1 **ABSTRACT**

2 Knowledge of the genetic structure of germplasm collections is crucial for conservation and
3 efficient use of genetic resources. This study assessed the diversity and genetic structure of a
4 collection of landraces of Spanish durum wheat (*Triticum turgidum* L.) using several marker
5 systems and correlated the diversity and agro-morphological traits with geographic and climatic
6 features. Analyzed genotypes were separated into nine populations with a moderate to great
7 genetic divergence among them. The three subspecies *dicoccon*, *turgidum* and *durum*, present in
8 the collection, largely determined the clustering of the populations. Genotype variation was
9 lower in *dicoccon* and *turgidum* than in *durum*. Genetic differentiation by the agro-ecological
10 zone of origin was greater in *dicoccon* and *turgidum* than in *durum*. DArT markers revealed two
11 geographic substructures, east-west for *dicoccon* and northeast-southwest for *turgidum*. The ssp.
12 *durum* had a more complex structure, consisting of seven populations with high intra-population
13 variation. DArT markers allowed the detection of subgroups within some populations, with agro-
14 morphological and gliadin differences, and distinct agro-ecological zones of origin. Two
15 different phylogenetic groups were detected; revealing that some *durum* accessions were more
16 related to ssp. *turgidum* from northern Spain, while others seem to be more related to *durum*
17 wheats from North Africa.

18

1 Introduction

2 Good understanding of the genetic structure of germplasm collections is critical for conservation
3 *per se*, and for efficient use of genetic resources. A comprehensive assessment of the extent and
4 distribution of genetic variation within endemic populations is essential for their exploitation by
5 breeders and in the development of core collections (van Hintum et al., 2000).

6 In wheat, Huang et al., (2002); Chao et al., (2007); Li et al., (2008), Royo et al., (2010)
7 and others have demonstrated the effectiveness of the single sequence repeats (SSRs) or
8 microsatellites DNA markers, in studies of germplasm collections using cluster analyses or the
9 model-based clustering implemented in the software STRUCTURE (Pritchard et al., 2000). SSRs
10 offer a number of advantages such as high polymorphism, locus specificity and co-dominance.
11 However, other types of DNA markers such as DArTs (Diversity Arrays Technology) offer a
12 deeper genome coverage and better effectiveness, in the sense that much higher numbers of
13 genotypes can be screened in a time and cost effective manner (Akbari et al., 2006). So, some
14 studies have applied DArT markers to the analyses of genetic diversity and population structure
15 in wheat (Stodart et al., 2007; White et al., 2008; Raman et al., 2010; Zhang et al., 2011;
16 Dreisigacker et al., 2012). Storage proteins such as gliadins can also serve as valuable markers
17 for the quantification of genetic diversity in wheat, and can be used to establish phylogenetic
18 relationships and associations with agro-climatic factors (Kudryavtsev et al., 1996; Melnikova et
19 al., 2010b). All diversity studies have shown that different factors such as selective pressures,
20 pedigree relations, desirable traits for humans, or ecological environments may contribute to the
21 genetic variability of accessions.

22 Landraces of the Spanish durum wheat (*Triticum turgidum* L.) are classified in three main
23 interfertile subspecies: *dicoccon*, *turgidum* and *durum* that share the same AABB genomic

1 constitution. The ssp. *dicoccon*, hulled wheat used for animal feed and human consumption,
2 represents the primitive stage in the crop evolution. It was gradually replaced by more advanced
3 free-threshing types of ssp. *durum* and *turgidum*, which evolved from ssp. *dicoccon* (Zohary and
4 Hopf, 1994). In Spain, ssp. *dicoccon* was less widespread, with its cultivation area restricted to
5 mountainous regions. In contrast, the ssp. *durum* was the most widely grown, and was adapted to
6 dry-summer conditions; ssp. *turgidum* was less common than ssp. *durum* and was grown in the
7 areas colder than *durum*. It was a mostly winter wheat with a prostrate growth habit and late
8 heading. Although both subspecies were consumed as pasta and semolina products, Spanish
9 landraces of *turgidum* had, in general, lower quality and higher tillering rate than the *durum*
10 types (Gadea, 1954). Most of these Spanish landraces were collected in the first half of the 20th
11 century, and maintained in the national collection. Several studies have shown that these
12 landraces have a great variability relative to other germplasm collections (Pflüger et al., 2001;
13 Aguiriano et al., 2006, 2008; Moragues et al., 2006). The evaluation of the genetic structure of
14 this collection appears worthwhile for better conservation, utilization, and eventual creation of a
15 core collection, and can be dramatically enhanced by using molecular genotyping tools.

16 The aim of this research was to study the genetic structure and genetic diversity of a wide
17 sample of Spanish durum wheat landraces selected from the national collection, using SSR,
18 DArT and gliadin-markers. The relationships among the three subspecies taxa present in the
19 collection (*dicoccon*, *turgidum* and *durum*) were assessed and geographic and climatic features,
20 as well as agro-morphological traits, were analyzed in order to obtain information for a more
21 efficient conservation and utilization of the collection.

22

1 MATERIALS AND METHODS

2 Plant Material and Agro-ecological Zones

3 A total of 190 genotypes of three subspecies: 13 of *T. turgidum* ssp. *dicoccon*, 38 of *T. turgidum*
4 ssp. *turgidum* and 139 of *T. turgidum* ssp. *durum*, were selected for this study from the national
5 collection of 555 Spanish accessions of *T. turgidum* L. maintained at the National Plant Genetic
6 Resources Centre. The *turgidum* accessions were distinguished from *durum* accessions by spike
7 morphology. Spikes of *turgidum* are usually lax and long, with rough awns which can fall off at
8 maturity. They have short glumes and round, soft grain. The *durum* types are always awned,
9 usually smooth at the base, have dense spikes compressed laterally and long grains. The number
10 of accessions selected for each subspecies was proportional to the number of landraces of each
11 subspecies cultivated before 1950 according to Gadea (1954). The set included 185 landraces
12 from all wheat growing areas in Spain as well as five old cultivars. The site from which each
13 accession was collected was ascribed to one of nine agro-ecological zones (Z) in Spain (Fig.1).
14 These zones were defined based on a cluster analysis of historical yield records from 1920 to
15 1991 in the Spanish provinces (MAPA 1920-1991) following the methodology used by Igartua et
16 al. (1998). Zones with similar yields but different climatic and geographic locations were
17 separated (Z3 and Z4, and Z6 and Z7). The number of landraces representing each zone and
18 province was chosen to be proportional to the number of landraces cultivated in that zone
19 (Gadea, 1954). The selection of accessions within provinces and zones was made using passport
20 data, local names and agro-morphological characterization to represent the diversity in the
21 national collection.

22 Eighty accessions had geographic coordinates (altitude, latitude and longitude) and
23 climatic data of the collection site. Climatic data from at least 20 years were extracted from the

1 SIGA service (Spanish acronym for Geographic Information System for Agriculture) of the
2 Spanish Ministry of Agriculture, Food and Environment
3 ([http://www.magrama.gob.es/es/cartografia-y-sig/temas/sistema-de-informacion-geografico-de-
5 datos-agrarios-siga/](http://www.magrama.gob.es/es/cartografia-y-sig/temas/sistema-de-informacion-geografico-de-
4 datos-agrarios-siga/)) (Table 1).

6 Seed samples were derived from single bagged spikes taken from single selected plants,
7 representative of each original accession. Seeds from bagged spikes were used for gliadin and
8 DArT analysis, and leaves from the same selected plants were used for the SSRs analyses.

9 **Molecular Markers**

10 For the SSR analysis, DNA was extracted from leaf samples using a standard CTAB protocol.
11 The set of 190 accessions was profiled with 39 microsatellites (SSRs) selected based on their
12 genomic distribution, profile quality and the polymorphism level. The list included markers
13 listed as WMC (Wheat Microsatellite Consortium), GWM (Gatersleben Wheat Microsatellite),
14 CFA (Clermont-Ferrand A genome), and BARC (Beltsville Agriculture Research Center) SSRs
15 (Sourdille et al., 2001; Song et al., 2005, Somers et al., 2004) (Table S1). The SSR primer pair
16 sequences and amplification conditions were obtained from the GrainGenes database
17 (<http://www.wheat.pw.usda.gov>). The forward primer of each marker was 5'-labelled with a
18 fluorescence tag, PCR products were analyzed on ABI PRISM[®] 3100 DNA analyzer (Applied
19 Biosystems, USA) and allele sizing was carried out by *Peak Scanner Software* v1.0 package
20 (Applied Biosystem, USA).

21 Gliadins were extracted from single seeds and fractionated in the polyacrylamide gel
22 electrophoresis (Lafiandra and Kasarda, 1985). Identification of *Gli*- alleles was performed

1 following the nomenclature proposed by Kudryavtsev et al. (1996) and Aguiriano et al. (2006,
2 2008). The alleles not catalogued in previous studies were termed as ‘new’.

3 For DArT genotyping, DNA was extracted from seeds using the *Ultra Clean Plant DNA*
4 *Isolation kit* (MO BIO), according to the manufacturer’s instructions, and sent for analysis to
5 Diversity Arrays Technology Pty Ltd (<http://www.triticarte.com.au/>) using the standard Durum
6 Wheat v2.0 array (with about 2,000 markers). From the 190 initial accessions, data were
7 collected for 184 accessions, due to logistical problems and analysis failures in six samples. In
8 total, 749 markers were polymorphic in the collection.

9 Correlations between genetic distances obtained with molecular markers were tested
10 using the Mantel test (Mantel, 1967).

11

12 **Analysis of the Genetic Structure of the Collection**

13 The genetic structure of the collection was investigated by SSRs using the Bayesian clustering
14 algorithm implemented in the software STRUCTURE v 2.1 (Pritchard et al., 2000). This model
15 delineates clusters of individuals based on their genotypes at multiple loci by identifying groups
16 of genotypes, termed “populations”, with distinctive allele frequencies in which the Hardy–
17 Weinberg equilibrium is maximized. In this study, each genotype corresponds to an accession, so
18 the populations obtained with the analysis represent groups of accessions. The program was run
19 independently five times with k ranging from 1 to 13 in each run using a burn-in of 100,000, run
20 length of 1000,000 and a model allowing for admixture and allele frequencies that are correlated
21 among populations. The five independent runs yielded consistent results. The true number of
22 populations (k) was determined by means of both an estimate of the posterior probability of the
23 data for a given k (as proposed by Pritchard et al., 2000) and the Evanno’s Δk (Evanno et al.,

1 2005) (Fig. 2A, B). A genotype was considered to belong to a population if its membership
2 coefficient was ≥ 0.50 (Royo et al., 2010).

3 To investigate population differentiation, F_{ST} (Weir and Cockerham, 1984) between
4 populations was calculated and tested using FSTAT 2.9.3.2 (Goudet, 2001). The total gene
5 diversity (H_T) and the relative magnitude of gene differentiation between populations (G_{ST}) were
6 calculated (Nei, 1973) with POPGENE 1.32 (Yeh and Boyle, 1997). For the DArT data analysis,
7 dendrograms were made by UPGMA aggregation method with the Dice distance (Dice, 1945).

8 9 **Agro-morphological Characterization**

10 The accessions were sown in an augmented design (Petersen, 1985) of four blocks with 54 plots
11 per block during the season 2006-07 in Alcalá de Henares (Madrid). Each accession was
12 cultivated in a single plot consisting of 3 rows 1.5 m in length with 30 plants per row. Cultivars
13 Senatore Cappelli, Cocorit 71, Simeto, Don Pedro, Vitron, and Claudio, with different agro-
14 morphological characteristics, were included in each block as checks to estimate the adjustment
15 factor for each block. Agro-morphological traits listed in Tables 2 and 3 were recorded according
16 to IBPGR (1985) from five different plants of each accession. One-hundred and thirty-nine
17 landrace accessions were classified according to their seasonal growth habit (winter, alternative
18 or spring) using the data of Gadea (1954). Differences of trait means among populations were
19 checked by the LSD of the ANOVA for quantitative data and χ^2 test for frequency data.
20 Relationships between variables were examined using Pearson correlation coefficients.

21

22 **RESULTS**

23 **Polymorphism of SSR, gliadin and DArT markers**

1 Among 190 accessions in the study, the 39 SSR markers used identified 641 alleles. The number
2 of alleles per locus ranged from 4 to 41, with the mean of 16 alleles per locus (Table S1). With
3 two exceptions (Xgwm0002 and Xgwm0095), all loci presented unique alleles. Mean value for
4 the polymorphic information content (PIC) was 0.77. The number of accessions with unique
5 alleles was notable, 10 out of 13 (77%) in *dicoccon*, 27 out of 38 (71%) in *turgidum* and 57 out
6 of 139 (41%) in *durum*.

7 The overall gene diversity for gliadins among the 190 genotypes was 0.80. The most
8 polymorphic loci were *Gli-A2* and *Gli-B2* ($H_T > 0.87$). The three subspecies displayed unique
9 alleles and 23 uncatalogued alleles were detected with low frequencies (Table 4). DArT
10 genotyping identified 749 polymorphic loci, of which 554 were used for subsequent analyses,
11 selected for having less than 5% of missing data. These markers were distributed among all
12 seven homologous groups of wheat chromosomes: with 87, 76, 93, 46, 56, 98, and 78 markers
13 per group 1 to 7, respectively (according to the information placed on:
14 http://www.triticarte.com.au/content/further_development.html). Twenty-eight DArT markers
15 were not assigned to any chromosome. PIC values ranged from 0.03 to 0.50 (the max. value for a
16 biallelic marker), with a mean value of 0.30. The Mantel test detected significant correlations (P
17 < 0.01) between the distances obtained with SSRs and gliadins ($r = 0.36$), SSRs and DArTs ($r =$
18 0.50), and SSRs and agro-morphological data ($r = 0.21$).

19

20 Genetic Structure of the Collection

21 STRUCTURE gave an optimum population (Pop) number (k) of nine (Fig. 2). The assignment of
22 genotypes into populations was consistent among the different runs. All but two genotypes of
23 ssp. *turgidum* and eight of *durum* were grouped into one of the nine populations. All the

1 populations (i.e. group of accessions) contained one subspecies each, except Pop 4 and Pop 5
2 (Fig. 2C). The three subspecies clustered separately with DArT markers, with the subspecies
3 *turgidum* being closer to *dicoccon* than to *durum* (Fig. 3).

4 Genetic differentiation among subspecies, agro-ecological zones and populations
5 quantified with SSRs and gliadins was significant (Table 5). According to Wright's classification
6 (Wright, 1978), pairwise F_{ST} values were high between *dicoccon* and *durum*, but moderate
7 between *dicoccon* and *turgidum* and between *durum* and *turgidum*. For each of the three
8 subspecies, the within-zone variability was greater than the between-zone variability ($G_{ST} <$
9 0.43). The differentiation among the nine populations was high and higher than among
10 subspecies and zones (Table 5). The inter-population variability was higher for the subspecies
11 ($G_{ST} = 0.79$) than for the zone ($G_{ST} = 0.17$). All population pairwise F_{ST} values were significant
12 (Table 6). According to these values, Pop 1 of *dicoccon*, was the most different population. The
13 three *turgidum* populations, Pops 4, 5 and 7 (Fig. 2C) had moderate differentiation, although
14 gene diversity detected with SSRs and gliadins, respectively, was higher in Pop 4 ($H_T = 0.71$
15 and 0.79) than in Pop 7 ($H_T = 0.59$ and 0.60). For the seven *durum* populations, Pops 2, 3 and 6
16 had the highest F_{ST} values, whereas Pops 8 and 9 showed the least differentiation. The greatest
17 gene diversity was for Pops 5, 8 and 9 (in the range of 0.62 - 0.72) and the lowest for Pops 2, 3
18 and 6 (in the range of 0.47-0.60).

19

20 Differences between Populations due to Geographic and Climatic Features

21 All *dicoccon* accessions came from the agro-ecological zones Z9, Z4 and Z1 (Table 7), located
22 in northern Spain (Fig. 1). The values of the climatic factors at the sites of origin showed
23 significant differences between Pop 1 and the remaining populations (Table 1).

1 Accessions of *ssp. turgidum* in Pop 4 originated from the North and East of Spain (Table
2 7, Fig. 1). By contrast, those included in Pop 7 originated mainly from the South and West of
3 Spain, and none originated from Z9. Accessions from Z4 (Central Spain) were present in both
4 populations (Pops 4 and 7), but those in Pop 4 originated mostly from the eastern provinces,
5 whereas those in Pop 7 were from the western provinces. Accessions in Pop 4 were collected in
6 the areas with a shorter dry-period and lower mean maximum temperatures of the hottest month
7 than those in Pop 7 (Table 1) in agreement with the north-south distribution of Pops 4 and 7.

8 Most accessions of *ssp. durum* originated from areas of Central or Southern Spain, with a
9 high frequency of specific agro-ecological zones (Table 7, Fig. 1). Few differences were found
10 for the climatic and geographic factors between the major populations, Pops 2, 3, 6, 8, and 9
11 (Table 1). By contrast, Pop 4 came from more humid and colder areas, and Pop 5 came mostly
12 from colder areas. Both these populations differed from the other durum populations in the
13 absence or higher presence of some agro-ecological zones, indicating that Pops 4 and 5 were
14 spread across different zones than others (Table 7).

15

16 **Differences between Populations in Agro-morphological Data, Gliadins and DArT Markers**

17 The agro-morphological data indicated that all Spanish *dicoccon* accessions had rough awns,
18 hairless glumes, and red grains (Table 2). The genotype in Pop 5 had dense spikes, the lowest
19 grain weight and a different gliadin pattern from those genotypes in Pop 1 (Tables 2, 3 and 4).
20 Fig. 4 shows the dendrogram based on DArT markers for the *dicoccon* genotypes. The *dicoccon*
21 of Pop 5 was separated from those included in Pop 1. The genotypes of Pop 1 formed three
22 subpopulations, A1, A2 and A3, with corresponding differences in agro-ecological zones of
23 origin, different *Gli-1* alleles and the agro-morphological traits such as growth habit, awnedness,

1 precocity, and 100-grain weight. There were only two *dicoccon* accessions with spring growth
2 habit (from Z4), in contrast to the winter or alternative growth class of the remaining accessions.

3 For *ssp. turgidum*, significant ($P < 0.05$) differences between Pops 4 and 7 were detected
4 for *Gli-A1* alleles (Table 4), growth habit and seed color (Table 2), and for quantitative data
5 (Table 3). For Pop 4, 86% and 5% of the accessions were winter and spring types, respectively.
6 By contrast, 33% and 42% of the accessions in Pop 7 were winter and spring types, respectively.
7 Significant correlations were observed between the longitude of the collection site and the
8 number of spikelets per spike ($r = 0.62$, $P < 0.01$), and between latitude and days to heading ($r =$
9 0.58 , $P < 0.05$), days to maturity ($r = 0.63$, $P < 0.01$) and spike length ($r = -0.49$, $P < 0.05$).
10 Earliness and long spikes were associated with southern collection sites, while greater spikelet
11 numbers were associated with the western origin. Cluster analysis with DArT data showed that
12 the genotypes of Pop 4 were separated from those of Pop 7 (Fig. 5). Three subdivisions appeared
13 in Pop 4 according to the agro-ecological zones.

14 For *ssp. durum*, significant differences ($P < 0.01$) among populations were detected at all
15 gliadin loci (Table 4), for all qualitative traits except for awnedness (Table 2), and for
16 quantitative traits (Table 3). No relationships were detected between populations and spring or
17 winter growth habits, perhaps because of a high proportion (95%) of spring types in this
18 subspecies. The altitude of the collection site correlated with the number of days to maturity ($r =$
19 0.29 , $P < 0.05$). In the dendrogram obtained from DArT data, the genotypes were separated into
20 seven subgroups (Fig. 6). The analysis of these subgroups within each population indicated that
21 over 80% of the genotypes of Pops 2 and 6 were included in a single subgroup. All genotypes of
22 Pop 3 and about 85% of the genotypes of Pops 4 and 9 were clustered in two subgroups. By
23 contrast, Pops 8 and 5 were more subdivided. Differences among subgroups within Pops 3, 4, 8,

1 and 9 were found for gliadins, some agro-morphological traits as for glume and seed color, and
2 for agro-ecological zones.

3 **DISCUSSION**

4 The suitability of SSR markers for evaluating genetic relationships of durum wheat germplasm
5 (Eujayl et al., 2002; Maccaferri et al., 2003; Royo et al., 2010) and the power of DArT markers
6 for assessing the population structure and genetic diversity in wheat collections have been
7 demonstrated previously (Stodart et al., 2007; White et al., 2008; Raman et al., 2010; Zhang et
8 al., 2011; Dreisigacker et al., 2012). To our knowledge, no diversity study has been conducted in
9 wheat with both types of markers. In this study, there was a large correspondence between the
10 results obtained with SSRs and with DArTs, reflected by significant correlations observed for the
11 genetic distances obtained with the two systems. These correlations can be found for related
12 cultivars or when linkage disequilibrium exists between the different markers' loci, which could
13 be due to the presence of genes for adaptation to local conditions. Although DArT markers
14 revealed less polymorphism information per locus than SSRs, they are useful in diversity
15 analyses because high numbers of markers can be processed quickly, providing a genome-wide
16 coverage and the power to detect even very small polymorphisms. In this study, the DArT
17 markers were very useful to explore the substructure of the collection and to discriminate
18 between subspecies, as has been recently proved in *Aegilops tauschii* (Sohail et al., 2012).

19 The level of diversity of 0.77 assessed with SSRs in our collection was greater than that
20 observed in other studies of durum wheat, using some coincident SSRs markers. Collections
21 from different countries such as Italy, Oman, Syria and Ethiopia showed average gene diversity
22 values between 0.55 and 0.68 (Eujayl et al., 2002, Maccaferri et al., 2003, Teklu et al., 2006, Al-
23 Khanjari et al., 2007, Achta et al., 2010). The diversity value of our collection assessed with

1 gliadins was 0.80, much higher than that found in other studies of durum wheat (0.53 in
2 Kudryavtsev et al., 1996, and 0.55 in Melnikova et al., 2010b) Thus, we conclude that we have
3 studied a sample of *T. turgidum* L. with considerable polymorphism, containing many unique
4 alleles, in which the assessment of population structure was essential.

5 According to STRUCTURE software, the collection was organized in nine populations or
6 groups of accessions with a moderate to great genetic divergence among them. The subspecies
7 taxa, *dicoccon*, *turgidum* and *durum*, had more effect on the differentiation of the populations
8 than the zones in which the accessions were collected. In fact, seven of the nine populations were
9 composed of only one subspecies (Fig. 2C). This separation among subspecies was consistent
10 when assessed with the gliadin and DArT markers (Table 4, Fig. 3). Genotype differentiation
11 was lower in *dicoccon* (one major population) and *turgidum* (two major populations) than in
12 *durum* (five major populations). The genotypes of *turgidum* showed an intermediate position
13 between those of *durum* and *dicoccon*, more related to *durum* with SSRs (Table 5) and to
14 *dicoccon* with DArTs (Fig. 3). The three subspecies originated from climatically different
15 growing areas with different requirements, especially the ssp. *dicoccon* which came from cool,
16 humid areas of northern Spain, in contrast to *durum*, which came from warmer areas in the South
17 (Tables 1 and 7, Fig. 1). The two populations of *turgidum* came from contrasting environments:
18 Pop 4 came from northern areas, whereas Pop 7 came from warmer southern areas, not unlike
19 those of *durum* (Table 1). Some *durum* genotypes of Pop 4 showed common characteristics with
20 *turgidum* and *dicoccon*, such as their northern geographic origin, prostrate growth habit, lax and
21 long spikes, red seeds, and the presence of the allele *Gli-B1new-1* (Tables 2, 3, 4, and 7).
22 Furthermore, some of them were the *durum* genotypes most closely related to *turgidum* in the
23 DArTs. By contrast, they were more similar to *durum* populations in awn length, grain filling

1 period and DArTs (Tables 1 and 3, Fig. 6). In fact these genotypes in Pop 4 had characteristics of
2 both subspecies. These results are in agreement with Mac Key (1966), who also found mixtures
3 of *durum* and *turgidum* in primitive endemic farms. For the remaining populations, the three
4 subspecies were clearly separated, based on SSR, gliadin and DArT markers, in agreement with
5 Mac Key (2005), who considered these taxa as subspecies. Moreover, genetic diversity in
6 *turgidum* was affected more by the geographic origin of the accessions and seasonal growth habit
7 than in *durum*. These differences between the two subspecies, attributed to their different
8 growing environments and human selection, were also detected by SSRs, which are under less
9 selection pressure than agronomic characteristics, even though some marker loci can suffer
10 frequency shifts if they are sufficiently closely linked to the genes targeted by selection.

11 Genetic differentiation by zones was greater in *dicoccon* and *turgidum* than in *durum*.
12 DArT analyses detected an eastern-western substructure in *dicoccon* (Fig. 1 and 4) associated
13 with agro-morphological and gliadin differentiation. In ssp. *turgidum*, differences between the
14 two main populations in the agro-morphological traits, in gliadins, as well as in geographic and
15 climatic features, and DArTs followed a northeast-southwest pattern (Tables 1, 2, 3, 4 and 7, Fig.
16 5). This geographic pattern was confirmed by the relationships between some agro-
17 morphological traits and the longitude and latitude of the collection sites. Similarly to ssp.
18 *turgidum*, a relationship among precocity, spring types and southern distribution has also been
19 observed among Spanish barley genotypes (Lasa et al., 2001; Yahiaoui et al., 2008). This north-
20 south pattern in barley was related to climatic differences in temperature and humidity (Yahiaoui
21 et al., 2008). The association of the distribution of genetic diversity with geographical patterns in
22 *dicoccon* and *turgidum* highlights the effect of selection pressure favoring allele associations

1 with a better local adaptation. These differences should be considered in the selection of
2 accessions for breeding programs.

3 The ssp. *durum* showed a more complex genetic structure. Seven populations or groups
4 of accessions were defined by the software STRUCTURE; high F_{ST} values, differences in agro-
5 morphological traits and gliadins indicated that there was also a significant separation of *durum*
6 populations overlaying a high intra-population variation (Tables 2, 3, 4, and 6). These
7 differences cannot be explained only by climatic and geographic variation (Tables 1 and 7).
8 However, minor climatic differences among the sites of origin of some populations could be the
9 result of a high frequency of some collecting zones in those populations e.g. the higher altitude of
10 the collecting zones of Pop 2 were due to the higher presence of the mountainous Z3 in this population. In
11 addition, Pop 9 was associated with warm and dry areas because included a high number of accessions
12 from Z6, which is the driest Spanish zone (Tables 1 and 7). Furthermore, some populations showed an
13 eastern (Pops 3 and 9) -western (Pop 8) differentiation associated with the presence or absence of
14 Z6 or Z8 (eastern), or Z5 (western) (Table 7, Fig. 1). In spite of these associations with
15 geographic origin, the studied populations also came from different agro-ecological zones,
16 suggesting that genetic diversity was not completely related to the geographic distribution. In
17 addition, genetic variation was larger within than between zones, indicating that genetic diversity
18 was preserved independently of the geographic region of origin of the accessions. A similar
19 result was obtained by Li et al. (2008) and Melnikova et al. (2010a) working with durum wheat
20 landraces from China and Bulgaria, respectively. Different human practices or germplasm
21 exchange could have contributed to the increased variation within populations.

22 The DArT markers based analysis detected the presence of subgroups within some *durum*
23 populations defined by STRUCTURE. This substructure reflected differences in agro-
24 morphological traits, mainly in spike characteristics, gliadins and the agro-ecological zones of

1 origin. Populations 2, 6 and 3 were less subdivided with DArTs, suggesting a higher isolation, in
2 agreement with their lower variability and higher differentiation (Table 6, Fig. 6). The accessions
3 in Pop 2 were distinguished by their late-heading and high altitude of collection sites, while those
4 in Pop 3 were characterized by their earliness (Tables 1 and 3). Interestingly, Pop 6 included a
5 distinct agrotype with erect growth habit and smooth awns (Table 2) coming from Z8, mainly
6 from the Balearic Islands. By contrast, Pops 4, 5, 8, and 9 showed more subdivisions, greater
7 variability and less differentiation from other populations, including Pop 1 of *dicoccon* (Table 6,
8 Fig. 6). These results indicate that Pops 4, 5, 8, and 9 are more heterogeneous with higher levels
9 of gene flow, with the subgroup G of Pop 4 being the most closely related to the subspecies
10 *turgidum*.

11 The lower diversity of *Gli-1*, together with the fact that the alleles with differences among
12 populations had high frequencies, suggests that selection pressure favors alleles associated with
13 good local adaptation. Moreover, *Gli-A1* and *Gli-B1* were the most fixed loci within zones in ssp.
14 *turgidum* and *dicoccon* ($G_{ST} = 0.45$ and 0.59 , respectively) in agreement with other studies that
15 have reported that some *Gli-1* alleles may provide some advantage under specific agro-climatic
16 conditions (Melnikova et al., 2010a,b). The lower diversity of *Gli-B1* could also be due to a
17 selection for quality, since these gliadins are genetic markers for gluten quality (Damidaux et al.,
18 1978). The *Gli-B1new-1* allele, widespread in Pop 4, was also the most common in *turgidum* and
19 very frequent in *dicoccon* (Table 4), confirming previous observations in accessions from
20 northern Spain (Aguiriano et al., 2008). This allele, associated with poorer quality than alleles *b*
21 and *c* (Aguiriano et al., 2009), has been reported to be very specific to Spanish germplasm
22 (Kudryavtsev et al., 1996; Melnikova et al., 2010b). In the *Gli-A2* locus, the allele *o*, present in
23 the old cultivar of Algerian origin, Senatore Cappelli, was very frequent in subgroup B of Pop 3,

1 to which this cultivar belongs. This allele was absent in *ssp. dicoccon*, *ssp. turgidum* and in Pop
2 4 of *ssp. durum*, i.e. in landraces from the northern areas (Tables 4 and 7, Fig. 1), supporting the
3 hypothesis of a North-African origin of this allele (Kudryavtsev et al., 1996). Similarly, *Gli-B2h*
4 of Senatore Cappelli, very common in Pop 2, subgroup B of Pop 3 and Pop 6 (Table 4), was
5 more frequent in the south and east of the country, in the Canary Islands, near North Africa, and
6 absent in the North of Spain. High frequencies of *Gli-A2o* were observed in cultivars of Algeria,
7 Morocco and Tunisia, and of *Gli-B2h* in many countries of Africa and South West Asia, with the
8 highest occurrence in cultivars from Algeria (Melnikova et al., 2010b).

9 A relationship between the SSR classification and the pedigree of wheat lines has been
10 shown in some studies (Macafferri et al., 2003; Chao et al., 2007; Royo et al., 2010). Our results
11 seem to indicate that genotypes in the subgroup B of Pop 3 and some genotypes of Pops 2 and 6
12 could share related ancestral lines from North Africa. Moragues et al. (2007) also found that
13 landraces from the Iberian Peninsula and North Africa (Egypt, Algeria, and Morocco) group
14 together, based on AFLPs and SSRs. Our results support the hypothesis of Moragues et al.
15 (2007) of two dispersal patterns of durum wheat across the Mediterranean basin, one along the
16 north side (Syria, Turkey, Bulgaria, Cyprus, Greece, and Italy) and the second along the south
17 (Egypt, Algeria, Morocco, Spain, and Portugal).

18 The genetic structure for the Spanish germplasm of *T. turgidum* L. showed that the
19 subspecies was the first level of separation, followed by the agro-ecological zone of origin for
20 *ssp. dicoccon*, but by geographic and seasonal growth habit for *ssp. turgidum*. Landraces of *ssp.*
21 *durum* showed a complex variation pattern, including different phylogenetic groups. Some
22 accessions were more related to the *ssp. turgidum* from northern Spain, while others, markedly
23 different, less diverse and more isolated, seem to be more related to *durum* wheats from North

1 Africa. Natural and human selection in combination with human migrations may have
2 contributed to the genetic diversity of *durum* wheat Spanish landraces. The knowledge of the
3 genetic and geographical structure of the collection is valuable for selecting accessions by users
4 and essential for the creation of the core collection by hierarchical sampling methods. The
5 detection of redundancies and missing traits, such as the absence of hairy and black spikes in
6 *dicoccon*, or the convenience of separation of *ssp. durum* and *turgidum* in evaluation studies help
7 to improve the conservation of the collection.

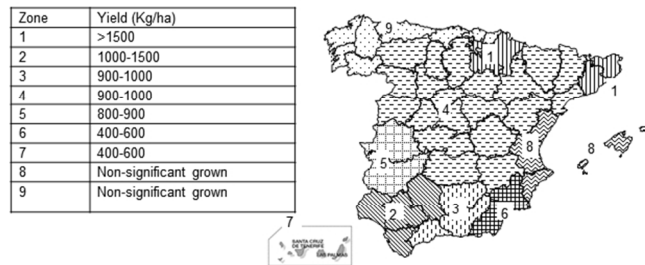

Figure 1. Map of Spanish provinces showing the nine agro-ecological zones for durum wheat cultivation according to long-term (1920-1991) average yield at each province.
254x190mm (96 x 96 DPI)

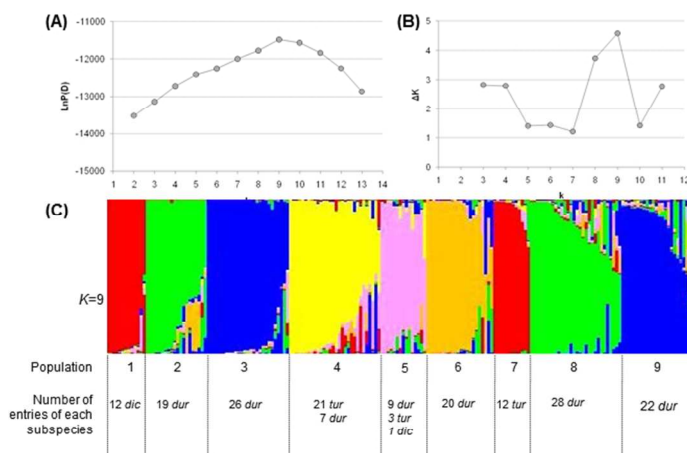

Figure 2. (A) Changes in the natural log probability of the data against the number of subpopulations (k). (B) Average Δk against k . Values are the mean of 5 runs of STRUCTURE simulations. (C) Inferred structure of the durum wheat collection based on 190 genotypes and genomic SSR markers using STRUCTURE. Each individual is represented by a line divided into colored segments that represent the individual's estimated membership fractions to each of the nine subpopulations. The subspecies are indicated as *dic* = dicoccon, *dur* = durum and *tur* = turgidum.

254x190mm (96 x 96 DPI)

Figure 3. Dendrogram of the DArT genotypes of the 184 accessions analyzed.
254x190mm (96 x 96 DPI)

Figure 4. Dendrogram of the DArT genotypes of the *ssp. dicoccon*. The populations (Pop), DArT subgroup (A) and agro-ecological zone (Z) are indicated.
254x190mm (96 x 96 DPI)

Only

Figure 5. Dendrogram of the DArT genotypes of the spp. *turgidum*. The populations (Pop) and agro-ecological zone (Z) are indicated.
254x190mm (96 x 96 DPI)

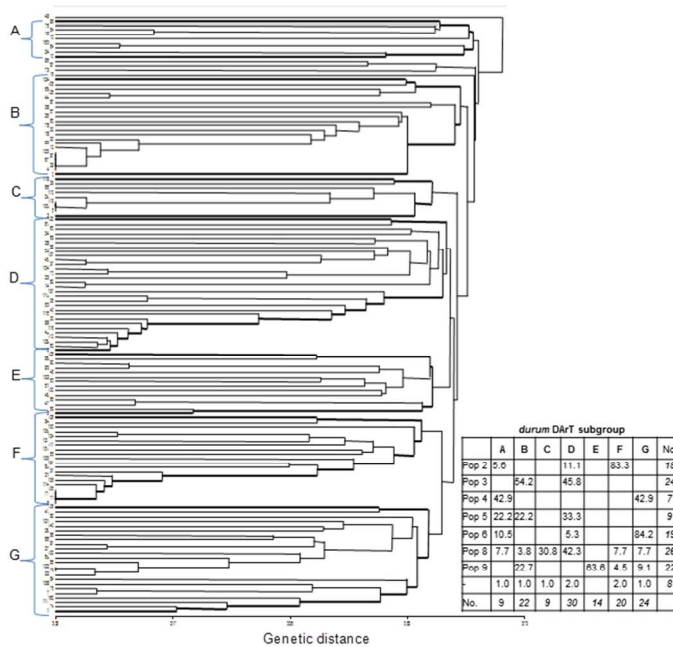

Figure 6. Dendrogram of the DArT genotypes of the *ssp. durum*. The DArT subgroups (A-G) are outlined in bold. The table shows the percentage of each population (Pop) classified in a DArT subgroup.
254x190mm (96 x 96 DPI)
