Alimentary Iodine Deficiency in the Federal Republic of Germany: Current Inefficiency of Goitre Prophylaxis

J. Habermann, K. Horn and P.C. Scriba
II. Medizinische Klinik, Universität München, München

Recent epidemiologic surveys showed that goitre is endemic in the FRG with an average incidence of 15 % (5) and that the alimentary iodine intake of 50 μg iodine/day (3, 4) is less than 30 % the optimum recommended by the PAHO (2). A successful iodine prophylaxis is hitherto not possible in the FRG: the law on dietetic food restricts the iodine content of iodinized salt to a maximum of 5 mg/kg (ppm) and the salt is only to be used for 'medically established' iodine deficiency. Therefore, the Thyroid Section of the German Society for Endocrinology recently recommended a goitre prevention program by compulsory iodination of salt with 10 mg iodine/kg (6). The present paper reports an investigation, in which the iodine content and its stability of available salts was studied.

Material and Methods

All salts were bought in groceries (23 table salts, 8 sea salts and 142 iodinized salts). In order to avoid mistakes depending on inhomogeneity of iodine within one packing, always 100 g of salt were dissolved in 1 liter of distilled water and this solution was diluted before the iodine determination to a concentration of approximately 4 μg iodine/100 ml. The iodine content was analyzed by an iodine determination on a modified PBI Autoanalyzer, as previously described (3). The iodine standards ranged from 0.5 to 7.0 μg/100 ml. The intrassay and interassay coefficients of variation were 4 and 6 %, respectively. The recovery of 5 standards added to solutions of 7 different table salts was 105 ± 15 % (mean ± SD). In 6 different commercial control sera 103 ± 16 % of the iodine content were found.

Results

The mean of the coefficients of variation of the iodide content within all different charges of 4 iodinized salts of the FRG was 7 %. In figure 1, the iodine content is plotted against the duration of storage of the unopened packages. Salt A (packed up in cartons) was iodinized sufficiently, but one charge was
Fig. 1. Iodine content and time of storage of 4 different iodinized salts (A, B, C and D) of the Federal Republic of Germany.

1 Salts packed up more tightly.
apparently iodinized twice. The loss of iodide during storage — also observed by other authors (1, 7) — was not statistically significant. Only 3 of 5 charges of salt B (packed up more tightly) were iodinized sufficiently. On average, there was no loss of iodide. Salt C (packed up in cartons) showed a fluctuating content of iodide between the different charges (CV = 20 %) and a progressive loss of iodide (p < 0.005). All charges of salt D contained only half of the demanded iodide. The loss of iodide is more pronounced, if the packings are stored after opening. In salts packed up in cartons, we found a loss of iodide with a half-life of 7 months, whereas salt B packed up more tightly, was stably over a year.

We also measured table salts, sea salts and iodinized salts of different European countries. The iodine content of all table salts was below 0.2 ppm. The sea salt preparations varied from 0.2 to 1.0 ppm, which is insufficient for goitre prevention. Only 2 iodinized foreign salts packed up more tightly, were iodinized sufficiently; the iodine content of 5 foreign salts packed up in cartons was less than claimed (table I).

**Conclusion**

The stability of iodide in the presently available salts is not yet satisfactory. The stability should be achieved by chemical stabilizers, or alternatively by iodination with iodate instead of iodide (1). It may also be improved by packing in tins.
