Abstract

A common phenomenon about transition economies is that the return to schooling improves as economic reform progresses. Existing research suggests that Vietnam is not an exception to the pattern. However, the rate of return for the period 1992-1998 is still relatively low, below 5%, relative to that of the world and other transitional economies. In addition, it is hard to see a clear trend in the current literature due to different methods applied and sets of variables controlled in the earnings equations (see Appendix B). The low returns may result from the gradual economic reforms applied in Vietnam, whilst in Eastern European countries the “Big Bang” transformation was conducted. Therefore, to test whether the return to schooling in Vietnam is rising and reaches other transitional economies’ rate of returns, we re-examine the trend in the rate of return to schooling in Vietnam over the 1998-2008 period, when the reforms have had a longer time to have an effect. We apply the OLS and Heckman selection estimator (Maximum Likelihood approach) and find that the return has increased quickly during the later economic reform but its pace has slowed down when the return reached the global average rate of returns around 10%.

Keywords: economic transition, returns to schooling, Vietnam

1. Introduction

A key stylized fact about transition economies is that the returns to schooling tend to rise as economic reform progresses (Orazem & Vodopivec, 1995). The rise marks the movement away from distorted labour markets and the effects of longer-term changes in patterns of human capital formation. Moreover, the increase in returns to schooling in transitional economies is especially marked for women, as found in the Czech Republic and Slovakia (Chase, 1998), and in Russia, Ukraine, Hungary and Poland (Brainerd, 1998).

Existing research suggests that Vietnam does not follow the pattern completely. In 1992, rates of return were very low at the beginning of transition: below 3% using basic Mincerian earnings equation and even below 2% if further controlled for other variables (Glewwe & Patrios, 1998; Gallup, 2002). Using both the basic and extended Mincerian earnings model, Gallup (2002) shows increasing returns between 1992-1998. However, when compared with the world rate of returns at about 9% to 10% around the same time (Psacharopoulos, 1994), the rates of returns for Vietnam are still low. Contrary to Gallup, estimates reported by Liu (2006) suggest falling rates of returns for men in Vietnam, from 5.9% in 1992 to 3.5% in 1998 and little increase for women, from 4.2% to 4.8% in the same period.¹ One possible reason for the divergence from the patterns in Eastern Europe is that gradual economic reform policies have been applied in Vietnam and the Vietnamese government has intervened in the economy substantially, whilst in Eastern European countries the “Big Bang” reforms were introduced. Therefore, conclusion on the trend of returns to schooling in Vietnam for the period is ambiguous.

To test whether the rate of returns to schooling in Vietnam improves during the economic transition, we re-examine the trend in the rates of returns to schooling in Vietnam over the period 1998-2008, called the later period of the reforms, when the reforms may have had longer time to have an effect. Moreover, recent years have seen continued development of the private sector (66% in GDP, and 91% in employment in 2008) which has stimulated competition in the labour market with consequent changes in relative wages. Concurrently, income inequality has also rose during the later reform period, with the Gini index rising from 0.35 in 1994 to 0.418 in 2002, and 0.42 in 2006 (GSO, 2004, 2006). Since participation rates in the wage labour market has risen during the period and wage earners have higher education achievement relative to non-wage

¹ Note that our comparison may be inappropriate because the different models, the Heckman selection correction and OLS model, are applied for 1992 and 1998 respectively. In the context of Vietnam, higher educated people tend to work in wage-paid jobs, so the selection models typically yield higher returns to schooling (Doan & Gibson, 2009). Given the higher returns by selection models, the decrease in males' returns over the period from 1992 to 1998 would be smaller; conversely the improvement in female returns would be greater.

earners (see Appendix A), the analysis not only relies on the basic Mincerian earnings function but also accounts for sample selection bias.

The next section reviews studies of the returns to schooling in transition economies. Section 3 discusses the data and econometric specifications. Section 4 presents the results. Discussion of possible explanations for the changing returns and conclusions are presented in Section 5.

2. Literature on return to schooling in transitional economies

Existing studies show that rates of return to schooling increase over time in transitional economies. For example, returns to schooling increased from 3.6% in 1988 to 12.2% by 1993 in China, from 1.5% in 1989 to 5.4% by 1994 in Estonia, and from 2.9% in 1986 to 7% by 1996 in Poland (Psacharopoulos & Patrinos, 2004, Table A4). Most of these studies use Ordinary Least Squares (OLS) which does not allow for endogenous school choice, but when Heckman and Li (2004) use Instrumental Variables (IV) they find even a higher rate of returns to each year of schooling, of around 14% for four-year college attendance in China. This rate is much higher than the rate of returns estimated by Chow (2001) for China in the 1980s which was much closer to zero. Johnson and Chow (1997) state that employment in the stationary state sector, which dominated in China's urban areas in the late 1980s, leads to lower rates of returns. Zhang et al (2005) also suggest that economic reform and technical changes have enhanced competition among workers in China, with the newly-skilled rewarded at an increasing rate. More evidence of the increasing returns during the reforms in transitional economies can be found in Fleisher (2005) and Fleisher, Sabirianova and Wang (2005). These authors find that the speed of economic transition and the degree of economic volatility explain the differences in the increase in the rates of return to schooling over time and across the economies.

Yet studies of Vietnam for either the single year 1992 or the period of 1992-1998 find low rates of return to schooling, and show a modest rise over time (Gallup, 2002; Glewwe & Patrinos, 1998; Liu, 2006; Moock, Patrinos, & Venkataraman, 2003). It is notable that the study by Liu (2006) was for over ten years of the economic reforms, yet the estimated rate of returns was still relatively low (3.5% and 4.8% for male and female in 1998, respectively). However, these studies may not have captured the full effects of the transition to a market-oriented economy given the cautiously gradual nature of early economic reforms in Vietnam. Hence, it is important to see the trend in the returns to schooling over the recent period 1998-2008, which is long enough to have an effect.

In addition to the timing issue, some existing studies on Vietnam ignored the important problem of sample selection bias (Gallup, 2002; Glewwe & Patrinos, 1998; Moock, Patrinos, &

Venkataraman, 2003).² Since there was a rising participation rate in the wage labour market during transition, the omission may bias not only the level of the estimated rate of returns but also the trend over time. Consequently, in this paper we control for sample selection bias.

3. Data and model specification

Data sets used in current paper are from the 1998, 2002, 2004, 2006 and 2008 rounds of the Vietnam Household Living Standards Survey (VLSS) conducted by the General Statistics Office of Vietnam (GSO). There are 5,999 households with 28,624 household members in VLSS1998, 29,542 households with 132,374 members in VLSS2002, 9,188 households with 40,419 household members in VLSS2004, 9,189 households with 39,071 members in VLSS2006, and 9,186 households with 38,247 members in VLSS2008. These samples are representative for the national levels of Vietnam. Sub-samples of wage-earners aged from 15 to 60 are used in the estimations, which yield 3,244 from VLSS1998, 26,268 from VLSS2002, 7,177 from VLSS2004, 7,436 from VLSS2006, and 7,532 from VLSS2008.

3.1 Mincerian earnings model

To estimate the returns to schooling, the Mincerian earnings equation is used:

$$\text{Ln}Y_i = \alpha + \beta_1.S_i + \beta_2\text{Exp}_i + \beta_3\text{Exp}_i^2 + \varepsilon_i \quad (1)$$

where $\text{Ln}Y$ is the natural log of hourly wages including bonuses, allowances, and subsidies (both in cash and in-kind), S is years of schooling,³ Exp is potential experience (calculated as age minus schooling years minus six) and the experience squared term, Exp^2 , is added in the model to allow a non-linear pattern in lifecycle earnings. To test increasing rates of returns to schooling over time, we use four pooled datasets, obtained from the base year of 1998 and compared years, so-called the second year (either 2002 or 2004 or 2006 or 2008) and an interaction term between years of schooling and a year dummy for the compared year. The model for regression is as follows:

$$\text{Ln}Y_i = \alpha + \beta_1.S_i + \delta_1.S_i*\text{Year}_2 + \beta_3\text{Exp}_i + \beta_4\text{Exp}_i^2 + \upsilon_i \quad (2)$$

where Year_2 is the second year survey. However, one may question that the effects of other controlling variables might vary over time. To capture the effects of the variations in the RHS

² Our previous study (Doan & Gibson, 2009) using datasets of 1998 and 2004 and taking into account the sample selection bias showed the fast increasing trend of returns to schooling in Vietnam. However, we did not test the difference in the returns over time, so the findings may be less conclusive.

³ In this study we use universalized general, higher education and technical & vocational training, whereas in our previous study (Doan & Gibson, 2009), we used only the general and higher education attainment; thus, the estimated returns are slightly different. This is consistent with Horowitz and Schenzler (1999); they find that in developing countries the returns of general education track exceed those of technical and vocational training/education.

variables (including the intercept), we include not only interaction terms of years of schooling and a year dummy for the second survey but also all other interaction terms between controlling variables and the second year dummy. In addition, to capture the gender difference in earnings, we also include a dummy variable for gender and its interaction term with the second year dummy.⁴ The estimation model now is as follows:

$$\begin{aligned} \text{Ln}Y_i = & \alpha + \delta_0 \cdot \text{Year}_2 + \beta_1 \cdot S_i + \delta_1 \cdot S_i * \text{Year}_2 + \beta_2 \cdot \text{Exp}_i + \delta_2 \cdot \text{Exp}_i * \text{Year}_2 + \beta_3 \cdot \text{Exp}_i^2 + \delta_3 \cdot \text{Exp}_i^2 * \text{Year}_2 \\ & + \beta_4 \cdot \text{Gender} + \delta_4 \cdot \text{Gender} * \text{Year}_2 + u_i \end{aligned} \quad (3)$$

3.2 Sample selection bias-corrected model

Sample selection bias results when the subset of wage earners used for the Mincerian earnings function is not randomly sampled from the general population. To address the problem we apply the sample selection model (Heckman, 1979) as follows:

$$\text{Wage equation:} \quad w_i = z_i \beta_1 + u_{1i} \quad (4)$$

Where z_i is a vector of schooling and experience variables for individual i

$$\text{Selection equation:} \quad h_i^* = x_i \beta_2 + u_{2i} \quad (5)$$

where h_i^* is a latent variable; and w_i is observed if $h_i = 1$, and $h_i = 1$ if $h_i^* > 0$, and w_i is not observed if $h_i = 0$, and $h_i = 0$ if $h_i^* \leq 0$. Furthermore, the assumptions about the errors are that:

$$u_{1i} \sim \text{NID}(0, \sigma^2) \text{ and } u_{2i} \sim \text{N}(0,1) \text{ and } \text{cov}(u_{1i}, u_{2i}) = \rho_{12}.$$

In the first estimation stage, a binary Probit model on all observations (those in wage employment and those not) is used to estimate the correction term λ_i , which is the inverse Mill's ratio or Heckman's Lambda: $\lambda_i = \phi(x_i \beta_2) / \Phi(x_i \beta_2)$. The term is then included in the second stage of the augmented earnings function:

$$w_i = z_i \beta_1 + \sigma_{12} \cdot \lambda_i + \eta_i \quad (6)$$

These two equations can also be estimated in one single step procedure using Heckman maximum likelihood estimator, which is more efficient (StataCorp, 2001) than the two-step procedure. Identification is achieved by including variables (x_i) such as household size and household non-wage income in the selection equation. Justification for the identification is that these variables affect wage employment participation probabilities, through changing the opportunity cost of being in the wage labour force, but an employer is unlikely to pay a different wage rate depending on one's household size or non-labour income. Household size may affect

⁴ Including the variables does not change the estimated returns much, so our estimates are compatible with the conventional basic Mincerian earnings equation estimates.

wage employment participation because low productivity and limited arable land in the agricultural sector have led to labour surplus in the sector if households have larger household sizes. For example, in 2006, 53% of Vietnam's labour force was in the agricultural sector, but that sector contributed only 17.6% to Vietnam's GDP (VDR, 2009). Therefore, household size relates to labour surplus and affects wage employment participation. Given the same household size, households with higher non-wage incomes from self-employed, family businesses and farming may not send their members out to work in the wage employment sector. Therefore, household size and non-wage income affect significantly the probability of being wage-earners.

4. Results

The descriptive statistics show that in 1998 the average educational attainment of wage earners in Vietnam was about 9 years,⁵ and 10 years by 2008 (Appendix A). Non-wage earners' education attainment is lower than that of wage earners in all years. The average hourly wage rate was 2,569 Dong (US\$0.187) in 1998 and in nominal terms had risen to 8,854 Dong (US\$ 0.537) by 2008.

4.1 Basic Mincerian estimates of the returns over time

Table 1 contains the basic earnings function estimates. All of the coefficients are statistically significant at the 1% level but the explanatory power of the model is substantially higher in 2008 than in 1998. The coefficient on years of schooling implies an average private rate of returns to an additional year of education of 2.9% in 1998 rising to 9.5% by 2008. These results obviously show the increasing returns to schooling during the recent economic reforms. The results are also quite consistent with the increasing trend found in other transition economies. For example, Zhang et al (2005) report a seven percentage point rise in the rate of return to schooling in China between 1988 and 2001.

The rate of returns to schooling rises over time. Specifically, the rate of return to an extra year of schooling rose by 6.6 percentage points, from 2.9 to 9.5% (Figure 1). The female wage premium is lower than males'. According to the coefficient on the gender dummy variable in the first column of Table 1, hourly wages were about 14.8% higher for men than for similar educated and experienced women in 1998; the gap was about 20% in 2008.⁶

⁵ Sample size and sampling strategy of VLSS2002 is quite different from the remaining surveys so the number of schooling years is slightly lower (see VHLSS, 2002 and 2004: Basic Information at http://siteresources.worldbank.org/INTLSMS/Resources/3358986-118173055198/3877319-1207074161131/BINFO_VHLSS_02_04)

⁶ For dummy variables in a semi-logarithmic regression the percentage is calculated as $100 \times (e^{\beta_i} - 1)$.

4.2 Selectivity-corrected estimates of returns to education

To overcome the selectivity bias and confirm the increasing trend, we apply the Heckman selection-correction model. After correcting for sample selection bias, the estimated rates of return to education are somewhat higher than in the OLS estimates reported in Table 1. However, the basic feature of a significant rise in the rates of return between 1998 and 2008 is not altered. The full results of using the bias correction model are reported in Table 2. The returns in most cases improve about 1% relative to the OLS estimates, except in 2002. The rise in the average private rate of returns to a year of schooling is illustrated in Figure 1 showing both the basic Mincerian earnings equation and selectivity-corrected estimates. Both sets of estimates show a rise of about 6.6 percentage points between 1998 and 2008.

The joint estimations of the selection and wage equations show that the residuals of the two equations are positively correlated for all the years. Specifically, the coefficient on the inverse Mills' ratio or λ varies from 0.12 to 0.285 and is always highly statistically significant. This implies a positive correlation between the selection equation errors and the wage equation errors, since $\lambda = \rho\sigma$ (and σ must be positive). In other words, individuals with a comparative advantage in entering the wage-earning labour force also have a comparative advantage in earning more than observationally similar workers. Hence the observed wage is higher than the wage that would prevail for a sample of individuals selected at random fashion from the working-age population.

The positive coefficients on years of schooling in the selection equations show a benefit of education which is omitted from the standard wage equations, which provides a higher probability of entering into waged employment. To help interpret the effect, the probit coefficients from the selection equation are transformed into marginal effects, showing the change in probability of being in waged employment for a unit change in the explanatory variable; we report the marginal effects of characteristics on probability of waged employment in Table 3.

There appears to be a substantial rise over time in the effect of education on the probability of waged employment participation. In 1998, an additional year of schooling raised the probability by just over one percentage point. But ten years later the marginal effect of an extra year of schooling had risen to over three percentage points. In other words, people with higher education have a higher likelihood of having waged jobs. It is also notable that the overall rise in the predicted probability of waged employment for an individual with average characteristics increased from 14% in 1998 to 34% by 2008. The rapid increase in the probability of being in waged work probably resulted from the rapid industrialization in Vietnam's urban and peri-urban areas which have helped generate more non-farm jobs and absorb surplus labour from rural areas

(demand side). Furthermore, the important Enterprise Law (a law for domestic private enterprises) passed in August 1999 (came into effect from 1st January, 2000) stimulated mass establishment of new businesses, especially small businesses which helped absorb surplus labour from the agricultural sector (mostly self-employed family farming) to waged employment sector (industrial and service sectors). The Vietnam enterprise statistics show that the number of enterprises increased impressively, from 42,288 in 2000 to 155,771 by the end of 2007, and 76% were domestic private and limited liability enterprises.⁷ These enterprises are the main labour absorbers in Vietnam (Tran & Doan, 2010). This helps to explain the reason behind a great rise in the probability of being wage earners over the studied period. The increasing significance of household size as a positive predictor of waged employment is also consistent with the surplus labour interpretation in rural areas (supply side). The opportunity cost of having a household member work in waged employment is lower for a larger family since other family members are able to continue to work either on-farm or in some non-farm informal enterprises. Finally, availability of other non-wage employment from household business, self-employment, and larger farming, which generates household non-wage incomes, reduces the likelihood of being in waged employment.

4.3 Checking the robustness of the increasing return to schooling over time

One may question the validity of across comparison of estimated returns between each year of 2002, 2004, 2006 and 2008 and the base year of 1998 using separate regressions. To validate the comparison and consolidate the finding of rising returns over time, we use pooled data and the interaction terms as discussed in Section 3. Specifically, VLSS1998 is pooled with, one after another, VLSS2002, VLSS2004, VLSS2006, and VLSS2008 to set up four pooled datasets.

The reason for using the interaction terms is to test whether the returns to schooling are the same over time. The hypothesis is that the slope of hourly wage in log (lnY) with respect to years of schooling (S) is the same for both years (1998 and the second year or compared years' survey). In other words, we test $H_0^A: \delta_1 = 0$ in the equation 3.

The results of the Mincerian earnings equation estimation are presented in Table 4. The estimated rates of returns to schooling using pooled data 1998/2002, 1998/2004, 1998/2006, and 1998/2008 are presented in columns 1, 2, 3 and 4 of Table 4 respectively. In the first column, the return to schooling for year 1998 is 2.9%. For 2002, the rate of returns is as $2.87\% + 4.69\% = 7.6\%$. Likewise, the rate of returns is 8.6%, 8.8% and 9.5% for 2004, 2006 and 2008 respectively (the last row of Table 4). The tests for difference in rates of returns between the compared years

⁷ Available at www.gso.gov.vn/default_en.aspx?tabid=479&idmid=4&itemID=8722

and the base year of 1998 are all statistically significant at the 1% level (see the test for H^A_0). Therefore, we are able to conclude that there is strong evidence against the hypothesis that the returns to schooling are constant over the period. From these estimates, the trend of increasing return is observed during the period 1998 to 2008. The trend is consistent with that we find using cross sectional datasets as in Table 1. Moreover, the parameter test rejects the hypothesis that all interaction terms jointly equal zero; it implies that the effects of not only education but also other factors on earnings, especially experience, vary over time.

To strengthen the finding, we apply the selection correction model to the pooled datasets, and the estimated results are shown in Table 5. In the first stage, the Probit model is applied to estimate the correction term (λ_i). The identification is achieved by including household size and household non-wage income and their interaction terms with the second survey dummies in the selection equation, and we also include the second survey dummy in the selection equation to capture the time effect on wage employment participation.⁸

The trend of increasing return is re-confirmed during the period 1998 to 2008 using the selection bias-corrected models with inclusion of the interaction terms. All the differences (δ_1) in rates of returns over time are significantly different from zero. The estimates on the interaction terms are all positive and get larger for later years (2002, 2004, 2006 and 2008) showing a clear rising trend of the returns from 1998 to 2008 (Figure 2). However, the return slowed down in the later years from 2004 to 2008. The interaction term coefficients of schooling year and the second survey for pooled 2004/2006 and 2006/2008 data turn out to be insignificantly different from zero.

Overall, the estimated returns for each year are not much different between the estimates using single cross-sectional datasets and pooled datasets with the interaction terms (comparing Figure 1 and Figure 2). The estimated results are robust with a trend of increasing returns to schooling over the studied period in Vietnam. The rate of returns seems to match the current world rates around 10% (Psacharopoulos, 1994).

The effects of the Asian financial crisis and minimum wages on earnings also appear in the time effect coefficients (δ_0) over time in Table 5. Because of the crisis, the Vietnamese government reduced minimum wages in late 1998 (see first column of Table 5), and many enterprises also reduced wage rates to keep costs lower in order to survive. During the period 1999-2004, nominal wages were almost kept the same. In other words, because of the wage rate cuts in late 1998, the average wage rate in 2004 is about 10% lower than in 1998. However, due to

⁸ To present the estimated results concisely, we do not report the selection equation estimates. They would be provided upon request.

spontaneous mass strikes in late 2005, the government had to raise minimum wages by 40% in early 2006 (Tran, 2007).⁹ The adjustment resulted in a great shift of the time effect (year dummy) in the columns 3, 4, 6 and 7 of Table 5.

5. Discussions and conclusions

The results reported in the current paper on returns to schooling in Vietnam using VLSS1998, 2002, 2004, 2006 and 2008 differ very substantially from the previous literature. The rate of returns for 2008 is much higher than estimates for either 1992 or 1998 reported by Gallup (2002), Glewwe and Patrios (1998), Liu (2006), and Moock, Patrinos and Venkataraman (2003). Moreover, although a rising trend between 1992 and 1998 found by Gallup (2002), or an ambiguous trend examined by (Liu, 2006), the returns to education for the early economic transition in Vietnam are still relatively low. The current results show a very rapid rise in the rates of return to schooling between 1998 and 2008. The rising trend appears to be robust to the self-selection consideration, e.g. the selection into the waged employment.

What could account for such a rapid rise in the rates of return to schooling, especially given the previously sluggish change reported in the literature? The period studied here coincides with further market opening and integration into the global economy, deeper reforms, and a consequent investment boom with accelerated structural change that has generated many technical-skilled jobs in Vietnam. Investment grew dramatically, from 32% of GDP in 1998 to 41% in 2008, with almost all of the investment into industry and services; about 94% in 2008. Consequently, the growth rate of the industry sector is very high, about 15.4% during the period 1998-2008 and the industrial growth helped absorb surplus labour from the traditional sector. There was also considerable growth in foreign trade and such that overall openness (the ratio of exports plus imports to GDP) reached over 160% by 2008.¹⁰

On the labour supply side, changes in labour market laws from the early 1990s were having increasing effects in the early period of the economic reforms. Initial reforms in 1993 to the labour contract system introduced the “basic wage” as the minimum wage. But employers often relied on the basic wage to compute actual wages for employees without concern for appropriate differentials for educational attainment, skills and productivity. Further impetus for negotiating and signing employment contracts came in 1994 when the Labour Code was passed, allowing employers more flexibility in hiring and firing workers. The greater flexibility is also likely to have offered greater mobility for workers, allowing the more highly educated employees to seek

⁹ The increase in minimum wages was applied for FDI enterprises. Even the government did not set minimum wages for domestic enterprises, but the labour strikes also happened in domestic enterprises, and therefore the enterprises did increase wages for employees to cool down the labour pressure and to keep employees with them.

¹⁰ The information used in the paragraph are available at www.gso.gov.vn/default_en.aspx?tabid=470&idmid=3

out jobs that paid an appropriate wage premium for their skills. On the labour demand side, resulting from the further economic reforms especially the first Enterprise Law issued in late 1999 and a Unified Enterprise Law issued in 2005, investment in industrial production and the service sector was untied. A huge increase in the number of enterprises and investment boom in the industrial and service sector as discussed earlier generated more wage-paid jobs for labourers. Moreover, higher-educated workers may have benefitted from recent technological modernization and the transfer of technical and managerial skills from FDI-invested enterprises which resulted from the boom of FDI in the opening period. These are likely causes for increasing returns to schooling.

The estimates of returns show that the returns to schooling in Vietnam had reached their peak around 2004-2008. However, Vietnam joined the WTO in January 2007 with a commitment to further open up markets, including the labour market, so growing competition between employers is likely to affect the returns to schooling. The rate of returns improved about 0.75% between 2006 and 2008,¹¹ slightly higher than the period 2004-2006 (Tables 4 and 5, Figures 1 and 2). As discussed in Fleisher, Sabirianova and Wang (2005), the returns during the reforms in transitional economies improve over time. The speed of economic transition and the economic volatility in labour market explain the differences in the increase in the rates of return to schooling over time and across the transitional economies. Hence, a continued rise in the rate of returns to schooling is likely until the country becomes a universally-recognized market economy.¹²

Finally, one might think about the endogeneity of education due to unobservable individual ability, hence the estimated returns to schooling would be biased. Fixed effect models with panel data can overcome the bias. In such a case, we may estimate returns to changes in schooling overtime (two periods of time). If there is an increase in individual education attainment over time; however, apart from the increase due to higher measurement errors of panel data, the increase would come from unofficial training or in-service training (technical and vocational training/education) because most wage-earners had stopped studying from the universalized general and higher education to take up work. Estimated rates of returns to schooling for vocational education would be lower since the rate of returns to unofficial education is typically lower than to official education (Horowitz & Schenzler, 1999). Consequently, one should not apply fixed effect models in estimating returns to education for Vietnam since the estimates would not reflect properly the returns to schooling.

¹¹ However, the difference is not statistically significant at the 5% level.

¹² By May 2010, only 22 countries had recognized Vietnam's market economy (Vietnamnet.vn, 28 May 2010).

Table 1: Basic Mincerian Earning Function Estimates by years (1998-2008)

Variables	1998	2002	2004	2006	2008
Years of schooling (years)	0.0287 (7.64)**	0.0756 (43.96)**	0.0861 (37.98)**	0.0877 (38.99)**	0.0952 (40.70)**
Experience (years)	0.0150 (2.90)**	0.0178 (7.43)**	0.0263 (8.69)**	0.0299 (10.66)**	0.0401 (14.05)**
Experience squared	-0.0006 (3.69)**	-0.0004 (6.19)**	-0.0006 (7.20)**	-0.0007 (8.52)**	-0.0010 (12.31)**
