Open Charm Yields in d + Au Collisions at $\sqrt{s_{NN}} = 200$ GeV

PRL 94, 062301 (2005) PHYSICAL REVIEW LETTERS 18 FEBRUARY 2005

brought to you by (STAR Collaboration)
Midrapidity open charm spectra from direct reconstruction of $D_0^{+}/D_0^{0} \rightarrow K^+\pi^-$ in $d+Au$ collisions and indirect electron-positron measurements via charm semileptonic decays in $p+p$ and $d+Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV are reported. The $D_0^{+}/D_0^{0}$ spectrum covers a transverse momentum ($p_T$) range of $0.1 < p_T < 3$ GeV/$c$, whereas the electron spectra cover a range of $1 < p_T < 4$ GeV/$c$. The electron spectra show approximate binary collision scaling between $p+p$ and $d+Au$ collisions. From these two independent analyses, the differential cross section per nucleon-nucleon binary interaction at midrapidity for open charm production from $d+Au$ collisions at BNL RHIC is $d\sigma/dy = 30 \pm 0.04(\text{stat}) \pm 0.09(\text{syst})$ mb. The results are compared to theoretical calculations. Implications for charmonium results in $A+A$ collisions are discussed.
Hadrons with heavy-flavor are unique tools for studying the strong interaction described by quantum chromodynamics (QCD). Because of the large mass of the charm quark (~1.5 GeV/c²), charm quark production can be evaluated by perturbative QCD (PQCD) even at low momentum through the introduction of additional scales related to the charm quark mass [1,2]. Therefore, a theoretical calculation of charm hadron total cross section integrated over momentum space is expected to be less affected by nonperturbative soft processes and hadronization [3]. Systematic studies of charm production in p + p and p + nucleus collisions have been proposed as a sensitive way to measure the parton distribution function in nucleons, and nuclear shadowing effects [4]. At BNL Relativistic Heavy Ion Collider (RHIC) energies, heavy quark energy loss [5], charm quark coalescence [6–9], possible J/ψ suppression [10], and charm flow [11] have been proposed as important tools in studying the properties of matter created in heavy ion collisions.

Identification of charmed hadrons is difficult due to their short lifetime [τ(D⁰) = 124 μm], low production rates, and large combinatorial background. Most measurements of the total charm cross section in hadron-hadron collisions have been performed at low center-of-mass energies (≤ 40 GeV) in fixed target experiments [12,13]. At √s ~ 52–63 GeV, the available measurements are not conclusive due to inconsistencies between different measurements [12,14]. The measurements at higher energy colliders have been at high pₜ only [15] or have included large uncertainties [16,17]. Theoretical predictions for the RHIC energy region differ significantly [18,19]. Therefore, precise measurements of charm cross sections in p + p and d + Au collisions in this energy region are crucial.

In this Letter, we report first results on open charm cross sections at √sNN = 200 GeV from direct charmed hadron D⁰(D⁰) reconstruction in d + Au collisions and from charm semileptonic decay in both p + p and d + Au collisions. These measurements are complementary, providing important experimental cross-checks.

The data used in D⁰ direct reconstruction and charm semileptonic decay analysis were taken during the 2003 RHIC run in d + Au and p + p collisions at √sNN = 200 GeV with the solenoidal tracker at RHIC (STAR). A minimum bias d + Au collision trigger was defined by requiring at least one spectator neutron in the outgoing Au beam direction depositing energy in a zero degree calorimeter. Detailed descriptions of the trigger and centrality definition in d + Au collisions have been presented in a previous publication [20]. A total of 15.7 × 10⁶ minimum bias triggered d + Au collision events were used in the D⁰ analysis. The data samples used in the electron analysis in d + Au and p + p collisions were described in Ref. [21]. The integrated luminosity is about 40 μb⁻¹ for d + Au collisions and 30 nb⁻¹ for p + p collisions.

The primary tracking device of the STAR detector is the time projection chamber (TPC) [22]. It was used to reconstruct the decay of D⁰ → K⁻π⁺(D⁰ → K⁺π⁻) which has a branching ratio of 3.83%. In what follows, we imply (D⁰ + D̅⁰)/2 when using the term D⁰ unless otherwise specified. The exact D⁰ decay topology cannot be resolved due to insufficient track projection resolution close to the collision vertex. The invariant mass spectrum of D⁰ mesons was obtained by pairing each oppositely charged kaon and pion candidate in the same event. The kaon and pion tracks were identified through ionization energy loss (dE/dx) in the TPC wherever the identification is possible. Candidate tracks were selected having momenta p (pₜ) > 0.3 (0.2) GeV/c and pseudorapidity |η| < 1. The D⁰ signal with pₜ < 3 GeV/c and |y| < 1 after mixed-event background subtraction [23] is shown in Fig. 1(a). The signal-to-background ratio (S/B) is about 1/600, and the figure of merit (S/√B) is about 6. This distribution was fit to a Gaussian plus a linear function to account for the residual background not described by the mixed-event spectrum [23]. The open symbols in Fig. 1(a) depict the D⁰ signal after the two-step background subtraction. HIJING simulations [24] have shown that dihadron correlations from jets can affect the line shape of the background spectrum since the shape (slope versus mass) from this contribution is different from that of random pairs. To estimate the uncertainty in the subtraction of the residual background, different normalizations, slopes, and fit ranges were tried. The resulting uncertainty in the D⁰ yield is estimated to be 15%.

FIG. 1 (color online). (a) Invariant mass distributions of kaon-pion pairs from d + Au collisions. The solid circles depict the signal after mixed-event background subtraction, the open circles after subtraction of the residual background using a linear parametrization. (b) dE/dx in the TPC versus particle momentum (p) with a TOF cut of |1/β − 1| ≤ 0.03. Inset: projection on the dE/dx axis for particle momenta 1 < p < 1.5 GeV/c.
Within statistical uncertainties, the yields of \( D^0 \) and \( \bar{D}^0 \) are equal. The \( D^0 \rightarrow K^+ \pi^- \) signal could be misidentified as a \( \bar{D}^0 \rightarrow K^- \pi^+ \) and vice versa when both of its daughters are beyond particle identification in the TPC. This misidentification results in double counting, which was corrected for in the \( D^0 \) yields through a Monte Carlo simulation.

Another detector used in this analysis was a prototype time-of-flight system (TOF) [25] based on multigap resistive plate chamber technology. It covers an azimuthal angle \( \Delta \phi \approx \pi/30 \), and \( -1 < \eta < 0 \). In addition to its hadron identification capability [21], it allows electrons/positrons to be identified at low momentum (\( p_T < 3 \text{ GeV}/c \)) by using a combination of velocity information (\( \beta \)) from TOF and \( dE/dx \) measured in the TPC. Figure 1(b) demonstrates the clean separation of electrons from hadrons using their \( dE/dx \) in the TCP after applying a TOF cut of \( |1/\beta - 1| \leq 0.03 \). This cut eliminated the hadrons crossing the electron \( dE/dx \) band. Electrons/positrons were required to originate from the collision vertex. Hadron contamination was evaluated to be about 10%–15% in a selection optimized for purity and statistics. At higher \( p_T \) (2–4 GeV/c), electrons could be identified directly in the TPC since hadrons have lower \( dE/dx \).

The gray band represents the systematic uncertainty in each panel. The fractions were derived from simulations. Bottom panel: The ratio of inclusive electrons to the total backgrounds. The results are shown in Fig. 3. Two different fitting methods were used to extract \( dN/dy \) for the \( D^0 \) at midrapidity. In the first corrections were determined from detailed simulations [21]. Total inclusive electron spectra from 200 GeV \( p + p \) and collisions are shown in Fig. 2.

Gamma conversions \( \gamma \rightarrow e^+e^- \) and \( \pi^0 \rightarrow \gamma e^+e^- \) Dalitz decays are the dominant photonic sources of electron background. To measure the background photonic electron spectra, the invariant mass and opening angle of the \( e^+e^- \) pairs were constructed from an electron (positron) in TOF and every other positron (electron) candidate reconstructed in the TPC [26]. A secondary vertex at the conversion point was not required. Simulations with both HIJING [24] and PYTHIA [27] with full detector description in GEANT yielded \( \sim 60\% \) efficiency for electrons with \( p_T > 1 \text{ GeV}/c \) from such background processes. More than 95% of the electrons from sources other than heavy-flavor semileptonic decays were measured with this method. The remaining fraction from decays of \( \eta, \omega, \rho, \phi, \) and \( K \) was determined from simulations. The results are shown as solid lines in Fig. 2. The overall uncertainty of the background is on the order of 20% and has been included in the systematic errors. Ratios of the inclusive electrons over the total backgrounds are shown in the bottom panels of Fig. 2. The signal is clearly in excess of the background above \( p_T > 1 \text{ GeV}/c \).

The nonphotonic electron spectra were obtained by subtracting the previously described photonic background from the inclusive spectra. The results are shown in Fig. 3. The \( D^0 \) invariant yields \( d^2N/(2\pi p_T dp_T dy) \) as a function of \( p_T \) from direct reconstruction are shown in Fig. 3 as solid squares. Two different fitting methods were used to extract \( dN/dy \) for the \( D^0 \) at midrapidity. In the first
method, \(dN/dy\) was extracted from an exponential fit to the \(D^0\) differential yield in transverse mass \((m_T)\) [23]. In the second method, a simultaneous fit was applied to both directly reconstructed \(D^0\)'s and the background subtracted nonphotonic electron distribution in \(d + A\) collisions. For this fit, it was assumed that the \(D^0\) spectrum follows a power law in \(p_T\) from which an electron spectrum was generated using the particle composition from [28] and the decay generators in PYTHIA. A set of parameters for the power law was found at the minimum of \(\chi^2\) for the \(D^0\) and electron spectra. The results are shown in Table I. The systematic error is dominated by the uncertainties in the background subtraction, the extrapolation due to finite \(p_T\) coverage, and the overall normalization (±14% in \(p + p\) and ±10% in \(d + A\) collisions [20,21]).

The yield of \(D^0\) at midrapidity is \(dN/dy = 0.028 ± 0.004 ± 0.008\) and the \((p_T)\) is \(1.32 ± 0.08\) GeV/c in \(d + A\) collisions. We used the ratio \(R = N_{p+p}/N_{e+e^-} = 0.54 ± 0.05\) from \(e^+e^-\) collider data [28] to convert the \(D^0\) yield to a total \(c\bar{c}\) yield. A \(p + p\) inelastic scattering cross section of \(\sigma_{inel}^{p+p} = 42\) mb was used in the calculation, and a factor of \(f = 4.7 ± 0.7\), estimated from simulation [18,27], was used to convert the \(d\sigma/dy\) at midrapidity to the total cross section. The total charm cross section per nucleon-nucleon interaction for \(d + A\) collisions at 200 GeV is \(\sigma_{c\bar{c}}^{NN} = dN_{c\bar{c}}^{d+A}/dy \times \sigma_{inel}^{p+p}/N_{bin}^{d+A} \times f/R = 1.3 ± 0.2 ± 0.4\) mb from \(D^0\) alone and \(1.4 ± 0.2 ± 0.4\) mb from the combined fit of \(D^0\) and electrons. The nucleon modification factor [20] was obtained by taking the ratio of the electron spectra in \(d + A\) and \(p + p\) collisions scaled with the underlying nucleon-nucleon binary collisions. It was measured to be \(1.3 ± 0.3 ± 0.3\), averaged over \(1 < p_T < 4\) GeV/c. This value is consistent with binary scaling within the measured errors.

The beam energy dependence of the cross section is shown in Fig. 4. Both default PYTHIA [27] and next to leading order (NLO) PQCD [18] calculations reasonably describe the results at lower energies, but underpredict the total charm cross section at \(\sqrt{s_{NN}} = 200\) GeV. A NLO PQCD calculation (solid line) with fragmentation and renormalization scales chosen to be \(\mu_F = 2m_c\) and \(\mu_F = m_c (m_c = 1.2\) GeV/c\(^2\)) reproduces our result. The underprediction by PYTHIA of the charm cross section is also evident in Fig. 3, the charm decayed electron \(p_T\) distribution shown as dot-dashed line. Furthermore, the slope of the PYTHIA distributions is much steeper than the measured distribution. There are also indications that a large charm production cross section at \(\sqrt{s_{NN}} = 300\) GeV is essential to explain available cosmic ray data [29].

At RHIC energies, binary scaling of the open charm production is expected between \(p + p\), \(p + A\), and \(A + A\) collisions [4]. If correct, the results of this study suggest a much larger charm yield in central \(A + A\) collisions than previously assumed in statistical thermal models [7–9], based on some PQCD/PYTHIA calculations. This would rule out several predictions [7–9] of charm production not previously excluded by the upper limit (below binary scaling) set by \(J/\psi\) production in central \(A + A\) collisions [30]. Future heavy ion runs at RHIC with open charm and \(J/\psi\) measurements will enable us to study the flow and thermalization of charmed particles.

In summary, the charm cross section and transverse momentum distribution for \(p + p\) and \(d + A\) collisions at \(\sqrt{s_{NN}} = 200\) GeV have been measured by the STAR collaboration at RHIC. Independent measurements of the reconstructed \(D^0\) and single electrons from charm semileptonic decay are consistent. The total cross section at this energy was compared to theoretical calculations. The result has important consequences for charm quark coalescence in \(A + A\) collisions at RHIC.

We are grateful for many fruitful discussions with D. Kharzeev and R. Vogt. We thank the RHIC Operations Group and RCF at BNL, and the NERSC Center at LBNL for their support. [12] S. P. K. Tavernier, Rep. Prog. Phys. 50, 1439 (1987). Total cross sections extrapolated from very high \(x_F\) and/or from correlations with low acceptance are not included in Fig. 4.
[27] T. Sjöstrand et al., Comput. Phys. Commun. 135, 238 (2001). PYTHIA 6.152 was used with the parameter settings: MSEL = 1, CTEQ5M1. Bottom contribution was estimated to be 20%–30% in \(p_T\) = 2–3 GeV/c, 40%–50% in 3–4 GeV/c to the total nonphotonic electrons, and negligible at lower \(p_T\).
[28] Particle Data Group, K. Hagiwara et al., Phys. Rev. D 66, 010001 (2002). \(N_{\gamma p}/N_{e^-}\) was derived from the measured open charm states in \(e^+e^-\) at \(\sqrt{s} = 91\) GeV. There is a 10% uncertainty taken into account in the branching ratios of open charm semileptonic decays used in the electron-to-charm fit, reflecting unknown production and branching ratios for individual states. The ratio in hadronic production, although somewhat reduced, is consistent with that in \(e^+e^-\) within errors.
