Abstract

Memory T cells can be divided into central–memory (T_CM) and effector–memory (T_EM) cells, which differ in their functional properties. Although both subpopulations can persist long term, it is not known whether they are maintained by similar mechanisms. We used in vivo labeling with deuterated glucose to measure the turnover of CD4+ T cells in healthy humans. The CD45RO+CCR7− T_EM subpopulation was shown to have a rapid proliferation rate of 4.7% per day compared with 1.5% per day for CD45RO+CCR7+ T_CM cells; these values are equivalent to average intermitotic (doubling) times of 15 and 48 d, respectively. In contrast, the CD45RA+CCR7+ naive CD4+ T cell population was found to be much longer lived, being labeled at a rate of only 0.2% per day (corresponding to an intermitotic time of approximately 1 yr). These data indicate that human CD4+ T_EM cells constitute a short-lived cell population that requires continuous replenishment in vivo.

Key words: T lymphocyte • immune memory • homeostasis • cell proliferation • cell lifespan

Introduction

One factor contributing to immunological memory is the much higher frequency of lymphocytes specific for the priming antigen in the memory pool than among naive cells. Long-term persistence of memory cells is achieved by a combination of two processes: first, the long-term survival of individual cells, and second, periodic cell division to balance attrition through cell death. Both processes are dependent on contact with MHC–peptide complexes and with cytokines such as IL-15 and IL-7 (1). Current understanding of how memory cell populations persist has been aided by studies investigating the kinetic behavior of T cells in various animal species, including humans, which have shown that those cells with a memory phenotype (CD45R0+ in humans) exhibit a considerably higher rate of turnover than naive phenotype T cells and have a relatively short lifespan, on the order of weeks or months (2–7). However, memory T cells are phenotypically and functionally heterogeneous, and it is not known if rapid turnover applies to all memory cells.

A major subdivision among memory T cells is that between central–memory (T_CM) and effector–memory (T_EM) cells (8). These subpopulations, which are identified among human CD45R0+ T cells as being CCR7−CD62L+ or CCR7−CD62L− respectively, exhibit distinct functional properties. T_CM cells enter LNs through high endothelial venules and recirculate primarily between blood and lymph, whereas T_EM cells migrate preferentially from the blood into peripheral tissues such as the lung or intestinal mucosa (9–11). In addition, T_EM cells express effector activity (e.g., cytolytic activity or secretion of cytokines such as IFN-γ, IL-4, or IL-5) more rapidly than T_CM cells upon restimulation with antigen (8, 9, 12), although some studies suggest that this distinction may be less clear for memory CD8+ T cells (13). On this basis, T_CM and T_EM cells have been proposed to play complementary roles in the secondary response to infection, with T_EM cells providing a rapid effector response at sites of pathogen entry and T_CM cells serving as an expanded pool of precursors that can proliferate in the secondary lymphoid organs to rapidly generate large numbers of effector cells (8).

Although both T_CM and T_EM CD4+ populations appear to persist long term in humans (8), the kinetic behavior of the cells which comprise these subpopulations is unknown. To measure turnover of human T_CM and T_EM CD4+ cells, we used H-glucose, which is incorporated into DNA via the de novo nucleotide synthesis pathway, to label dividing
cells in vivo (14). The results show a clear difference in turnover rates between these subpopulations, with T\textsubscript{EM} CD4\textsuperscript{+} cells being much shorter lived. The implications for maintenance of T cell memory are discussed.

Materials and Methods

**In Vivo Labeling with \textsuperscript{2}H\textsubscript{2}-Glucose.** Six young healthy volunteers (ranging from 19 to 30 yr of age) were given a primed 24-h i.v. infusion of \( \approx \) 1 g/kg 6,6-\textsuperscript{2}H\textsubscript{2}-glucose (Cambridge Isotopes). During this time, their diet was restricted to small, low energy meals. For measurement of plasma glucose \( \textsuperscript{3}H \) enrichment, blood was taken at \( \approx \)4-h intervals during infusion. For estimation of \( \textsuperscript{3}H \) enrichment in cell DNA, 50 ml heparinized blood samples were taken at 3, 4, 10, and 21 d after commencement of the infusion. All subjects gave written informed consent under protocols approved by the Local Research Ethics Committee.

**Cell Sorting.** PBMCs were isolated from blood by Ficoll-Paque (Amersham Biosciences) density gradient centrifugation and stained \( (10^7$/ml in PBS + 0.2% BSA) in one of three ways. (i) Mouse anti-human CCR7 (IgM) (BD Biosciences), goat anti-mouse IgM F(ab\textsuperscript{2})-RPE (Southern Biotechnology Associates Inc.), anti–CD45RA-RPE-PC5 (Serotec Ltd.) and anti–CD4–APC. (ii) Anti–human CCR7, anti-IgM (Fab\textsubscript{2})-PE, anti-CD45RA-biotin (BD Biosciences), streptavidin–PerCP (BD Biosciences), and anti–CD4–APC. (iii) Anti–human CCR7, anti-IgM (Fab\textsubscript{2})-PE, anti–CD4–biotin (BD Biosciences), streptavidin–PerCP, anti–CD45RO–allophycocyanin (CALTAG). Similar results were obtained using any of these staining strategies. Stained cells were sorted using a MoFlo flow cytometer (Cytomation). Typical purities and cell yields for the three major subpopulations (naive, T\textsubscript{EM}, T\textsubscript{CM}) were 85–98% and 1–6 \times 10\textsuperscript{6}, respectively; much smaller numbers of RA\textsuperscript{+} cells were obtained \( (\approx 4 \times 10^5) \), and purity was usually lower than for the other three populations.

**Analysis of Deuterium Enrichment and Modeling of Proliferation.** Enrichment of deuterium in DNA was assayed essentially as described previously (7, 15). Briefly, cellular DNA was extracted and digested enzymatically to deoxynucleosides. Purified deoxyadenosine was converted to its aldononitrile triacetate derivative and digested enzymatically to deoxynucleosides. Purified deoxyadenosine was converted to its aldononitrile triacetate derivative and digested enzymatically to deoxynucleosides. Purified deoxyadenosine was converted to its aldononitrile triacetate derivative and digested enzymatically to deoxynucleosides.

\[ F(t) = \frac{p}{d_p} (1 - e^{-d_p t}) \quad t \leq \tau \quad \text{during the labeling period} \]

\[ F(t) = \frac{p}{d_p} (1 - e^{-d_p t}) e^{-d_{p^*} (t-\tau)} \quad t > \tau \quad \text{after the labeling period} \]

where \( t \) is time and \( \tau \) is the length of the labeling period.

In this model, no assumption of equality between \( p \) and \( d^* \) has been made; \( p \) represents the average proliferation rate of the whole population, whereas \( d^* \) refers only to labeled cells (i.e., cells which divided during the labeling period). For a kinetically heterogeneous population, even one at steady-state, these two rates will not be the same, as discussed elsewhere (7). Where the day 3 value fell below the day 4 value for the same lymphocyte pool, it was assumed that the day 3 value lay within the lag phase between division and appearance in the circulation, and it was excluded from modeling. Where proliferation is expressed as doubling time \( (t_d) \) or disappearance as half-life \( (t_{1/2}) \), these were calculated as \( \ln2/p \) and \( \ln2/d, \) respectively. Data are expressed as means. Comparisons between groups were made by Student’s \( t \) test.

**Results and Discussion**

To measure T cell turnover in vivo, healthy volunteers were infused with \( \textsuperscript{2}H \)-labeled glucose for 24 h, and enrichment of \( \textsuperscript{2}H \) in the DNA of isolated subpopulations of peripheral blood lymphocytes was determined at several time points. Day 3 was chosen as the earliest time point since previous work has shown that the appearance of labeled T cells in the blood peaks at \( \approx 3–4 \) d after starting the infusion (7). CD4\textsuperscript{+}CD3\textsuperscript{+} cells were subdivided by cell sorting into four populations: CD45RO\textsuperscript{+} (or CD45RA\textsuperscript{−}) CCR7\textsuperscript{+} T\textsubscript{CM} cells, CD45RO\textsuperscript{−} (or CD45RA\textsuperscript{+}) CCR7\textsuperscript{−} T\textsubscript{EM} cells, CD45RO\textsuperscript{−} (or CD45RA\textsuperscript{+}) CCR7\textsuperscript{−} naive cells and CD45RO\textsuperscript{−} (or CD45RA\textsuperscript{+}) CCR7\textsuperscript{−} cells (referred to as RA\textsuperscript{+} cells). Lack of CCR7 expression on the latter subset, which represents a small fraction of total CD45RA\textsuperscript{+} CD4\textsuperscript{+} T cells, suggests that RA\textsuperscript{+} cells are not naive; antigen-primed cells have been identified previously among CD45RA\textsuperscript{+} CD4\textsuperscript{+} cells based on an absence of CD31 expression (16). On average, these subpopulations represented \( \approx 21\% \) (T\textsubscript{CM}), 12\% (T\textsubscript{EM}), 64\% (naive), and 3\% (RA\textsuperscript{+}) of total peripheral blood CD4\textsuperscript{+} T cells in the subjects studied.

From the measurement of \( \textsuperscript{2}H \) enrichment in DNA, the proportion of cells in each subpopulation that was labeled at the different time points was calculated, and these values are shown in Fig. 1. Based on the results, several points can be made. First, labeling of naive cells was extremely low, confirming previous work showing that there is little proliferation within this subpopulation (2–7). Second, labeling of T\textsubscript{EM} cells occurred at a substantially higher rate than for T\textsubscript{CM} cells. This was observed clearly in five of the six subjects studied. In the sixth subject (C15), similar rates of labeling were observed for T\textsubscript{EM} and T\textsubscript{CM} cells, which appeared to be due to a higher than average labeling of T\textsubscript{CM} cells in this individual. Third, RA\textsuperscript{+} cells showed a relatively rapid rate of labeling, consistent with the view that these cells are not naive but rather are antigen-primed; the exact relationship
between these cells and TCM or TEM cells remains to be defined. Peak height values (the maximum measured fraction of labeled cells) for each subpopulation are summarized in Table I. Mean values were higher in CCR7\(^+\)/H11002 than CCR7\(^+\)/H11001 populations for both CD45R0\(^+\)/H11001 and CD45RA\(^+\)/H11001 cells.

To determine the rates of proliferation (p) and disappearance (d\(^*\)) for the various cell subpopulations, curves were fitted to the data based on the fraction of labeled cells detected at each time point (Fig. 1). Note that in modeling the data it was assumed that maximal labeling was present at 24 h (i.e., at the cessation of \(^2\)H infusion) and that label disappeared exponentially thereafter with a disappearance rate constant, d\(^*\); this model takes into account cell death between the end of labeling and first sampling on day three. As shown in Table II, p was significantly higher for TEM than TCM cells. For the five subjects where this was the case, p for TEM cells was on average five times that of p for TCM cells; TEM and TCM cells had roughly equivalent proliferation rates in the sixth subject. Overall, the average proliferation rates for TCM and TEM cells were 1.5 and 4.7\% per day, respectively. From p, the average intermitotic time for cells within that population (t2) can be calculated, yielding values of 48 d for TCM cells and 15 d for TEM cells.

Disappearance rates, though more variable, were also higher for TEM than TCM cells in five of the six subjects. On average, the disappearance rates were 4.1\% per day for TCM cells and 11.3\% per day for TEM cells (equivalent to half-lives \([t_1/2]\) for disappearance of the cells of 17 and 6 d, respectively). Note that d\(^*\) is a measure of the disappearance rate of labeled cells only, whereas p applies to all cells, explaining why d\(^*\) can exceed p at steady-state (even though d, the disappearance rate of the entire population, must equal p). As discussed previously, several explanations can be proposed for the relatively rapid disappearance of recently divided cells (7). Although this was true for both

Figure 1. Kinetics of labeling of naive, TCM, TEM, and RA\(^+\)7\^- CD4\(^+\) T cells after infusion of \(^2\)H-glucose. Subjects were infused with \(^2\)H-glucose for 24 h starting from time 0, and the proportion of labeled cells (relative to total cells in each subpopulation) at different time points is shown for CD45RA\(^+\) (left) and CD45R0\(^+\) CD4\(^+\) T cells (right). Data for CCR7\(^+\) and CCR7\(^-\) cells are indicated by filled or open symbols, respectively; error bars represent the SD of triplicate GCMS measurements. Lines represent best-fit curves calculated based on the data points and assuming maximal labeling at 24 h.
Rapid Turnover of Effector–Memory CD4⁺ T Cells in Healthy Humans

TEM and TCM cells in many subjects, it is notable that labeled TCM cells in two individuals exhibited negligible disappearance rates, implying that some TCM cells can differentiate into long-lived cells after division. In contrast, d* was higher than p for TEM cells in all subjects. For naive CD4⁺ T cells, p was very low, 0.2% per day, which converts to a t² for the naive population of about a year (Table II). This contrasts with the rapid proliferation observed among RA⁺7⁻ cells, which had an average p of 3.3% per day (t² 21 d). The labeling that does occur amongst truly naive CD4⁺ T cells could reflect division of precursors in the thymus and their release into the blood over the time course of the analysis. Alternatively, some proliferation of mature naive cells could occur in the secondary lymphoid organs, perhaps in response to contact with homeostatic cytokines (17–21). Whichever the case, however, it is evident that the contribution of cell division to maintaining the naive CD4⁺ T cell pool in young adults is minimal.

T_EM and T_CM cells in many subjects, it is notable that labeled T_CM cells in two individuals exhibited negligible disappearance rates, implying that some T_CM cells can differentiate into long-lived cells after division. In contrast, d* was higher than p for T_EM cells in all subjects.

For naive CD4⁺ T cells, p was very low, ~0.2% per day, which converts to a t₂ for the naive population of about a year (Table II). This contrasts with the rapid proliferation observed among RA⁺7⁻ cells, which had an average p of 3.3% per day (t₂ = 21 d). The labeling that does occur amongst truly naive CD4⁺ T cells could reflect division of precursors in the thymus and their release into the blood over the time course of the analysis. Alternatively, some proliferation of mature naive cells could occur in the secondary lymphoid organs, perhaps in response to contact with homeostatic cytokines (17–21). Whichever the case, however, it is evident that the contribution of cell division to maintaining the naive CD4⁺ T cell pool in young adults is minimal.

In addition, the disappearance rate for the majority of naive (CD45RA⁺CCR7⁺) CD4⁺ T cells was shown to be extremely slow. In fact, we found that d* for CD45RA⁺CCR7⁺ cells in all subjects was too small to estimate using this method. This contrasts with earlier results showing a relatively rapid disappearance rate for labeled total CD4⁺CD45RA⁺ cells of >7% per day (7). This disparity may be partly explained by the disproportionate contribution of RA⁺7⁻ cells to labeling in the previous study, since labeled cells in this population disappear rapidly. The present data are striking in their implication that human naive CD4⁺ T cells can remain in interphase for extremely long periods of time after their derivation from dividing precursors.

Overall, the relative quiescence of naive CD4⁺ T cells and rapid turnover of memory–phenotype cells reported
here are in agreement with the general pattern of kinetic behavior that has been observed for these cells in many different species. Our data show that TCM and TEM CD4+ T cells in humans have distinct rates of turnover, with TEM cells typically being replaced in a much faster rate than TCM cells. These results imply that an almost continuous input of new cells is required to maintain the TEM CD4+ T cell population, which could have important implications for vaccination given that TEM may serve to provide a rapid effector response to reinfection. At face value, it could be argued that the shorter lifespan observed for TEM cells in the blood is simply a consequence of these cells having an ability to migrate rapidly and irreversibly into tissues. However, if one assumes that the number of TEM cells in tissues is constant (rather than increasing) under steady-state conditions, turnover of cells in the blood ultimately reflects what is occurring in the total TEM population. Therefore, it is evident from the rapid rate of production that there is also a rapid rate of disappearance among TEM cells.

Several factors could contribute to differences in the kinetic behavior between TCM and TEM cells. First, their distinct patterns of migration make it likely that the extent to which they contact cell division- and survival-inducing factors will differ (22). Second, it has been shown that TCM and TEM cells exhibit intrinsic differences in their responsiveness to homeostatic cytokines (23). In particular, TEM cells have higher cell surface expression of the IL-2/IL-15R β-chain, allowing them to proliferate in response to lower concentrations of IL-15 than TCM cells. This difference could potentially account for the higher proliferation rate among TEM cells. Third, TEM and TCM cells may also differ in their intrinsic death rates or their ability to respond to survival factors.

The present data should be considered with respect to the uncertainty that exists in understanding the lineage relationship between TCM and TEM cells, specifically whether these cells represent independent subpopulations or merely different activation states along a common differentiation pathway. Previous work has shown that phenotypic conversion can take place between TCM and TEM cells, suggesting that one subpopulation could serve as a source for the other; this has been observed for human CD4+ cells, where TCM cells can acquire characteristics of TEM cells in response to stimulation through the TCR or by cytokines (23), and in the reverse direction for mouse CD8+ T cells, where virus-specific TEM cells were shown to convert to TCM cells with time after infection (24). In contrast, based on analysis of T cell clonotypes present among TCM and TEM CD8+ T cells it was concluded that these cells represent independently regulated cell subpopulations in humans (25). Although the present kinetic data could indicate that TCM and TEM cells are maintained as separate pools with distinct turnover rates, they are also compatible with a model in which interconnection of TCM and TEM cells occurs in both directions. According to this latter model, TEM cells are maintained primarily through cell division, either by existing TEM cells or by TCM cells that acquire a TEM phenotype concomitant with division. Replacement of TCM cells would occur through more limited cell division among TCM cells that do not change phenotype and by phenotypic reversion of TEM cells after these cells have returned to a quiescent state. Future studies will be required to distinguish between the two models.

Finally, these results raise the question of whether further heterogeneity exists in the kinetic behavior of human CD4+ T cells. Previously, evidence for kinetic heterogeneity amongst antigen-primed human CD4+ T cells had been suggested by analysis of total memory-effector-phenotype CD4+ T cells (26). By using CCR7 as a marker, we were able to demonstrate that there are distinct subpopulations with differing turnover rates present in both CD45RA+ and CD45RO+ CD4+ T cell populations. In the future, it will be of interest to use other cell surface markers, for example, those associated with recent activation, to characterize the in vivo behavior of additional cell populations.

We are grateful to Dr. B. Asquith for advice on modeling and to Dr. M. Lipp for anti-CCR7 antibodies used in preliminary experiments.
