Effect of the unpolarized spin state in  
spin-correlation measurement of two protons  
produced in the  $^{12}\text{C}(d,^2\text{He})$  reaction

**Abstract**

In this note we discuss the effect of the unpolarized state in the spin-correlation measurement of the  $^1S_0$  two-proton state produced in  $^{12}\text{C}(d,^2\text{He})$  reaction at the KVI, Groningen. We show that in the presence of the unpolarized state the *maximal* violation of the CHSH-Bell inequality is lower than the classical limit if the purity of the state is less than  $\sim 70\%$ . In particular, for the KVI experiment the violation of the CHSH-Bell inequality should be corrected by a factor  $\sim 10\%$  from the pure  $^1S_0$  state.

# 1 Introduction

In an experiment performed at the Kernfysisch Versneller Instituut (KVI), Groningen [5] with the goal to test Bell inequality violation in Nuclear Physics (perhaps to be applied in quantum information physics), the experimental group, by bombarding a  $^{12}\text{C}$  target with 170 MeV  $d$ , was able to generate a singlet-spin, two-proton state coupled to unpolarized state with  $\sim 10\%$  contribution. In this paper we will analyze the experimental results of this experiment and we will show that the effect of the unpolarized state is important and could not be neglected.

## 2 CHSH inequalities and entanglement in a mixed ensemble

Bell-type inequalities relating averages of four random dichotomic variables  $a, a'$  and  $b, b'$  representing measurements of spin in directions  $\hat{a}, \hat{a}'$  and  $\hat{b}, \hat{b}'$ . The Clauser, Horne, Shimony and Holth (CHSH) [3] form of Bell-type inequalities for spin 1/2 case could be written in this form

$$|E(\phi_1, \phi'_1, \phi_2, \phi'_2)| = |E(\phi_1, \phi_2) + E(\phi_1, \phi'_2) + E(\phi'_1, \phi_2) - E(\phi'_1, \phi'_2)| \leq 2, \quad (1)$$

where  $\phi_i$  is the analyzer angular setting for the  $i^{\text{th}}$  particles ( $i = 1, 2$ ) and  $E(\phi_i, \phi_j)$  is the correlation function defined as

$$E(\phi_i, \phi_j) = \frac{N_{++} + N_{--} - N_{+-} - N_{-+}}{N_{total}}. \quad (2)$$

In quantum-theory language the CHSH operator corresponding to the CHSH inequality is represented by an operator

$$\mathcal{B} = \hat{a} \cdot \sigma \otimes (\hat{b} + \hat{b}') \cdot \sigma + \hat{a}' \cdot \sigma \otimes (\hat{b} - \hat{b}') \cdot \sigma, \quad (3)$$

acting in Hilbert space  $\mathcal{H}_A \otimes \mathcal{H}_B$  in  $2 \otimes 2$  dimension. The correlation function is given by the mean value of the operator  $\hat{a} \cdot \sigma \otimes \hat{b} \cdot \sigma$ . For a pure state this correlation function could be easily computed, *e.g.* for singlet state we have

$$E(\phi_i, \phi_j) = -\cos(\phi_i - \phi_j). \quad (4)$$

For mixed state, however, the mean value should be averaged over the ensemble and therefore the CHSH inequality not a sufficient condition to test the presence of entanglement[7]. Different measures of the entanglement have been proposed in the literature for mixed state<sup>1</sup>, *e.g.* entanglement of formation, distillation, relative entropy of entanglement, negativity, etc. . . Here we will use the entanglement of formation as our measure of the entanglement.

---

<sup>1</sup>Any measurement of the entanglement should not increase by local operation (*e.g.* unitary transformation) and classical communication (*e.g.* phone calls.), known as LOCC

In a mixed ensemble any bipartite quantum state  $\rho_{AB}$  can be written as:

$$\rho_{AB} = \frac{1}{4} \left( I \otimes I + \mathbf{A} \cdot \boldsymbol{\sigma} \otimes I + I \otimes \mathbf{P} \cdot \boldsymbol{\sigma} + \sum_{i,j=1}^3 D_{ij} \sigma_i \otimes \sigma_j \right). \quad (5)$$

$\sigma_i$  are the pauli matrices,  $I$  is the identity operator,  $\mathbf{A}$  and  $\mathbf{P}$  are vectors in  $\mathcal{R}^3$ . The  $D_{ij}$  form a  $3 \times 3$  matrix called the correlation matrix  $D$ . In this representation of the density matrix the mean value of the CHSH-Bell operator is given by [4]

$$\langle \mathcal{B} \rangle = \hat{a} \cdot [D(\hat{b} + \hat{b}')] + \hat{a}' \cdot [D(\hat{b} - \hat{b}')] . \quad (6)$$

Using the representation of the density matrix given in Eq. (5), we characterize any bipartite quantum state  $\rho_{AB}$  by

- The entanglement measured by the ‘‘tangle’’,  $\tau$ , of the entanglement of formation [6] and defined by

$$\tau = \max\{\lambda_1 - \lambda_2 - \lambda_3 - \lambda_4, 0\}, \quad (7)$$

where the  $\lambda$ 's are the square roots of the eigenvalues, in decreasing order, of the matrix,  $\rho_{AB}(\sigma_y \otimes \sigma_y \rho_{AB}^* \sigma_y \otimes \sigma_y)$  and  $\rho_{AB}^*$  is the complex conjugation of  $\rho_{AB}$  in the computational basis  $\{|++\rangle, |+-\rangle, |-+\rangle, |--\rangle\}$ .

- The maximum amount of the CHSH-Bell violation of the state  $\rho_{AB}$  [4]

$$\langle \mathcal{B} \rangle^{max} = 2\sqrt{M(\rho_{AB})}. \quad (8)$$

$M(\rho_{AB})$  is the sum of the two larger eigenvalues of  $DD^\dagger$ <sup>2</sup>.

- The purity of the state that measures how far the state is from pure state

$$S_L = \text{Tr}(\rho_{AB}^2). \quad (9)$$

### 3 Analysis of the experimental data of the KVI experiment

The spin state of the two protons produced in the  $^{12}\text{C}(d,^2\text{He})$  reaction at  $E_d = 170$  MeV at KVI [5] is a singlet state mixed with the unpolarized (random contamination) state with  $\gamma$  ( $0 \leq \gamma \leq 1$ ) controlling the degree of mixing (the details of the experimental setup and analysis method of the  $(d,^2\text{He})$  reaction

<sup>2</sup>In this case the directions  $\hat{b}$  and  $\hat{b}'$  of the analyser setting are equal to  $\cos(\theta)\hat{c}_{\max} \pm \sin(\theta)\hat{c}'_{\max}$  and the direction  $\hat{a}$ ,  $\hat{a}'$  are equal to  $\frac{D\hat{c}_{\max}}{\|D\hat{c}_{\max}\|}$ ,  $\frac{D\hat{c}'_{\max}}{\|D\hat{c}'_{\max}\|}$ , respectively.  $\hat{c}_{\max}$  and  $\hat{c}'_{\max}$  are two unit (not unique) and mutually orthogonal vectors in  $\mathcal{R}^3$  that maximize the function  $\|D\hat{c}\|^2 + \|D\hat{c}'\|^2$  (see Ref. [4] for more detail).

Figure 1: Plot of  $\langle \mathcal{B} \rangle_{Werner}^{max}$  (dashed line) and  $\tau$  (solid line) versus the purity  $\gamma$ . The dotted line is the Bell limit, the circle is the KVI limit for  $\gamma \sim 0.9$ .

were described in detail in Ref. [5]). Given all that, we can write the density matrix of such state as

$$\rho_W = (1 - \gamma) \frac{I}{4} + \gamma |\Psi^-\rangle \langle \Psi^-| \quad (10)$$

which interpolates between the unpolarized state  $I/4$  and singlet state  $|\Psi^-\rangle = (|+-\rangle - |-+\rangle)/\sqrt{2}$ . This class of states is called Werner states [7]. The purity of Werner states is a monotonic function of  $\gamma$ . Thus, in this paper we use  $\gamma$  as our measure of purity. Also, for Werner state it is easy to prove using the condition noted above that

$$\langle \mathcal{B} \rangle_{Werner}^{max} = \gamma \langle \mathcal{B} \rangle_{pure}^{max}. \quad (11)$$

Note that, a violation of the modified Bell-inequality does not exclude an explanation with a hidden variable theory. In Fig. 1 we plot  $\langle \mathcal{B} \rangle_{Werner}^{max}$  and the tangle  $\tau$  versus the purity  $\gamma$ . As we can see in this figure the Werner state does not violate the Bell inequality if its purity  $\gamma$  is less than  $1/\sqrt{2} \sim 70\%$ . However, the entanglement is still non-zero in the Werner state until  $\gamma > 1/3 \sim 33\%$ . Therefore, some quantum correlation cannot be seen only

Table 1: Experimental data and quantum theory predictions for a pure singlet states (case 1) and mixed Werner states (case 2) for several violating cases of the CHSH-Bell inequality according to the definition given in Eq. 1.

CHSH-Bell Inequality	QM case 1	QM case 2	Exp. Data
$E(50^\circ, 0^\circ, 25^\circ, 75^\circ)$	2.46	2.21	$0.67 \pm 2.30$
$E(60^\circ, 0^\circ, 30^\circ, 90^\circ)$	2.60	2.34	$1.21 \pm 2.42$
$E(70^\circ, 0^\circ, 35^\circ, 105^\circ)$	2.72	2.45	$1.54 \pm 2.76$
$E(80^\circ, 0^\circ, 40^\circ, 120^\circ)$	2.80	2.52	$2.11 \pm 2.86$
$E(90^\circ, 0^\circ, 45^\circ, 135^\circ)$	2.83	2.55	$2.23 \pm 2.48$
$E(100^\circ, 0^\circ, 50^\circ, 150^\circ)$	2.79	2.51	$2.39 \pm 2.87$
$E(110^\circ, 0^\circ, 55^\circ, 165^\circ)$	2.69	2.34	$2.58 \pm 2.91$
$E(120^\circ, 0^\circ, 60^\circ, 180^\circ)$	2.50	2.25	$2.75 \pm 2.95$
$\chi^2$	1.26	0.85	

by measuring the violation of the Bell-type inequality because some of them (Werner states) are entangled but still do not violate Bell inequality. Note that there is a possible experimental measurement of the entanglement based on the entanglement witness [8] that we think to implement in the future experiment.

In Tab. 1 we compare the quantum theory predictions assuming a pure singlet state (case 1) and mixed Werner states (case 2) for the spin of the two detected protons for several violating cases of the CHSH-Bell inequality. The value of  $\chi^2 = \sum_i (\frac{R_{th}^i - R_{exp}^i}{\Delta R_{exp}^i})^2$  is given in the bottom of the table for both cases. We have found that  $\chi_{Werner}^2 < \chi_{Singlet}^2$  as expected. However, we cannot judge this result as evidence of the mixing of the singlet with the unpolarized state because the experimental data suffer from large errors.

## 4 Conclusion

In this paper we have discussed the effect of the unpolarized state in the spin correlations measurement of the  $^1S_0$  two proton state produced in  $^{12}\text{C}(d, ^2\text{He})$  reaction at KVI. We have shown that even a small coupling (less than 10%) of the pure singlet state with the unpolarized state changes dramatically the Bell-violation value. After introducing the contribution of the unpolarized state we have found a better  $\chi^2$ . The experimental results are suffering from a large statistical error and therefore not conclusive for testing Bell's inequality, but with a modified experimental setup, measurements with significantly improved precision will become feasible.
