every node should be allowed to update its keys only a given number of times. After exceeding this time, a node should no more establish a secure communication between new deployed nodes, due to being unable to update its keys. In RoK [5] this time duration is set to 10 *generations*, which is almost the maximum battery life of a node. This binding is provided by the backward and forward hash chains.

As a result of this binding, the keys obtained from captured nodes get old by time and new established links remain safe. This decreases the ratio of compromised links with every *generation*, if adversary stops capturing new nodes. The decrease in this ratio, i.e. the improvement in resiliency, is also called the self-healing of the network.

The working principle of RoK scheme consists of two phases:

- Node Configuration Phase
- Key Establishment Phase

2.1 Node Configuration Phase

At the beginning of each generation, a set of sensor nodes are deployed with forward and backward key rings. These key rings are hashed at the end of each generation, so that the new key rings are identified with the new generation. This way nodes maintain their lives among generations. When a key ring is hashed LT times, which is the preassigned cryptographic lifetime of a node, the node can no more establish a new link. In this scheme, forward and backward hash chains, constitute the update mechanism mentioned above, satisfying its security requirements thanks to the irreversibility of hash functions.

Each element of the forward and backward hash chains will be referred as a *Forward Key* or *Backward Key*. The key rings are sets containing a number of chosen *Forward Keys* and *Backward Keys* from the pools, called *Forward Key Pool* and *Backward Key Pool*.

The *Forward Key Pool*, at *Generation 0*, i.e. the first deployment of the network, is defined as follows. Please refer to Table 1 for the definitions of symbols:

$$FKP^0 = fk_1^0, fk_2^0, \dots, fk_{P/2}^0, \quad (1)$$

where each fk_i^0 is randomly generated. At *Generation $j + 1$* , the *forward keys* are refreshed as follows:

$$FKP^{j+1} = fk_1^{j+1}, fk_2^{j+1}, \dots, fk_{P/2}^{j+1}, \quad (2)$$

where

$$fk_i^{j+1} = H'(fk_i^j) . \quad (3)$$

Table 1. Symbols used in multiphase keying

P	Key Pool Size
m	Key Ring Size
FKP	Forward Key Pool
BKP	Backward Key Pool
fk	Forward Key
bk	Backward Key
g_X	The generation of node X
X_i^j	Item X with Generation j & index i
LT	Life Time of the key ring of a node.
H', H''	Two different hash functions.
$fk_i^j - bk_i^j$	A forward-backward key pair.

The Backward Key Pool, is first generated for *Generation n*, i.e. the last generation of the network. The *backward keys* at *Generation n*, are initialized with random values:

$$BKP^n = bk_1^n, bk_2^n, \dots, bk_{P/2}^n \quad (4)$$

At *Generation j*, the backward keys are refreshed as follows:

$$BKP^j = bk_1^j, bk_2^j, \dots, bk_{P/2}^j \quad (5)$$

where

$$bk_i^j = H'(bk_i^{j+1}) \quad (6)$$

Therefore, at *Generation j + 1* the *backward key pool* is defined as:

$$BKP^{j+1} = bk_1^{j+1}, bk_2^{j+1}, \dots, bk_{P/2}^{j+1} \quad (7)$$

which means that the bk_i^j key of *Generation j* is obtained from the key bk_i^{j+1} of *Generation j + 1*, using the hash function H' .

Every node is configured with *forward* and *backward* keys in the following way: For a node with ID A and deployment generation g_A , the i^{th} key of the *Forward Key Ring* is the key from the *Forward Key Pool* of index $H''(ID_A || i || g_A)$. This is done for all $m/2$ keys in the *Forward Key Ring*.

For the *Backward Key Ring* the same operation is performed using the indices of the *Backward Key Pool*.

2.2 Key Establishment Phase

After deployment, a node A broadcasts ID_A and its generation, g_A . A receiver node B , at first, decides if their generations are close enough or not. This is done by testing if $|g_A - g_B| < LT$. In addition to this, if $g_A < g_B$ and the above holds, then, they can share keys starting from *Generation g_B* up to *Generation " $g_A + LT - 1$ "*.

Secondly, Node B calculates $H''(ID_A||i||g_A)$ and compares them with its indices $H''(ID_B||i||g_B)$ for all $i, j \in 0, 1, m/2$. If there are collisions such that

$$H''(ID_A||x||g_A) = H''(ID_B||y||g_B) , \quad (8)$$

where

$$x, y \in 1, 2 \dots m/2 , \quad (9)$$

then, it is known that they both have the forward key $f k_{H''(ID_B||y||g_B)}^{g_B}$ and the backward key $b k_{H''(ID_B||y||g_B)}^{g_A+LT-1}$ in their memory. This way, all colluding local indices $a, b, z \in 1, 2 \dots m/2$ are found and the following becomes their pairwise symmetric key:

$$\begin{aligned} K = & H'(f k_{H''(ID_B||a||g_B)}^{g_B} || \\ & b k_{H''(ID_B||a||g_B)}^{g_A+LT-1} || \dots || \\ & f k_{H''(ID_B||z||g_B)}^{g_B} || \\ & b k_{H''(ID_B||z||g_B)}^{g_A+LT-1}) . \end{aligned} \quad (10)$$

Any attacker needs all these *forward* and *backward keys* to compromise this pairwise key. These keys can not be reached using a particular *forward – backward* key pair. A *forward key* is reachable only through a suitable past *forward key* and a *backward key* is reachable only through a suitable future *backward key*. Furthermore, these suitable keys need to have the same indices with the keys in 10. Therefore, an adversary would construct a table that is filled with the hash chains of the captured keys. This way future *forward keys* and past *backward keys* can be calculated using the hash function as in 3 and 6. In case a *forward – backward* key pair is captured by adversary, the links that were established in the past are secured through *forward keys* since the captured *backward key* will reveal all its hashes, while future links are secured through *backward keys* in the opposite way.

3 Comparison of Multiphase Keying and Basic Scheme

The forward and backward hashing mechanisms of multiphase node deployment has several advantages over basic scheme [9]. First, in case of an attack that lasts only a fixed period of time(*temporary attack*), the ratio of compromised active links in the network decreases to zero gradually after the attack is stopped. Second, in case of an attack that lasts continuously(*constant attack*), the ratio of compromised active links shows constant periodic behavior and does not increase further. Third, despite updating the key pools, new deployed nodes are able to communicate with nodes that have older versions of the keys. Therefore old nodes are still used in network. As a result the update mechanism improves resiliency without wasting nodes of previous generations.

3.1 Self Healing

In the scenario with temporary attacker, the majority of links established after the attack ends are away from adversary's reach. Whatever the length or the degree of the attack

is, the self healing ability of network eliminates the effect of adversary in a few phases. If ring keys of nodes are bound to 10 generations, there will be no links established with keys that are captured 10 generations earlier, in the extremum case. Fortunately, simulations in Castelluccia and Spognardi [5] show that the network self heals in 5 or 7 generations.

The same scenario in basic scheme does not have self healing property as a result of using keys that are probably at hand of adversary. Therefore, new established links are at the risk of being compromised. In the simulations of Castelluccia and Spognardi [5], basic scheme results in 0.4 compromise ratio for active links with an attacker capturing 10 nodes in each generation between generations 5-15. Despite the attacker stops capturing nodes in *Generation 15*, the compromise ratio is still around 0.4 until the end of network.

3.2 Resiliency against Continuous Attack

In case of continuous attack, the ratio of compromised links over all links in the network shows a continuous increase in basic scheme, while in multiphase keying this ratio has a constant periodical behavior in a certain range. The behavior of basic scheme is more intuitive. The continuous capture of nodes causes compromise ratio of active links to approach 100%. However, the steady behavior of multiphase deployment in the ratio of compromised active links is due to the update mechanism of keys. Looking from adversary's point of view, the keys that are captured in previous phases of the network turn out to be useless. As a result, continuous capture of new nodes is necessary in order to keep the compromise ratio of active links in certain levels.

Resiliency improvement in multiphase keying does not depend on sacrificing previous nodes. Deployment is performed considering the link connections between nodes of old and new generations. Despite the fact that the improvement in resiliency is achieved with key updates, newly deployed nodes are able to establish connections with neighboring older nodes, except for very old nodes that are of 10 or more generations back.

4 Proposed Schemes

The hashing mechanism in RoK [5] and its usage of time dimension through generations provide the *self healing* ability of the network. In our study, we modify the node deployment model of RoK by using nodes of future generations. Therefore the network acts as if it has the state of a few generations later, which results in a faster *self healing* process.

In this study, we propose to use nodes that belong to a random future generation, at each deployment. This method will be referred as *Future Random Generations*. Two different models on how to choose from future generations are proposed as explained below. In the classical RoK approach, the attacker is able to compromise keys of established links provided that the captured nodes and the link that is to be captured have overlapping generations. In the proposed models, we enable a faster *self healing* and improve resiliency by reducing the probability of overlapping generations via future random generations.

At the end of each generation, some of the nodes including the newly deployed ones have key rings that belong to a few generations ahead. In this way, each node in the network happen to live in a different generation than most of its neighbors. Therefore, this can be referred as a generation mixture or traveling in time.

The early deployment of *Future Random Generations* would cause a decrease in connectivity. Actually our method creates a trade off between resiliency and connectivity, which is analyzed in Sect. 5.

4.1 Deployment Models

In RoK [5] at each generation, the new nodes that are deployed over the field are chosen such that they belong to current generation. However in our schemes, the generations of the new nodes are chosen randomly. The range of generations from which the generation of each new node is randomly selected is defined as *deployment window*. The position of the deployment window on the time scale shifts towards future at each generation. The rules of shifting the deployment window constitute our deployment models. We propose two such models, namely COFRG (Constant Offset Future Random Generations) and GOFRG (Growing Offset Future Random Generations), that are detailed in the following subsections. In both models, the size of the *deployment window* is fixed to 10 generations.

In our models, each new node is assigned a uniformly random generation picked out of the current deployment window.

Constant Offset Future Random Generations (COFRG). In COFRG, the deployment window has a constant offset to current generation. The deployment window shifts one by one at each generation. In this way, the offset between the deployment window and the current generation remains unchanged.

In COFRG, the network is initialized without considering the deployment window rules and all the nodes are deployed as *Generation 0* nodes. However, all nodes to be deployed after *Generation 0* have generations randomly selected out of *deployment window*.

The discrete uniform random variable that determines the generation of a specific node, G_{COFRG} , is defined as follows.

$$G_{COFRG} = \begin{cases} 0 & \text{if } T = 0 \\ T + D + X & \text{if } T > 0 \end{cases} ,$$

where X is a random integer uniformly distributed in $\{0, 1, \dots, 9\}$, T is the index of current generation and D is the offset to current generation.

At *Generation T*, the deployment window covers the range $T + D$ to $T + D + 9$. The generation of each node to be deployed is a uniform random variable, G_{COFRG} , picked out of this deployment window. In the next generation, $T + 1$, the deployment window is shifted one step forward having the range $T + 1 + D$ to $T + 1 + D + 9$. The generation of all nodes to be deployed at $T + 1$ is selected randomly from this deployment window. This goes on for all consecutive generations.

Figure 1 exemplifies both deployment window and the existing generations on the field in COFRG with $D = 5$. Each cell with dotted background is a deployment window

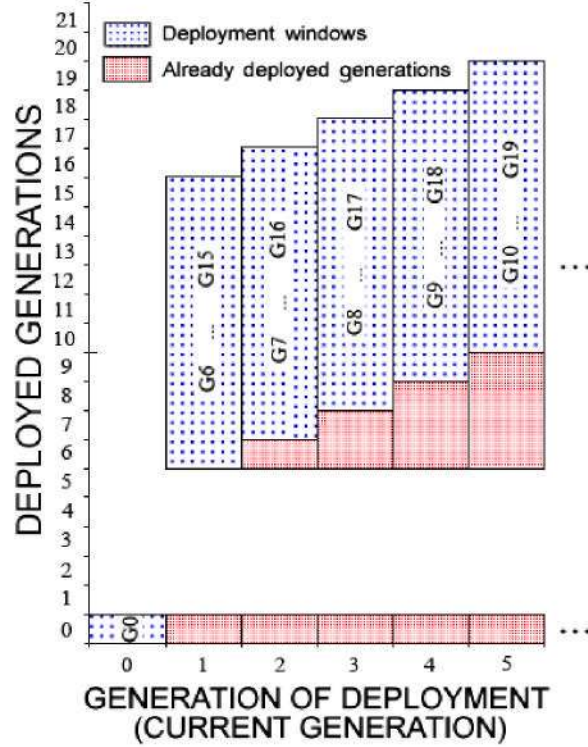

Fig. 1. Deployed Generations vs. Generations of Deployment in COFRG

and the symbols in these cells represent the range of generations in that deployment window. The horizontal axis shows the current generation. For an example, the deployment range of *Generation 4* is between the generations 9 and 18 (inclusive). A node that is to be deployed in the current generation is assigned a future random generation out of the *deployment window* that corresponds to this current generation.

The vertical axis is a reference to observe the existing generations on the field. In addition to dotted background that corresponds to deployment window of current generation, the generations with red grid texture show the ones that have been deployed prior to current generation. For example, the deployed generations at the time of *Generation 3* are *Generation 0* and the generations between 6 and 17.

The generations between 1 and 5 are never deployed in any generation. This is due to the constant offset feature of COFRG.

Growing Offset Future Random Generations (GOFRG). In GOFRG, the deployment window shifts towards future with some jumps. Each node is assigned a generation which is determined by a discrete uniform random variable, G_{GOFRG} , as follows.

$$G_{GOFRG} = \begin{cases} 0 & \text{if } T = 0 \\ (T - 1) * JUMP + T + X & \text{if } T > 0 \end{cases} \quad ?$$

where X is a random integer uniformly distributed in $\{0, 1, \dots, 9\}$, T is the index of current generation and $JUMP$ is the length of additional offset.

Besides the natural increase in the time scale (one by one), the deployment window in GOFRG makes additional shifts with the length of $JUMP$ at each generation. Hence, a deployment window of GOFRG increases its offset to current generation with constant speed. The $JUMP$ parameter is constant for a given GOFRG model.

Figure 2 illustrates the deployment windows and existing generations upto the fifth generation of the network in GOFRG with $JUMP=2$. The deployment range at *Generation 3* is between 7 and 16. In this case the deployment has an offset of 4 to current time. The following generation (*Generation 4*) has the deployment window with range 10 to 19, which has an offset of 6 to the current generation. In this way, the difference between the deployment window and current generation increases as generations go by.

Fig. 2. Deployed Generations vs. Generations of Deployment in GOFRG

For each deployment in both COFRG and GOFRG, the links established using generations that are deployed for the first time cannot be compromised using the nodes captured in previous generations. The number of these safe generations is $(JUMP + 1)/10$ of the length of the deployment window. This ratio is 1/10 in COFRG. Therefore, as compared to COFRG, higher fraction of generations are out of reach of adversary in

GOFRG. This difference leads to higher resiliency values for GOFRG as will be discussed in 4.3.

In COFRG scheme, the offset is kept constant in order not to be too far from the current generation. Consequently, connectivity is kept within reasonable levels. However, this balance between offset and connectivity is not taken into consideration in GOFRG for the sake of better resiliency.

4.2 Key Establishment Phase

The key establishment phases of both models COFRG and GOFRG are identical with RoK, however the results are different as explained in 4.3. The generation overlaps in COFRG and GOFRG are fewer compared to RoK. The reason is that, the deployment generations are mostly chosen from future time domains, so the generation overlap probabilities between the key rings of nodes are reduced. Therefore, less node pairs are able to establish shared keys, however, the resulting key becomes more resilient in GOFRG than RoK, as explained in 4.3.

As in most of the WSN applications, whenever two neighboring nodes are not able to establish a pairwise key using the key rings in their memories, they apply *path key establishment* procedure in order to communicate in a secure way. The path key establishment phase has the following steps:

1. One of the nodes broadcasts a message that contains the IDs of the two nodes in question, looking for an anchor node that shares a key with both of the nodes.
2. This broadcast is flooded across the network until it reaches an anchor. This step will increase the communication overhead of the nodes involved. Therefore the broadcast is allowed to make at most, say, 3 hops.
3. The anchor node generates a random pairwise key for the two nodes and sends it to both parties using the secure channels established earlier.

The path key establishment is supposed to keep the connectivity in COFRG and GOFRG in desired levels, with a cost of energy consumption due to communication overhead. However, the positive effects of path key establishment on connectivity are not shown in the figures below in order to observe the connectivity prior to path key establishments.

4.3 Performance Evaluation

RoK scheme [5] explains in detail how *Multiphase Keying* mechanism improves resiliency over time. This behavior is called the *self healing* ability of the network, which addresses the decrease of adversary ability to compromise new links with a given number of captured nodes. As a result the fraction of compromised active links used in the network decreases.

Since our goal is to speed up the *self healing* process and observe the resulting resiliency and connectivity metrics by employing the proposed *Future Random Generations* approach, the simulations to compare multiphase deployment and previous schemes which was done in Castelluccia and Spognardi [5], are not repeated here.

Simulation Details and Performance Metrics. The simulations were implemented in C# .Net 2005 on Windows XP SP2. Each simulation run 20 times for the sake of accuracy.

COFRG and GOFRG schemes were tested together with RoK. For simplicity 20*20 area is used to deploy 400 nodes. With vertical and horizontal neighboring, each node has exactly 4 neighbors.¹

At the end of each generation, the nodes that run out of battery are replaced with new nodes, which are configured according to the rules of the related scheme. This replacement obviously is not feasible in real life but to cope and compare the results with RoK scheme, a similar deployment is adopted.

For all scenarios, the sizes of both *forward* and *backward pools* are 100.000 and the sizes of *forward* and *backward rings* of a node are both 100.

The lifetimes of nodes are decided according to Gaussian distribution with mean 5 and standard deviation 10/6.

The simulations were run with two attacker models: In the first group, the attacker, called the constant attacker, captures 5 nodes per *round*. In the second, the attacker, called the temporary attacker, captures nodes only until the end of *Generation 9*, again with a rate of 5 nodes per *round*.

The figures below show two kinds of measurements, the *compromise ratio* and the *local connectivity* for all the models RoK, COFRG and GOFRG. For the calculation of the compromise ratio, all links that are compromised by adversary are counted except the links that belong to captured nodes. This count is divided by the total of all links that belong to non captured nodes. In addition, this ratio was calculated separately for active and total compromised links in order to differentiate between the compromise of active and dead links. Noting that the compromise ratio is the inverse of resiliency metric and the drop in compromise ratio implies the increase in resiliency and visa versa. Here a *dead link* refers to a link which has at least one of its end nodes has gone out of battery. An *active link* is visa versa, i.e. both of its ends have enough battery to communicate.

For local connectivity, the key establishment requests between neighboring nodes are counted. In these key establishment attempts, the number of successful ones that end up with valid key establishments were divided into the total of all the attempts. The result show the amount of success of the related scheme in terms of local connectivity. Despite that low connectivity is supported by path key establishments, this support is not reflected the graphs below in order to observe the connectivity performances of all schemes.

Simulation Results. Figure 3 shows the number of all compromised links over all the links established since the beginning of the network versus generations, with the constant attacker model. Here, at the early stages of the network the adversary is able to benefit from the captured nodes and increase the compromise ratio immediately, which is due to the majority of *Generation 0* nodes in the area. After this early dramatic increase until around *Generation 5*, all the schemes change their behavior. The reason is that by *Generation 5* the majority of the nodes scattered in *Generation 0* are out of battery and replaced by new nodes. In this way, all the schemes start to follow a

¹ These parameters are kept the same with Castelluccia and Spognardi [5].

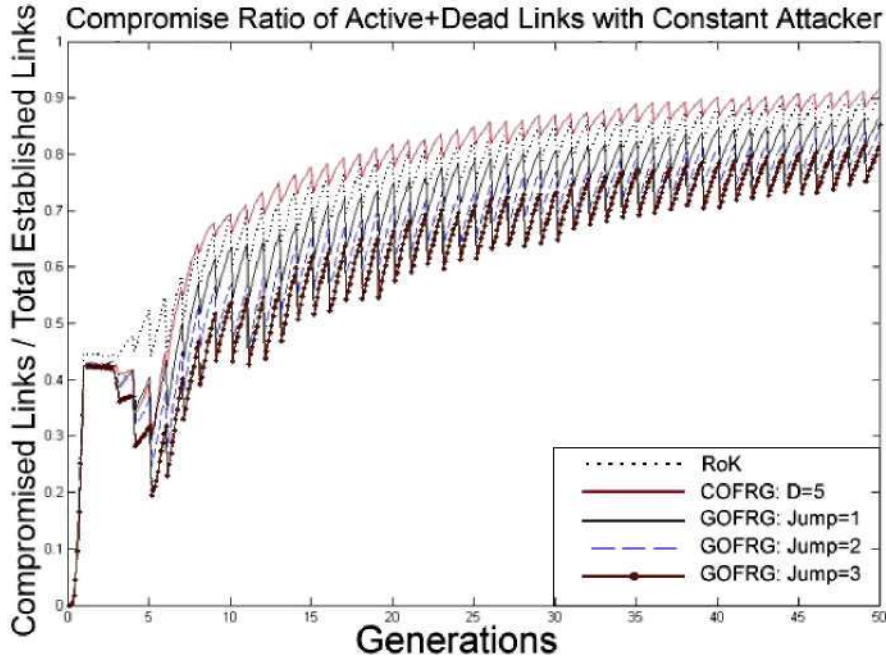

Fig. 3. Compromise Ratio of Dead and Active Links together, for Constant Attacker Model

steady behavior. At the beginning of the network, all schemes record above 0.4 compromise ratios. After that, a significant drop in compromise ratio, implying the improve in resiliency for COFRG and GOFRG schemes can be seen; where GOFRG with Jump 3 reaches around 0.2 compromise ratio. Finally, the resiliency of all schemes begin to drop slowly until the end of the network due to the compromise rate of 50 nodes per generation. Despite this, *multiphase* approach prevents the adversary to go beyond 91% of compromise ratio at worst case.

In RoK [5], there is no generation mixture, so at each new deployment only keys belonging to a single generation are introduced to the network. Therefore, they are certainly unknown to adversary at the time of deployment.

On the other hand, for each deployment of COFRG, after the network reaches a steady state after *Generation 5*, the generations of the nodes that are deployed contain already deployed generations with ratio 9/10. In other words, only 1/10 of the deployed nodes are from generations that do not exist in the area yet. This causes high compromise ratios in the latter stages. However it has around 0.3 compromise ratio at *Generation 5* while RoK records 0.45 at that time. This advantage for the resiliency in COFRG is due to having *Offset 5* from current time and the majority of nodes on the area being of *Generation 0* (see Fig. 1).

The only difference of GOFRG compared to COFRG is the JUMP parameter which is 0 in COFRG and has larger values for GOFRG. The performance of both schemes is similar until *Generation 5*, where a significant drop in compromise ratio is achieved. In order to maintain this performance, at each deployment, extra jumps towards future is

Fig. 4. Ratio of Successful Key Establishments over all attempts

made by GOFRG. This results in a better resiliency performance than both of COFRG and RoK throughout the network life.

Meanwhile, using future generations in COFRG and GOFRG pays off with lower connectivity performance (Fig. 4). This is due to the nodes from future generations that have lower probabilities of having colliding generations with their neighbors compared to RoK. Figures 1 and 2 show the generation diversity at a given time. As it is seen in Fig. 1, with COFRG at *Generation 5* the generations between 0-19 exist in the network. Therefore it is more difficult for COFRG nodes to have colliding generations between their neighbors, according to RoK which has nearly 10 generations at a given time, considering the battery lifetimes of nodes. The same applies for GOFRG, where the diversity of generations causes loss in connectivity too. In Fig. 2, at *Generation 5* there are 22 generations ranging from *Generation 0* up to *Generation 22*. However, the low connectivity is tolerated with path key establishments which increase the communication overhead. Despite this communication overhead, the tradeoff between connectivity and resiliency is desirable since resiliency has no alternative.

Figure 5 shows the compromise ratio of active links, which are certainly more valuable than the dead links for most of the applications of WSNs. The compromise ratio of all schemes oscillate with certain equilibrium and do not exceed certain limits, despite the capture rate of 5 nodes per round. In Fig. 5, the low compromise ratio of GOFRG throughout the whole network life, compared to RoK and COFRG show that, its high resiliency values is also valid for active links. During the steady state of the network, COFRG is around 0.7 of compromise ratio and RoK oscillates between 0.55 and 0.4. However, GOFRG perform better with oscillations between 0.21 and 0.45.

The temporary attacker in Fig. 6, does not compromise any nodes after *Generation 9*. In addition to that, the adversary can compromise new links only until *Generation*

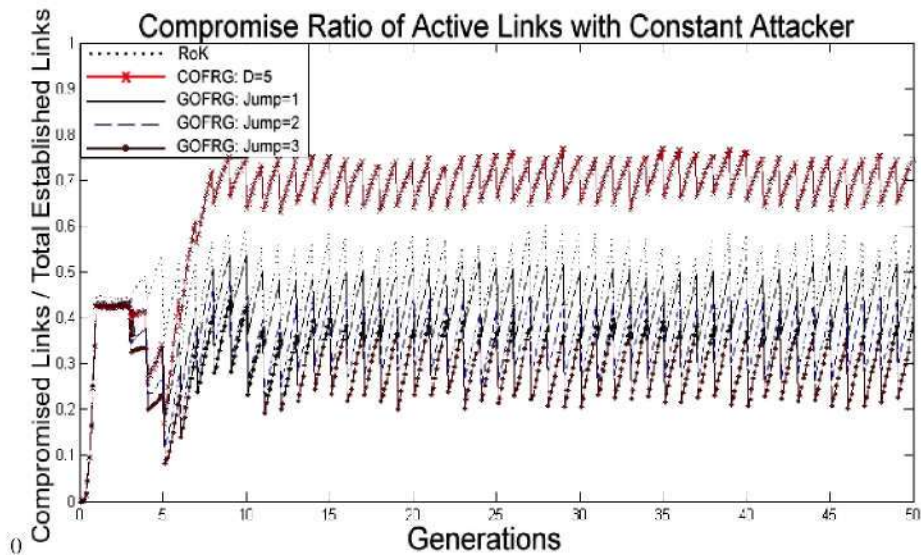

Fig. 5. Compromise Ratio of Alive Links. for Constant Attacker Model

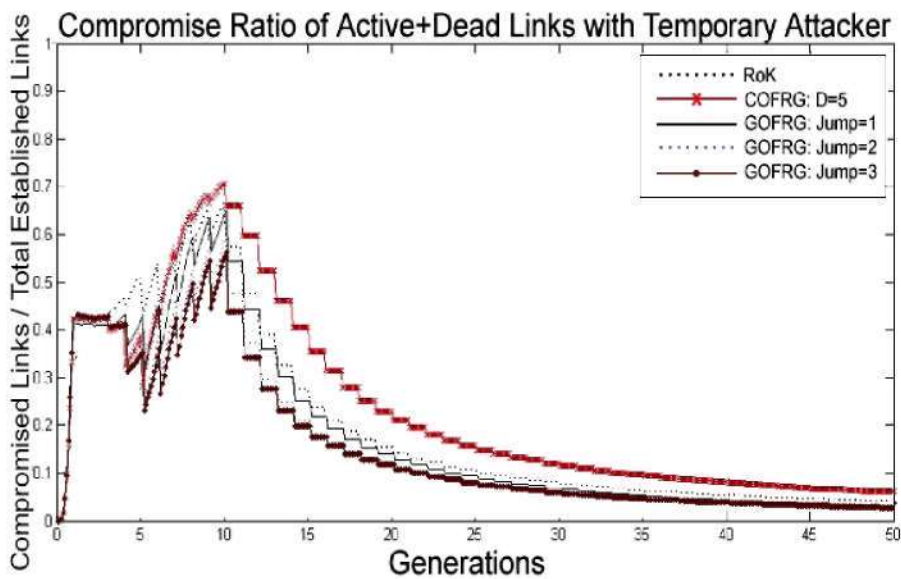

Fig. 6. Compromise Ratio of Dead and Alive Links. for Temporary Attacker Model

19 in COFRG, which is the extremum case. In GOFRG, adversary can not compromise links after *Generation* 12. Later on, the compromise ratio that does not reach 0 is due to the dead links at the hand of adversary that are taken into account in Fig. 6.

Meanwhile, Fig. 7 is decisive in terms observing the *self healing* abilities of all the schemes. Figure 7 shows for all schemes that the number of compromised active links

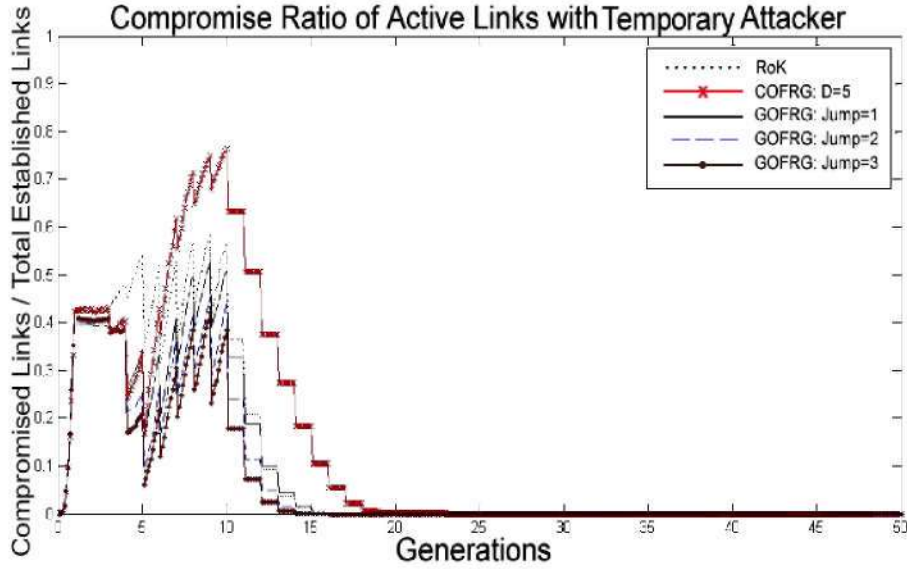

Fig. 7. Compromise Ratio of Alive Links. for Temporary Attacker Model

becomes 0, which implies that the *self healing* of all schemes manage to heal the network completely. However, GOFRG Jump 3 and GOFRG Jump 2 reach 0 compromise ratio by *Generation 14*. While, GOFRG Jump 1 and RoK achieve it by *Generation 15*. Finally, COFRG achieve the same level by *Generation 18*. Noting that these statistics are not the only difference between the schemes, since until the complete *self healing* achievement of the schemes, high resiliency values of GOFRG against RoK and COFRG is notable.

Path Key Establishment Results. For those node pairs that are not able to establish a common key, path key establishment process is applied. In our simulations all schemes reach 98% and higher connectivity levels. As a result, with GOFRG we have better resiliency and equivalent connectivity with RoK scheme.

However, path key establishments consume high amount of energy resources due to high communication traffic. Considering that sensor nodes are limited in energy resource and batteries can not be replaced, this fact is crucial.

5 Discussions

The fast *self healing* of GOFRG is observed in simulations, however this model gives us a wide range of new issues to consider, like the tradeoff between connectivity and resiliency, dynamic lifetime of key rings and non-captured nodes that turn to be useless. In this section we discuss these issues.

5.1 Connectivity versus Resiliency Tradeoff

Deploying some of the nodes earlier than their own generations obviously will make it harder for the attacker to compromise new links, however it will also make it harder for new nodes to establish keys with older ones. In this case, path key establishments, certainly with some energy cost, bring connectivity to desired levels. Keeping in mind that resiliency is rather harder to tolerate, this scenario would be fairly desirable for attack sensitive applications. In these applications, low local connectivity can be balanced by path key establishments in order to achieve reasonable connectivity levels.

5.2 Dynamic Lifetimes of Key Rings and Wasted Non-captured Nodes

In RoK [5] all nodes have a fixed key ring lifetime, LT . Considering that a random mix of generations are deployed in COFRG and GOFRG, those key rings may expire earlier than expected. This is due to the fact that there may not be any colliding generations between the node in question and the neighboring nodes deployed a few generations later. This problem causes for some sensor nodes to become useless even though they have enough battery to maintain their role in the network. Assuming that *node A* is of *Generation X* and all neighboring nodes are of *Generation Y* where $X + 10 \leq Y$, *node A* will be disconnected from the network, despite it has enough energy to operate.

Considering the scenarios above, battery lifetimes of sensor nodes should be adjusted such that the time between disconnection of a node and depletion of its battery is as short as possible.

6 Related Work

In 2002, Eschenauer and Gligor [9] proposed a random key predistribution model, for pairwise key sharing of sensor nodes. This study inspired many researchers and motivated them towards hiding the cryptographic credentials using randomness. Such as the authors Du et al.[8], Mehta et al.[11], Yu and Guan[13] and Anjum[2] developed their own ways using random predistributions.

Du et al. [8] use randomness to apply Blom Scheme [3] into large scale wireless sensor networks with the advantage of deployment knowledge. Therefore, nodes that are not supposed to communicate due to geographic distance, do not waste their memory to have the same keys.

The study of Yu and Guan [13] divides the field into n-gon shapes and focuses on the parameters of geometric design according to the outcomes of connectivity and resilience. In these designs multiple key spaces are used and lambda-degree security is provided.

In a relative study, Mehta et al. [11] use hash chains and hide key space identifiers to improve resilience against key space targeted attacks.

In another study, Yang et al. [12] use the location identifiers as node IDs. Two sensor nodes are able to establish a pairwise key if they know the approximate location of each other, using polynomial calculations. There is no need to use extra memory for unused keys. However, in order to increase the security of polynomial spaces node-to-node

communication is done over temporary chosen group heads. Therefore there is a need for secure in-group key establishment with another key distribution algorithm.

Camtepe and Yener [4] consider a number of block designs to construct key pools and construct both deterministic and randomized algorithms. This model is referred as Combinatorial Approach which results in improved connectivity with less memory consumption in comparison to Eschenauer and Gligor[9].

Anjum [2] adds security to the random key rings of sensor nodes using random beacons from anchor nodes, and these beacons are attached to the pairwise keys in order to increase resiliency. In this scenario neighboring nodes will possibly receive the same beacons and are able to increase the security of their existing keys.

A recent deterministic method by Dong and Liu [7], uses a number of assisting nodes, that are used only for key establishment and correspond to a fraction of 0.8% over all the nodes. In Dong and Liu[7] assisting nodes are deployed with hashes of master keys of all the regular nodes. When a key establishment is needed between a couple of nodes, one of them calls for the assistance, then each of the neighbouring assisting nodes provide randoms encrypted with each of the master keys of the nodes in question. The encrypted randoms are sent to the couple. These two nodes xor all the randoms they receive to get the pairwise key.

The study of Lu et al. [10] is considering the routing mechanism. This work devises a heterogeneous network structure where some of the nodes have extra capabilities in terms of storage, transmission power etc. Applying previous schemes on top of this scenario turns out to have better connectivity measures due to considering routing scenarios.

Chan and Perrig [6] use intermediate nodes for a scalable key establishment algorithm, where communication and memory overheads grow sublinearly with the growth of network size. This study provides higher resilience using multiple intermediate nodes for a single key establishment.

Castelluccia and Spognardi [5] propose the RoK scheme which limits the activity of sensor nodes to a given amount of time. This requires new nodes to be added to the network sequentially, in return, some of the captured nodes turn out to be useless in terms of compromising new links.

The significance of RoK [5] is that it considers another dimension, the time, which is clearly, a point where previous key distribution schemes underestimated while dealing with the problem of compromised keys.

7 Conclusions

Despite the limited resources in wireless sensor networks, significant amount of energy and memory are spent for security needs. However, the time dimension is an immature aspect which was not considered to improve performance until recently.

In recently proposed RoK Scheme [5], the key rings of nodes are updated such that older versions of the same key do not reveal the new version benefiting from the irreversibility of hash chain mechanisms. This scheme results in a *self healing* property of the network that improves resiliency in time.

In this study, we propose to speed up the self-healing process of RoK, which gives better results in terms of resiliency. Two new models, namely COFRG (Constant

Offset Future Random Generations) and GOFRG (Growing Offset Future Random Generations) are described and their performances are analyzed and compared to RoK scheme. Both proposed models make use of generations that are assigned for future uses. COFRG keeps the offset to the current generation unchanged. Meanwhile GOFRG makes jumps towards future in order to increase the offset to current generation. *JUMP* parameter defines the amount of increase in the offset at each generation in GOFRG. In our simulations, the compromise ratio of GOFRG with *JUMP*=3 approaches 0.2 where RoK scheme records more than 0.5 of compromise ratio. That means, GOFRG shows better resiliency as compared to RoK. The local connectivity value for GOFRG with *JUMP*=3 is around 0.5, whereas this metric for RoK is around 0.89. However, local connectivity increases in GOFRG for smaller *JUMP* values with a cost of reduced resiliency. These analyses indicate a tradeoff between connectivity and resiliency in our schemes. This tradeoff is the main difference between the proposed GOFRG scheme and RoK.

The COFRG model, which is actually a special case of GOFRG with zero *JUMP*, is a baseline for resiliency in terms of the *JUMP* parameter. The advantage of GOFRG is that its deployment window shifts more than one generation each time, whereas the deployment window in COFRG shifts one by one. This small difference makes a big effect throughout the network life and resiliency significantly drops in GOFRG. In other words, GOFRG takes the advantage of time dimension in a better way than COFRG.

The advantage of GOFRG in terms of resiliency pays off with low connectivity values. This tradeoff between resiliency and connectivity can be justified considering that connectivity can be tolerated with path key establishments, where low resiliency cannot be cured.
