This is an Accepted Manuscript of an article published by Taylor & Francis Group in International Journal of Remote Sensing on 23/09/2016, available online: http://dx.doi.org/10.1080/01431161.2016.1226527
Abstract

In the past, oil palm density has been determined by manually counting trees every year in oil palm plantations. The measurement of density provides important data related to palm productivity, fertilizer needed, weed control costs in a circle around each tree, labourers needed and needs for other activities. Manual counting requires many workers and has potential problems related to accuracy. Remote sensing provides a potential approach for counting oil palm trees. The main objective of this study is to build a robust and user-friendly method that will allow oil palm managers to count oil palm trees using a remote sensing technique. The oil palm trees analysed in this study have different ages and densities. QuickBird imagery was applied with the six pansharpening methods and was compared with panchromatic QuickBird imagery. The black and white imagery from a false colour composite of pansharpening imagery was processed in three ways: (1) oil palm tree detection, (2) delineation of the oil palm area using the red band, and (3) counting oil palm trees and accuracy assessment. For oil palm detection, we used several filters that contained a Sobel edge detector, texture analysis co-occurrence, and dilate, erode, high-pass, and opening filters. The results of this study improved upon the accuracy of several previous research studies that had an accuracy of about 90–95%. The results in this study show (1) modified intensity-hue-saturation (IHS) Resolution Merge is suitable for 16-year-old oil palm trees and have rather high density with 100% accuracy; (2) Colour Normalized (Brovey) is suitable for 21-year-old oil palm trees and have low density with 99.5% accuracy; (3) Subtractive Resolution Merge is suitable for 15- and 18-year-old oil palm trees and have a rather high density with 99.8% accuracy; (4) PC Spectral Sharpening with 99.3% accuracy is suitable for 10-year-old oil palm trees and have low density; and (5) for all study object conditions, Colour Normalized (Brovey) and Wavelet Resolution Merge are two pansharpening methods that are
suitable for oil palm tree extraction and counting with 98.9% and 98.4% accuracy, respectively.

Keywords: filter, oil palm, oil palm counting, pansharpening, remote sensing, segmentation

1. Introduction

Oil palm density, age, management, and parent material all affect oil palm production. Oil palm tree density is one of the parameters used to determine if replanting is needed and affects oil palm production (Ng, 1972; Corley, 1973; Breure et al., 1990; Corley and Tinker, 2003; Huth et al., 2014; Bonneau et al., 2014). Therefore, one way to increase oil palm production has been to develop new varieties that are suitable for planting at high densities (Breure, 2010). Managers of oil palm plantations typically measure oil palm density manually every year. This important data can be used to estimate oil palm productivity, the amount of fertilizer needed, periodic weeding costs, and the number of workers needed, and is related to other activities (Ng, 1972; Kiama et al., 2014). Of course, counting oil palm trees manually requires many workers and has the potential problem of inaccurate counting.

In the past few years, several studies have dealt with the monitoring and mapping of oil palm using remote sensing in the various contexts. The Moderate Resolution Imaging Spectroradiometer (MODIS) has been used for studies on the primary productivity of oil palm trees as it is related to the global carbon balance (Cracknell et al. 2013; Tan, Kanniah, and Cracknell 2014; Cracknell et al. 2015). Tan, Kanniah, and Cracknell (2013) studied the age of oil palm trees using the Disaster Monitoring Constellation 2 and Advanced Land Observing Satellite phased array L-band synthetic aperture radar. Moreover, remote sensing has been applied for the identification and monitoring of basal stem rot disease (Lelong et al. 2010; Helmi Z M
Shafri et al. 2011; Liaghat et al. 2014; Helmi Zulhaidi Mohd Shafri and Hamdan 2009; Santoso et al. 2011); several research studies have used remote sensing for oil palm tree detection and counting. Jusoff and Pathan (2009) used airborne hyperspectral sensing with linear spectral mixture analysis, along with a mix to a pure converter and Euclidean norm techniques to map individual oil palm trees. Shafri et al. (2011) achieved 95% accuracy using high spatial resolution airborne imagery with several steps to discriminate oil palms from non-oil palms using spectral analysis, texture analysis, edge enhancement, a segmentation process, morphological analysis and blob analysis. Kattenborn et al. (2014) using unmanned aerial vehicle imagery with point cloud classification (reconstruction of oil palm trees using 3D processing) and achieved a mapping accuracy to 86.1% for the entire study area and 98.2% stands of dense oil palm. Srestasathiern and Rakwatin (2014) using QuickBird imagery with 90% accuracy. They used a vegetation index for distinguishing oil palms from the background, and then applied rank transformation, a non-maximal suppression algorithm and semi-variogram analysis to determine the appropriate window size. In addition, Wong-in et al. (2015) achieved 90% accuracy using aerial images with several steps such as removing non-tree components from an image, distinguishing oil palms from other components using a low-pass filter and normalized cross correlation, identifying individual oil palm trees, and counting the number of oil palms. Korom et al. (2014) segmented the shape of oil palm canopies/crowns using WorldView-2 imagery based on watershed segmentation and achieved an accuracy of about 77%.

Based on previous research, oil palm plantation managers (oil palm practitioners) need a simple method that is easy to implement for counting oil palm trees in plantations. The main objective of this study is to build a robust and easy-to-use method for counting oil palms using remote sensing.
2. Methods

This study analysed oil palms at an oil palm estate in Medan, North Sumatra, Indonesia (3°1.58′–3°13.92′N and 99°5.49′–99°13.44′E; Fig. 1), with several oil palm densities. Basal stem rot disease in trees infected by *Ganoderma boninense* caused the observed heterogeneity of oil palm density. QuickBird imagery archived on 4 August 2008 was used in this study with bands consisting of visible red (630–690 nm), green (520–600 nm) and blue (450–520 nm), NIR (near infrared, 760–900 nm) and panchromatic (450–900 nm). Fig. 2 provides a map of the oil palm density conditions in this study area.

Study sites 1, 2, 3 and 4 had 16 (Fig. 2(a)), 21 (Fig. 2(b)), 15 and 18 (Fig. 2(c)), and 10 (Fig. 2(d)) year-old oil palms, respectively. Various conditions surrounding oil palm trees, such as the density of grass and other weeds, will affect oil palm tree detection and counting (Jusoff and Pathan, 2009; Shafri, et al., 2011; Kattenborn et al., 2014; Wong-in et al., 2015). Therefore, the main target in the present study is to build a robust method for oil palm detection and counting under any oil palm conditions and densities.

Fig. 3 shows the flow of the three-part method proposed in the present study: 1) oil palm tree detection, 2) delineation of the oil palm area, and 3) oil palm tree counting and accuracy assessment. ENVI 5.2, ERDAS Imagine 2015, and ArcGIS 10.2.2 were the types of software used in this study. As a common standard for digital image processing, converting a digital number into radiance was done using ENVI 5.2. In this research study, pansharpening was used for oil palm detection because this allows the shape of the oil palm canopy to be detected into detail. Johnson et al. (2012) reported that a pansharpened image has more spatial information and minimizes the distortion of spectral information of a multispectral image with lower resolution. Lin et al. (2015) reported that pansharpening can improve and increase the classification accuracy of land use and land cover using WorldView-2 imagery.
Several pansharpening methods were used and compared with each other in the present study to determine the best pansharpening method for oil palm detection. Panchromatic imagery was also used in this study. Colour Normalized (Brovey), Gram-Schmidt Spectral Sharpening, and PC Spectral Sharpening methods were processed with ENVI 5.2. Meanwhile, Subtractive Resolution Merge, Modified HIS Resolution Merge, and Wavelet Resolution Merge were processed with ERDAS Imagine 2015.

2.1 Oil palm detection

First, a pre-processing step was employed. All processing steps in the first part were completed using ENVI 5.2. The false colour composite RGB 432 (NIR-R-Green) images were built from pansharpening imagery and were then converted to a grayscale image (Korom, et al., 2014). The pre-processing step continued using ENVI colour tables with a grayscale image as an input file. We chose a black and white linear colour table and then adjusted the stretch bottom slider to the right side and stretch top slider to the left until 70–75% of a wide slider (ENVI, 2014). The image became light in the background, black in the foreground (oil palm canopy), and then the new image was saved (Guijarro et al., 2011; Muller-Lunow et al., 2015). The further steps conducted after pre-processing are described below:

- Edge enhancement. The oil palm canopy shape was detected using a Sobel edge detector with approximately 75–85% of an image added back.
- Texture analysis in this study used co-occurrence with a mean parameter, 5 × 5 of processing windows and 3 × 3 of co-occurrence shift.
- Morphology analysis in this study consisted of two filters, a dilate filter with a 3 × 3 kernel size and an erode filter with a 5 × 5 kernel size.
In the extracting objects step, a high-pass filter with a $9 \times 9$ kernel size was used and then we continued using an opening filter with a $5 \times 5$ kernel size. When the detected object was an oil palm tree, it was converted to a polygon.

Fig. 1. The study site is on an oil palm plantation in North Sumatra, Indonesia; A) vicinity map showing the vicinity of the study site on the island of Sumatra; 2) map of the study site (Source map: Indonesian Geospatial Board- http://www.bakosurtanal.go.id/download/)

Fig. 2. Oil palm density condition in this study showing parts of (a) study site 1 (150.16 ha); (b) study site 2 (139.31 ha); (c) study site 3 (130.49 ha); (d) study site 4 (128.99 ha)

Fig. 3. The study flow chart: (I) oil palm tree detection; (II) delineation of oil palm area, and (III) oil palm tree counting and accuracy assessment

The second part of the delineation of the oil palm area, a pre-processing step, was needed; this was done in the same way as the first part, but using the red band (Santoso et al., 2011) from pansharpening imagery as an input file. The image had become lighter in the foreground (oil palm area) and darker (black) in the background.

After pre-processing, the morphology operation in this part was a closing filter with a $5 \times 5$ or a $7 \times 7$ kernel size. The object that was detected was the oil palm area and should be converted to polygon format as a masking polygon. In the final part in this study, oil palm tree counting was done in ArcGIS 10.2.2 using an overlay of both polygons from first and second parts; then the conversion processes were completed using polygons from overlay results as point features.
2.2 Accuracy assessment

An accuracy assessment was applied for the oil palm feature extraction (as a point feature layer in GIS) and compared with the result of manual counting (Shafri, et al., 2011) using on-screen digitization in five square polygons (each square polygon is 1 ha), four of which were distributed in the fourth corners of every site area plus one polygon in the centre. The number of oil palms counted manually and the number extracted digitally from QuickBird imagery were selected in the five (5) square polygons using ArcGIS 10.2.2; the results of these two counting methods were compared with each other to determine the accuracy of oil palm detection and extraction.

3. Results and discussion

The proposed methods for oil palm tree detection and counting in the present study were tested in several areas with different oil palm ages and densities. Fig. 4 shows an example of the results of each process in the proposed method that was used in the present study. Fig. 4(a) shows the shape of the oil palm canopy as dark-black with the light areas indicating the background. An oil palm canopy takes on a star-like shape; there are outer angular shapes around the centre of the canopy. The Sobel edge detector, texture analysis, and dilate filter were applied to minimize the outer shape of the oil palm canopies (see Fig. 4(b), 4(c), and 4(d)). The erode filter produced an oil palm canopy outline as a square shape (Fig. 4(e)) and the high-pass filter sharpened this square shape (Fig. 4(f)). Moreover, the opening filter converted the square shape into the object that was selected and the background is erased or left empty (Fig. 4(g)).

During oil palm tree extraction, several oil palm canopy/trees were not extracted and some objects were also extracted that were not oil palms (Fig. 4(i)). This is caused when some of the vegetation that surrounds oil palm trees has the same radiance values.
as the radiance values of oil palms. Moreover, some areas were classified as noise. In a
further step, the noise was reduced using the oil palm area extraction areas with the red
band. Meanwhile, a part of the oil palm canopy was not extracted; this was caused when
the oil palm canopy had some different pixel radiance values while only a small part of
a particular tree had the same values with oil palm radiance; however, in these cases, the
majority of the oil palms had the same values as the surrounding radiance values.
Moreover, the small part of the pixel values of oil palm radiance were erased by some
kernel/window size areas in filters applied in this study (Hosoi, et al., 2012; Warner et
al., 2006). In addition, this change affected the accuracy assessment. The oil palm area
extraction results will affect the accuracy of oil palm tree counting because they are
used to reduce noise during oil palm tree extraction.

3.1 Oil palm tree counting and accuracy assessment

After using a red band to reduce noise during oil palm area extraction, oil palm trees
could be counted from the results of the converted polygon of oil palm extraction to
create a point layer. The present study encompassed a total area of 548.95 ha for testing
the proposed methods, which were divided into four different study sites areas to
determine oil palm density and age. Tables 1–4 show the ability of the method to count
oil palm trees and the count accuracy assessment for study sites 1–4. We assumed the
manually counted values were accurate because we used QuickBird pansharpening
imagery to manually count trees based on screen digitized imagery of oil palm trees in
five square areas where each area covered 10,000 m². Each area and pansharpening
method used in this study resulted in different oil palm tree counts. The research results
from Wyczalek and Wyczalek (2014) produced similar results while using a different
method of pansharpening that will affect the classification results. Tables 1–4 show the
potential of the four pansharpening methods for counting oil palm trees using PC
Spectral Sharpening, Colour Normalized (Brovey), Subtractive Resolution Merge, and Modified Resolution Merge, at study sites 1–4, respectively.

Fig. 4. Example results of the proposed methods in this study: (a) black and white imagery; (b) image from Sobel applied; (c) image after texture analysis; (d) image after dilate filter; (e) image after erode filter; (f) image after high-pass filter; (g) image after opening filter; (h) oil palm object extraction; (i) polygon of oil palm extraction with pansharpening imagery as background

The potential of using the pansharpening method for counting oil palm trees in different areas is shown in Table 5. Study sites 1, 2, 3, and 4 had 16, 21, 15/18, and 10-year-old oil palm trees, respectively. Study sites 1, 2, 3, and 4 had rather high, low, rather high, and low oil palm density, respectively. With these conditions, the best pansharpening methods for study sites 1, 2, 3, and 4 were Modified IHS Resolution Merge pansharpening (100% accuracy), Colour Normalized (Brovey) pansharpening (99.5%), Subtractive Resolution Merge pansharpening (99.8%), and PC Spectral Sharpening (99.3%), respectively. Two pansharpening methods employed for oil palm tree extraction and counting in this study had 98.4% and 98.9% accuracy and were Wavelet Resolution Merge and Colour Normalized (Brovey), respectively (Table 6; Fig. 5).

When compared with the accuracy of oil palm tree counting in previous research studies that used several methods, the methods proposed in the present study are potentially useful for oil palm planters and plantation managers and could be adopted and implemented as part of oil palm management practices. This proposed method is simple and all the steps and filter are available in ENVI software. In addition, it is possible to use different image processing software that has a grayscale convert function,
a foreground and background stretching function, a Sobel edge detector, and texture
analysis co-occurrence, as well as dilate, erode, high-pass, and opening filters.

We believe the accuracy achieved using the methods employed in the present
study is adequate for estate managers to use so they can employ remote sensing to
rapidly determine oil palm density. In oil palm management, if the estate has planting
records, especially stand maps of oil palm plantations, monitoring oil palm trees
individually in the field is very easy. However, sometimes oil palm plantation managers
need a second opinion and can accurately monitor oil palm density using imagery based
on remote sensing.

4. Conclusions

The pansharpening method used with multispectral satellite imagery such as a QuickBird image has potential for use in oil palm tree detection and counting. The different pansharpening methods provided different results for oil palm tree counting. The methods proposed in the present study exhibited about 98% accuracy and provide potential methods for oil palm tree detection and counting as part of oil palm management. The methods proposed in the present study are easy to use with ENVI or other image processing software that have a grayscale conversion function, stretching foreground and background functions, a Sobel edge detector, texture analysis co-occurrence, as well as dilate, erode, high-pass, and opening filters. The proposed methods will be tested using images from unmanned aerial vehicles that many oil palm companies currently operate for surveillance and monitoring of oil palm coverage.

Highlighted are results of highest accuracy.
Fig. 1. The study site is on an oil palm plantation in North Sumatra, Indonesia; A) vicinity map showing the vicinity of the study site on the island of Sumatra; 2) map of the study site (Source map: Indonesian Geospatial Board- http://www.bakosurtanal.go.id/download/)
Fig. 2. Oil palm density condition in this study showing parts of (a) study site 1 (150.16 ha); (b) study site 2 (139.31 ha); (c) study site 3 (130.49 ha); (d) study site 4 (128.99 ha)
Fig. 3. The study flow chart: (I) oil palm tree detection; (II) delineation of oil palm area, and (III) oil palm tree counting and accuracy assessment.
Fig. 4. Example results of the proposed methods in this study: (a) black and white (BW) imagery; (b) image after Sobel applied; (c) image after texture analysis; (d) image after dilate filter; (e) image after erode filter; (f) image after high-pass filter; (g) image after opening filter; (h) oil palm object extraction; (i) polygon of oil palm extraction with pansharpening imagery as background.
Fig. 5. Oil palm extraction and counting using Colour Normalized (Brovey) in study site 2 (a) and using Wavelet Resolution Merge in study site 3 (b)
