(Received 2 March 2017; published 12 June 2017)

Using resonant soft x-ray techniques we follow the magnetic behavior of a strained epitaxial film of CoCr₂O₄, a type-II multiferroic. The film is [110] oriented, such that both the ferroelectric and ferromagnetic moments can coexist in-plane. X-ray magnetic circular dichroism (XMCD) is used in scattering and in transmission modes to probe the magnetization of Co and Cr separately. The transmission measurements utilized x-ray excited optical luminescence from the substrate. Resonant soft x-ray diffraction (RXD) was used to study the magnetic order of the low temperature phase. The XMCD signals of Co and Cr appear at the same ordering temperature $T_C \approx 90$ K, and are always opposite in sign. The coercive field of the Co and of Cr moments is the same, and is approximately two orders of magnitude higher than in bulk. Through sum rules analysis an enlarged Co²⁺ orbital moment (m_L) is found, which can explain this hardening. The RXD signal of the (q q 0) reflection appears below T_S , the same ordering temperature as the conical magnetic structure in bulk, indicating that this phase remains multiferroic under strain. To describe the azimuthal dependence of this reflection, a slight modification is required to the spin model proposed by the conventional Lyons-Kaplan-Dwight-Menyuk theory for magnetic spinels.

DOI: [10.1103/PhysRevB.95.224413](https://doi.org/10.1103/PhysRevB.95.224413)**I. INTRODUCTION**

Multiferroics, materials with multiple memory phenomena, have been the subject of intense research over the past decade [1,2]. This is mostly due to the technological prospects presented by magnetoelectric multiferroics, which possess magnetic and ferroelectric order simultaneously. In this context, significant attention has been given to type-II multiferroics, in which magnetic order drives the electric polarization, such that both order parameters are strongly coupled to each other. Strong enough coupling could allow applications in which magnetization is switched by electric, instead of magnetic fields. This can lead to new energy-efficient applications, because using a voltage to apply electric fields can eliminate the Joule heating associated with the electric current required to generate magnetic fields.

A significant setback in the study of type-II multiferroics is that most known materials of this class possess antiferromagnetic order, and therefore no remnant magnetic moment, a prerequisite for most magnetic applications. Spinel CoCr₂O₄ (CCO), which crystallizes in space group $Fd\bar{3}m$ #227, is a rare example of a type-II multiferroic that exhibits ferroelectricity and a remnant magnetic moment in the same phase. CCO is a well-characterized ferrimagnet known since the 1960s [3]. Two well-established magnetic phases are known. A collinear ferrimagnetic phase appears below $T_C \approx 92$ K, in which CCO acquires a remnant magnetic moment [3] from noncompensating sublattices of Co and Cr aligned antiparallel to each other along [001]. This is known as the Néel state. Below $T_S \approx 27$ K a spiral component is added to the magnetic structure [3], modulated by an incommensurate $\mathbf{Q} = 2\pi(q$ q 0) modulation vector [4] with $q \approx 2/3$ [5] (q is slightly

temperature dependent), which results in conical magnetic order. A slight rise in magnetization is also observed in this phase, most likely due to a change in the balance between the magnetizations of the different sublattices. Renewed interest in CCO was sparked upon the discovery of ferroelectricity: the appearance of the spiral is accompanied by the appearance of ferroelectric polarization [6]. Furthermore, strong magnetoelectric coupling is evidenced by the switching of both \mathbf{M} and \mathbf{P} with a magnetic field [6]. The appearance of the magnetic spiral and the multiferroic behavior are evidence of strong magnetic frustration. A number of additional magnetic features were reported. A first-order transition at $T_L \approx 14.5$ K has been reported by several authors [6–10]. This transition includes a lock-in of the q value, as well as a flip in the sign of \mathbf{P} [8], and a splitting of the (q q 0) modulation vector. Several authors have reported an anomaly around 50 K [6,11–13]. This feature is often referred to as T_{kink} , and may be linked to ordering of Cr moments or a short range ordered spiral.

Theories aimed at describing the magnetic behavior of AB_2O_4 -type spinels were already introduced several decades ago (in the present case A and B refer to Co and Cr, respectively). Yafet and Kittel [14] proposed a model which considered the exchange coupling between adjacent A or B ions (described by the terms j_{AA} , j_{BB} , and j_{AB}). An important aspect of the model is a stability parameter of the form $u \propto j_{BB}/j_{AB}$, and the system was said to prefer the Néel state when $u \leq 8/9$. An expanded theory known as LKDM [4,15] (named after Lyons, Kaplan, Dwight, and Menyuk) suggested that the conically ordered phase is the ground state when $8/9 < u < 1.298$. The conical order refers to a ferrimagnetic order with a transverse spiral component (i.e., in the plane perpendicular to the ferromagnetic axis). The theory correctly

predicted characteristics of the magnetic behavior in these spinels, such as the $[110]$ direction of the modulation vector and the shape of the magnetization's temperature dependence.

Most known multiferroic systems are not suitable for technological applications, usually because the electric polarizations they exhibit are too weak. Therefore the focus in recent years has shifted towards the questions of how to maximize and how to control ferroic orders. To this end, a promising route is the use of epitaxial strain [16]. A number of studies have shown how strain can affect different multiferroic properties. A recent study of CCO films demonstrated that significant variations in magnetic anisotropy can occur due to strain [17]. However the study did not address the multiferroic phase.

In this work we describe a detailed study of the magnetic behavior in strained CCO using resonant x-ray techniques. Resonant x-ray techniques are often employed to study complex oxides. One of their key advantages is element selectivity, which allows separation of signal contributions from one or more constituent ions. CCO is an ideal example of a material where such advantages are required because both the Co and the Cr ions contribute to the macroscopic magnetic behavior. Choi *et al.* [8] employed resonant x-ray diffraction (RXD) to study single crystals of CCO, focusing mainly on the spiral handedness in the multiferroic phase. Liu *et al.* [18] employed photoemission and x-ray resonant magnetic scattering around the Co and Cr L edges to characterize epitaxial films.

Here we used RXD to follow the conical order of the multiferroic phase. X-ray magnetic circular dichroism (XMCD) was used to follow the average net moments of the Co and the Cr sublattices in reflection (scattering) and in transmission modes. We specifically employ x-ray excited optical luminescence (XEOL) in transmission to conduct XMCD sum rules analysis. We will show that epitaxial strain can enhance coercivity by 2 orders of magnitude, without canceling the multiferroic spin spiral (conical) phase.

This paper is divided in the common form, with sections describing the experiments, results, a discussion, and a

summary. For clarity, the results section is divided into four subsections, each describing a separate experiment.

II. EXPERIMENTS

An 81-nm-thick CCO film was grown on a $[110]$ -oriented MgO substrate by pulsed laser deposition (PLD) assisted by reflection high-energy electron diffraction (RHEED). A ceramic CoCr_2O_4 pellet made by a solid-state reaction was used as a target, from which the material was ablated. Laser pulses from a Lambda Physik COMPex Pro 205-KrF laser with a wavelength of 248 nm, at a frequency of 0.5 Hz, were used. The growth took place in a 0.01-mbar oxygen plasma atmosphere, created by an Oxford Scientific mini-electron cyclotron resonance-plasma source in order to improve the film's oxidation. The laser fluence, target-substrate distance, and substrate temperature were 3 J/cm^2 , 50 mm, and 500°C , respectively. Further details regarding post-annealing and substrate preparation are given in Ref. [17]. The precise sample thickness was determined using x-ray reflectivity. Sample crystallinity was characterized by x-ray diffraction at beamline X04SA of the Swiss Light Source (SLS) [19]. The a , b , and c lattice constants were determined to be 8.292, 8.294, and 8.383 \AA , corresponding to strain values of 0.48%, 0.45%, and -0.61% , respectively (positive values denote compressive strain). From these values we find that the $[110]$ direction is 0.9% strained, and almost no strain is present along the $[1\bar{1}0]$ direction ($\sim 0.02\%$). A three-dimensional depiction of the conventional unit cell is presented in Fig. 1(a). A small deviation from 90° was observed in the angle between the $[100]$ and $[010]$ directions ($\gamma = 90.5^\circ$). The effect of this deviation is presented in Figs. 1(b) and 1(c), which depict side views of unstrained and strained unit cells.

Bulk CCO and MgO are both cubic. Nevertheless growing CCO on $[110]$ -oriented MgO can lower the symmetry of CCO due to lattice mismatch, which could produce a number of different structural domains. In bulk CCO, the macroscopic observables \mathbf{M} , \mathbf{P} , and \mathbf{Q} are all perpendicular to each other,

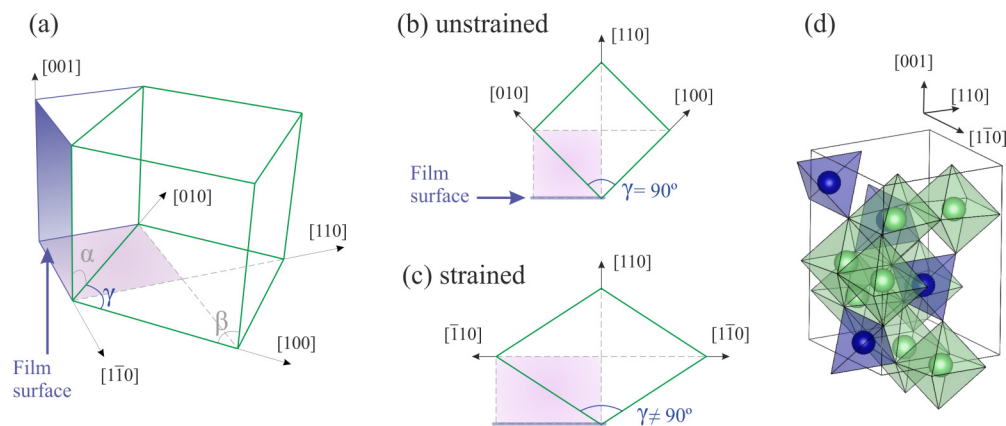

FIG. 1. Geometry of strained $[110]$ -oriented CoCr_2O_4 . (a) A 3D view of the unit cell in cubic setting. The dark shaded (blue) area represents the film's surface. The lightly shaded (pink) area represents the square enclosed by diagonals. (b) and (c) The 2D projection of the cubic unit cell onto the ab plane, in the unstrained and the strained cases, respectively. The lightly shaded (pink) area from (a) is also shown here to emphasize that the diagonals remain orthonormal. The film surface is also shown as a thick (blue) line. (d) Alternatively defined unit cell of CoCr_2O_4 in a tetragonal setting, containing four formula units. This unit cell becomes orthorhombic when strained. The pink areas in (b) and (c) are actually projections of this unit cell.

being along $[1\bar{1}0]$, $[001]$, and $[110]$ or other equivalent axes, respectively [6]. We have not observed any significant ambiguity in the directions of the macroscopic observables,¹ and therefore we do not consider other structural domains besides the $[110]$ surface orientation. This orientation sets both macroscopic observable quantities (\mathbf{P} and \mathbf{M}) in-plane and perpendicular to each other, and it sets \mathbf{Q} out-of-plane. Bulk CCO can be described by a tetragonal unit cell which contains four formula units, instead of eight in the cubic setting. This unit cell is defined by the same $[110]$, $[1\bar{1}0]$, and $[001]$ directions [see Fig. 1(d)]. Figure 1(c) illustrates that these directions remain orthonormal even when $\gamma \neq 90^\circ$. The tetragonal cell thus becomes orthorhombic.² To avoid confusion, all crystallographic directions in this paper are given in the cubic notation.

Magnetization measurements were conducted using a commercial MPMS SQUID magnetometer equipped with a 7 T magnet. Substrate contributions were not subtracted from the data. In field dependent magnetization measurements, linear contributions to magnetization above saturation were subtracted. X-ray scattering measurements at the Co and Cr $L_{2,3}$ edges (~ 780 and ~ 590 eV, respectively) were conducted using the RESOXS [20] high vacuum diffractometer at beamline X11MA of the SLS [21]. Data were collected using an IRD AXUV100 photodiode covered by a 400-nm-thick aluminum foil for blocking visible light. The scattering geometry is schematically shown in Fig. 2(a). X-ray excited optical luminescence (XEOL) measurements were conducted at the Co and Cr $L_{2,3}$ edges using the high-field XTreme end station at beamline X07MA of the SLS [22]. Transmission spectra were recorded using XEOL by correcting for the energy dependence of luminescence from the bare substrate, as demonstrated by Kallmayer *et al.* [23]. Other authors have since employed XEOL [24–27], and the luminescence of bulk MgO was studied in detail by Vaz *et al.* [28]. The spectra were recorded by continuously scanning the incoming photon energies at a rate of 0.44 and 0.36 eV/s around the Co and Cr resonances, respectively. The cold head's sample mount was designed to accommodate a photodiode *behind* the sample. The experiment was conducted with the substrate mounted in front of a small hole, through which light from the substrate can reach a photodiode. The hole is the only opening of the photodiode region. For sum rules analysis data were binned using 0.25 eV steps, which is well above the energy resolution of this experiment. Reducing the bin size even by a factor of 2 does not appreciably affect the results.

III. RESULTS

A. Magnetization

Figure 3(a) presents the temperature dependence of magnetization measured upon warming along the $[001]$ direction and along $[110]$, the film normal. Before the measurements

¹As shown in later sections, the $[001]$ is the easy magnetization axis, and the ordering wave vector \mathbf{Q} is along $[110]$.

²For this we also assume that the difference between the a and b lattice constants is negligible, as it is close to the limit of our experimental resolution.

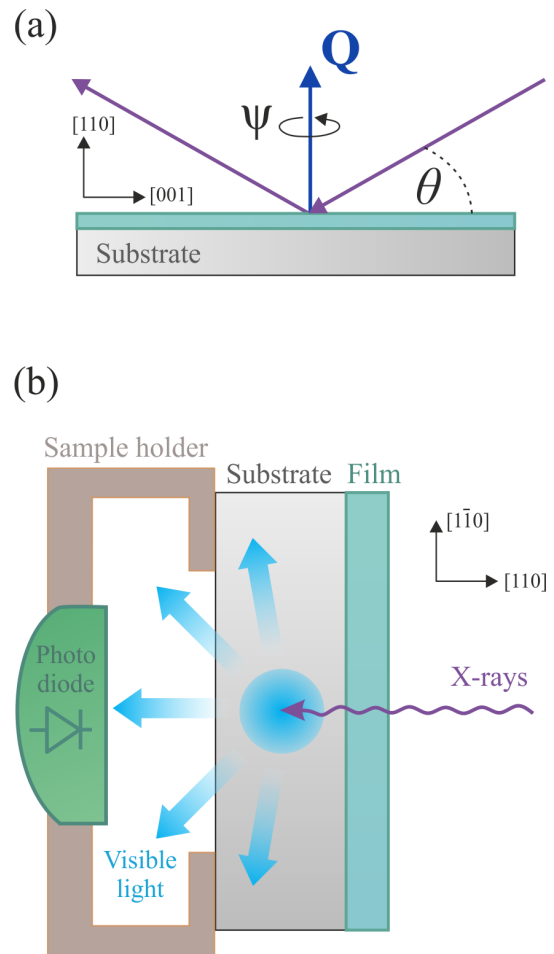

FIG. 2. Schematics of the soft x-ray experimental setups. (a) The scattering setup. Ψ is the rotation angle around the momentum transfer vector \mathbf{Q} , and $\Psi = 0^\circ$ is defined when the $[001]$ direction is in the scattering plane (directions shown correspond to this orientation). (b) The XEOL setup. The sample is mounted on a cold copper piece with a ~ 3 mm hole through which the substrate can luminesce to the photodiode.

the sample was cooled under a field of 2 T, and a field of 10 mT was applied during the measurements. We find that the magnetization along $[001]$ is nearly 50% higher than in bulk (compared to Ref. [6]). The sharp rise at the lowest temperatures is most likely due to a Curie-Weiss behavior of substrate impurities. This contribution is strongly suppressed upon warming, as shown in Ref. [17].

Figure 3(b) presents two magnetization curves measured along $[001]$ as function of magnetic field at different temperatures. Similar measurements along $[110]$ exhibited no hysteresis (not shown). Direct comparison with bulk data such as in Ref. [8] reveals that the coercive field is two orders of magnitude larger in our strained film. A similar observation was made for a $[001]$ -oriented strained film in Ref. [17]. At 5 and 15 K the 7 T field available was unable to saturate the sample. Data were also taken out-of-plane, along $[110]$ (not shown), and no clear hysteresis or saturation were observed, as expected for a hard axis.

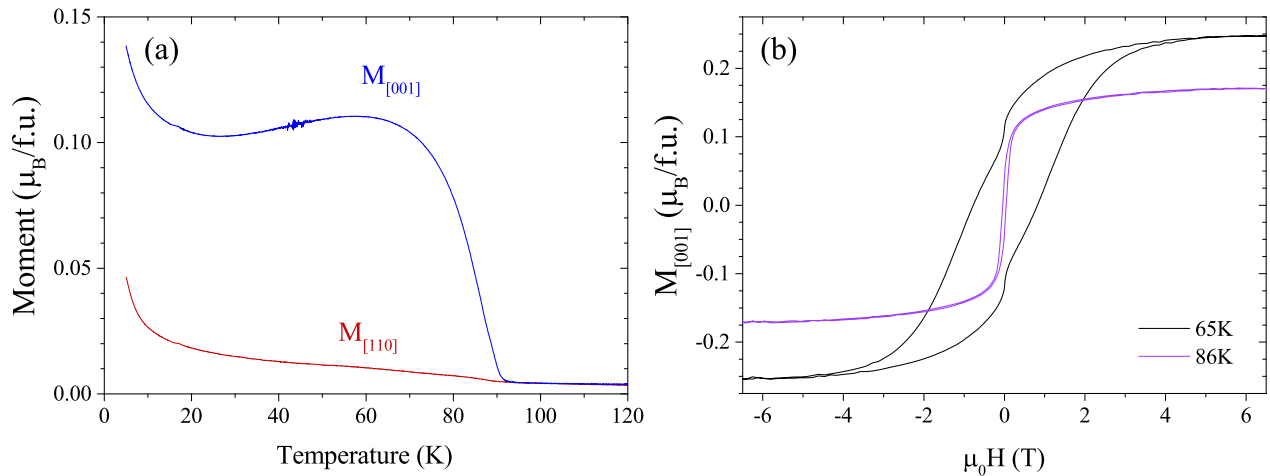

FIG. 3. Magnetization of the CCO sample. (a) Magnetization as function of temperature, measured upon warming along [001] and along [110]. Measurements were done under a field of 10 mT after field cooling in 2 T (fields were applied along the measurement direction). The noise at ~ 45 K is most likely an experimental artefact. (b) Magnetization as function of magnetic field along [001], measured at 65 and 86 K. Linear contributions were removed above 6 T, which is above the saturation field of the hysteresis (see main text).

The data in Fig. 3 suggest that the [001] axis is the easy magnetization axis, as in bulk. To obtain further insights on the favored direction of the spins we performed *ab initio* calculations using LSDA+*U* as implemented in the Vienna *ab initio* simulation package [29], in a similar manner as done in Ref. [17]. We used a projector augmented wave pseudopotential [30] and fixed the strength of the effective on-site Coulomb interaction and effective Hund's rule coupling to $U_{\text{Co}} = 4$ eV, $J_{\text{Co}} = 1$ eV and $U_{\text{Cr}} = 3$ eV, $J_{\text{Cr}} = 1$ eV for Co^{2+} and Cr^{3+} , respectively. For simplicity, in the following calculation, energies are derived for the tetragonal unit cell of bulk CoCr_2O_4 shown in Fig. 1(d). For such settings we use a $9 \times 9 \times 5$ Monkhorst *k*-points mesh. Note that energies calculated in Ref. [17] were for a unit cell with only two formula units.

The relaxed (i.e., bulk) unit cell acquired through LSDA+*U* has a lattice constant of 8.212 Å in the cubic setting. To determine the crystallographic structure in the film we fixed the in-plane lattice constants: the [1 $\bar{1}$ 0] was fixed to its size in the relaxed cell, and the [001] was set to 1.006 times its size in the relaxed cell (0.6% tensile strain). We then relaxed the out-of-plane lattice direction [110] and the ionic positions within the unit cell. The [110] out-of-plane length of the resulting strained unit cell was determined to be 11.582 Å (in cubic setting). The relaxation was performed in absence of spin-orbit couplings and keeping the spins of Cr^{3+} antiparallel to those of Co^{2+} . Interestingly, the *ab initio* relaxation results in a reduction of approximately 0.3% in the out-of-plane length along the [110] direction (with respect to the bulk value). While it maintains the correct direction and order of magnitude, this underestimates the experimentally observed 0.9% reduction.

To estimate the easy axis of magnetization, the energy of different spin configurations was calculated. In each configuration the spins' direction was fixed at an angle ϕ between two crystallographic axes in the strained unit cell (described above). Figure 4 presents results for two rotations: between the [001] and [110] directions (black circles), and between the [001] and [1 $\bar{1}$ 0] directions (blue circles).

From these calculations we conclude that the minimal energy occurs for spins oriented along [001]. Furthermore, the energy difference between [001] and the other two axes is nearly the same. In other words, the [1 $\bar{1}$ 0] axis is the hard axis in-plane, and is nearly as hard as the out-of-plane [110] direction.

The calculated energy dependence fits well to the dependence of anisotropy described in Ref. [17] as $E(\phi) = \alpha \cos^2 \phi + \beta [\cos^4 \phi + \sin^4 \phi]$ (see dashed curves in Fig. 4). The parameters α and β describe second and fourth order terms of

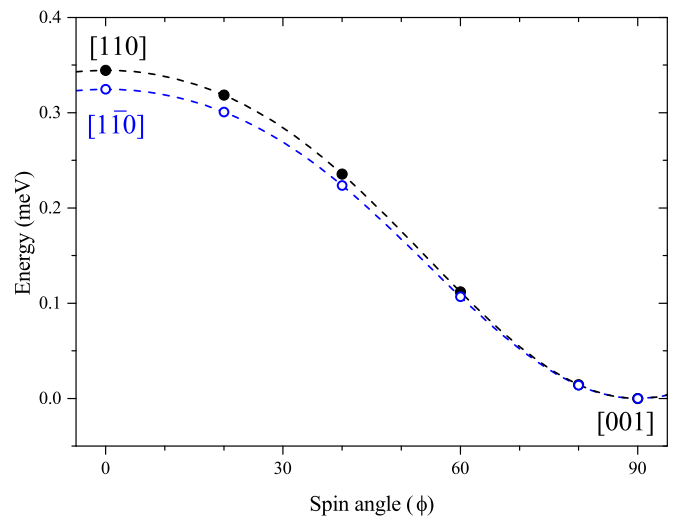

FIG. 4. Energy dependence of different spin arrangements. In each arrangement the spins are set along an axis at an angle ϕ between the two crystallographic directions. Solid circles (black) indicate spins along an axis between [001] and [110]. Open (blue) circles indicate spins along an axis between [001] and [1 $\bar{1}$ 0]. Dashed lines are the best fits (see main text). In all cases the Cr^{3+} spins are kept antiparallel to the Co^{2+} spins. Calculations were done for a unit cell with four formula units, and the energy of $\phi = 90^\circ$ (spins along [001]) is subtracted for clarity.

TABLE I. Best fit parameters to the dependence of energy on spin rotation, following Ref. [17], for the energy values calculated and shown in Fig. 4 for a unit cell with four formula units. Bulk values are from [17].

| Rotation direction | α (μeV) | β (μeV) |
|---|-----------------------------|----------------------------|
| [110] \rightarrow [001] | 344.56 | -68.80 |
| [$\bar{1}\bar{1}0$] \rightarrow [001] | 324.61 | -68.45 |
| Bulk CCO (cubic) | 0 | -44.5 |

the spin anisotropy from all magnetic sublattices. The best fit parameters are listed in Table I.

B. Resonant x-ray scattering

Resonant x-ray scattering is an element-selective probe of a material's electronic state [31], including its magnetic configuration. For transition metals such as Co and Cr, electric dipole ($E1$) excitations at the L_2 and L_3 absorption edges are direct probes of the unoccupied $3d$ electronic levels. We begin by employing x-ray magnetic circular dichroism (XMCD) to follow the net moments of the Co and Cr ions separately.

Since the film is an insulator, conventional electron yield measurements are not possible. Conventional transmission measurements are also not possible, since the substrate is 0.5 mm thick. As an alternative, we employ XMCD in reflectivity mode. Figures 5(a) and 5(b) present the energy dependence of scattered intensity around the Co and the Cr $L_{2,3}$ edges, measured using either left- or right-handed circularly polarized incoming light. We refer to the intensity measured from scattering circularly polarized incident light as I_{\pm} , where \pm indicates the handedness of the incoming light. The experimental configuration is such that the [001] crystal axis, the easy axis of magnetization, is in the scattering plane, as in Fig. 2(a). The measurement was done at 10 K, and the sample was cooled prior to the measurement in a field of 450 or -450 mT applied along [001]. A clear contrast is observed between the spectra measured with I_+ and I_- . The incident angles of the light on the sample were shallow ($\theta = 4.1^\circ$ and 7.3° for Cr and Co, respectively), and were chosen because they exhibited largest circular dichroism.

Figures 5(c) and 5(d) present a temperature dependence of I_+ and I_- at the Co and Cr L_3 edges. The energy with the highest contrast between I_+ and I_- were used: 779.15 and 577.9 eV, marked by vertical lines in Figs. 5(a) and 5(b). The

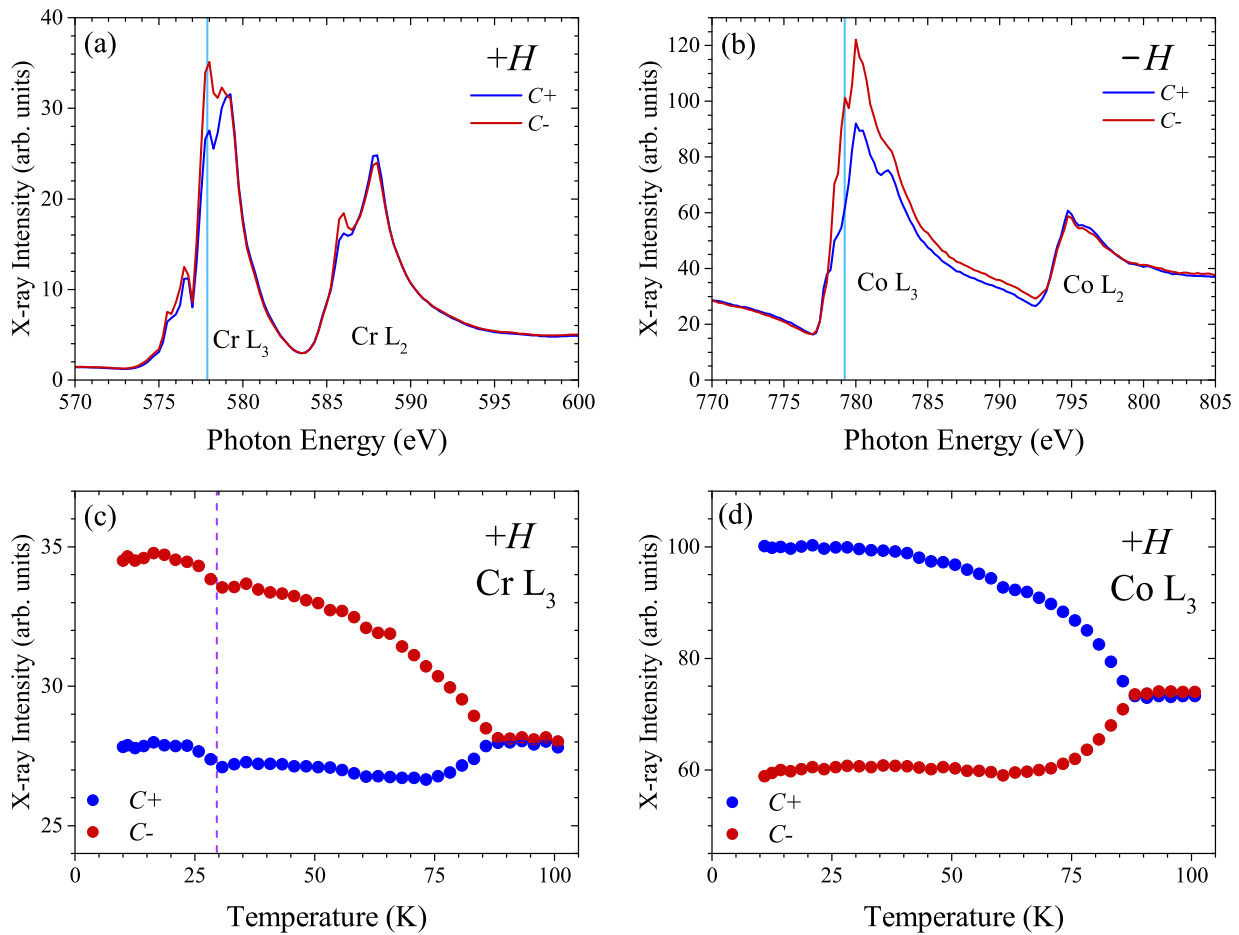

FIG. 5. Reflectivity data taken from CCO using circular light after field cooling. (a) and (b) Reflectivity signals as functions of incoming photon energy around the Co and Cr L edges, respectively. Data were taken at 10 K, and at incident angles of $\theta = 4.1^\circ$ and 7.3° for Cr and Co, respectively. Vertical lines represent the energies used in (c) and (d). (c) and (d) Reflectivity at the L_3 edges as functions of temperature. Prior field cooling was conducted in $\pm H = \pm 450$ mT. Note that (b) presents data taken after field cooling in $-H$, while the other panels were taken after cooling in $+H$. Error bars are smaller than the symbols and lines.

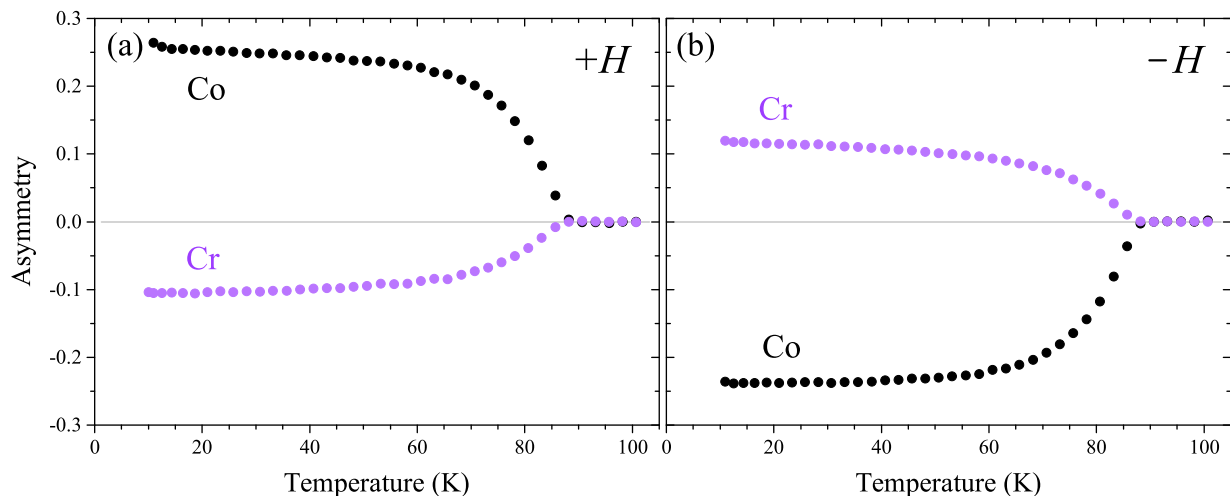

FIG. 6. Magnetic asymmetry as a function of temperature measured at the Co and Cr L_3 edges (779.15 and 577.9 eV). The left and right panels present four heating cycles conducted with the exact same procedure, but after cooling in magnetic fields of opposite signs: -400 and 400 mT, applied along $[001]$. Error bars are smaller than the symbols.

circular dichroism disappears above $T_N \approx 90$ K, indicating that the dichroism is indeed due to magnetic order (XMCD). Furthermore, the reflectivity at the Cr edge rises by $\sim 5\%$ below ~ 27 K (for both circular polarizations), which can be attributed to the appearance of conical magnetic order, known to occur in bulk CCO below $T_S = 27$ K [indicated by a dashed line in Fig. 5(c)].

For further analysis of the measured intensity, the resonant magnetic scattering amplitude in the case of an $E1$ - $E1$ event can be written as [32]

$$f_{E1E1} \propto \{(\hat{\epsilon}'^* \cdot \hat{\epsilon})F^{(0)} - i\hat{m} \cdot (\hat{\epsilon}'^* \times \hat{\epsilon})F^{(1)} + (\hat{\epsilon} \cdot \hat{m})(\hat{\epsilon}'^* \cdot \hat{m})F^{(2)}\}. \quad (1)$$

Here the magnetic moment is represented by \hat{m} , the terms $F^{(n)}$ represent prefactors, and $\hat{\epsilon}$ and $\hat{\epsilon}'$ are the incoming and outgoing polarization vectors. For magnetic scattering, the second term is of primary importance, as it is linear with respect to the magnetic moment. In order to maximize sensitivity to \hat{m} , the direction of incoming light should be almost parallel to the magnetic axis. This is equivalent to the notion that XMCD in absorption or transmission experiments is sensitive to the moment parallel to the incoming beam. In the present case, the magnetic easy axis is in the film plane (along $[001]$), so high sensitivity can be achieved with a small incident angle θ , and when the film is oriented such that $[001]$ is in the scattering plane [as in Fig. 2(a)].

Scattered intensity will generally follow $\propto |f_0 + f_{E1E1}|^2$, so any signal that is linearly proportional to \hat{m} can only arise from interference between the first and second terms of Eq. (1) (f_0 is the nonresonant scattering amplitude, and it interferes in the same manner). From a detailed inspection of Eq. (1) with the experimental geometry described above, we find all such linear contributions go as $\cos \theta$ or as $\cos \theta \cos 2\theta$. The nonmagnetic contributions go as $\cos 2\theta$ and $\cos^2 2\theta$, and the $|F^{(1)}|^2$ second-order contribution (i.e., proportional to \hat{m}^2) goes as $\cos^2 \theta$. All other contributions to intensity from Eq. (1) include powers of $\sin^2 \theta$, and are therefore negligible in the limit of small θ . Therefore, the intensity linearly proportional to \hat{m} is the only

significant term expected to produce circular dichroism in the limit of small θ .

The data in Figs. 5(c) and 5(d) indicate that the resonant nonmagnetic term [first term in Eq. (1)] is the largest contribution to the resonant signal. The XMCD, which comes from the interference between the first and second terms of Eq. (1), is the second major contribution, representing up to $\sim 20\%$ of the measured signal. In the Cr data presented in Fig. 5(c), the 5% rise of intensity below 27 K bears the same sign in I_+ and I_- . It is therefore either due to the second-order magnetic term [second term in Eq. (1)], or due to a change in the nonmagnetic term of Eq. (1). This feature is notably absent in the signals from the Co edge in Fig. 5(d).

The data in Figs. 5(b) and 5(d) were both taken around the Co L edges, but after field cooling in opposite fields. The circular dichroism contrast between I_+ and I_- is therefore reversed in the two panels. The same reversal effect occurs at the Cr edge. To easily follow this effect, we define magnetic *asymmetry* as $(I_+ - I_-)/(I_+ + I_-)$. Figure 6 presents asymmetry calculated from the temperature dependence. Figures 6(a) and 6(b) correspond to data taken after field cooling in 450 and -450 mT, respectively. The results indicate a complete reversal of the Co and Cr asymmetry with opposite field cooling, and that the moment directions of Co and Cr are clearly opposite to each other. This is in agreement with the models presented in Ref. [13]. Also, worth noting is the absence of any significant change around T_S , indicating that the rise observed in Fig. 5(c) below T_S does not contribute to circular dichroism, and can therefore arise from nonmagnetic terms, or from the term proportional to an even power of \hat{m} (e.g., \hat{m}^2), as mentioned above. The latter could imply that a change in x-ray magnetic linear dichroism (XMLD) occurs at T_S , which is a strong effect for certain multiplet features in antiferromagnetic oxides [33,34]. However, the total Cr moment is not known to change in size below T_S , so a change in XMLD is likely to be accompanied by a change in XMCD, which is not observed.

The magnitude of asymmetry is different for Co and Cr, but this depends largely on experimental parameters such as

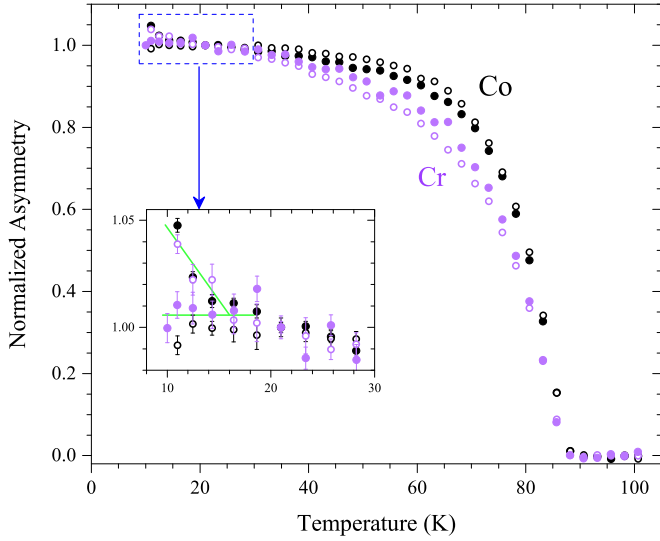

FIG. 7. Normalized asymmetry as a function of temperature. All curves from Fig. 6 normalized to their value at 21 K for direct comparison. Solid (open) symbols are data taken after cooling in 450 mT (-450 mT). The inset is a closeup of the low temperature region (lines are guides for the eyes).

the incident photon energies used. However, the temperature dependence of asymmetry from the two sublattices is also qualitatively different. Figure 7 presents all four asymmetry curves from Fig. 6, normalized to their value at 21 K (this temperature was chosen because both curves are nearly flat there). These normalized curves for Co and Cr differ most around ~ 70 K. This is in agreement with the magnetization measurements [see Fig. 3(a)], which show that the total moment is highest in this temperature region [6], assuming that the Co and Cr moments are similar at low temperatures. A second observation is that although all four field coolings were conducted under the same field strength, the gap between Co and Cr is different in magnitude for the two opposite field directions (open and solid symbols). This may indicate the existence of an exchange bias, or it could be an experimental artefact due to the manual use of a permanent magnet for applying the field.

It is also worth noting that below ~ 16 K, the data indicate that an additional rise in magnetization may occur, as shown in the inset: for field cooling in $-H$, the Cr magnetization grows further upon cooling, while for $+H$ the Co magnetization grows further upon cooling (corresponding to the same moment direction). This coincides with the temperature at which an additional first-order magnetic transition is known to occur in bulk CCO [7,8]. This effect cannot be explained by a difference in the magnitude of applied field, as the effect is the same for opposite fields. It can be explained as the result of an exchange bias, possibly coming from the interface to the substrate.

C. XMCD study using x-ray excited optical luminescence

The main setback in conducting XMCD experiments in reflectivity mode, as previously described, is that it is difficult to obtain quantitative information. One of the major

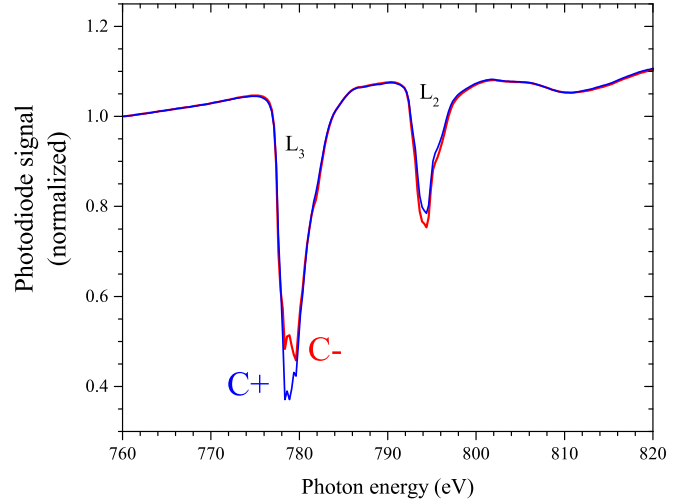

FIG. 8. XEOL data from CCO around the Co L edges. CCO data are taken with the sample at 15.5 K, and using opposite helicities of circularly polarized incoming light. The spectra are normalized to their value at 760 eV.

advantages of XMCD is sum rules analysis, which can provide a quantitative estimate of spin [35] and orbital [36] moments. This is commonly used in XMCD experiments conducted in absorption or transmission modes.

We now aim to employ sum rules analysis to quantify the average moments on the Co and Cr sublattices. As mentioned, conventional electron yield or transmission experiments are not possible. As an alternative to these methods, we use the sample's substrate as a scintillator. For this we utilize the intense x-ray excited optical luminescence (XEOL) of the substrate, which is a measure of the intensity of the beam transmitted through the thin film. XEOL is not a commonly used method, but it has been successfully employed before [37], both as an XMCD probe [26] and specifically for sum rules analysis [23]. The efficiency of XEOL varies with energy. To account for this, the transmitted intensity as a function of the sample's thickness can be described as

$$I(z) = I_0 \Lambda(E) e^{-\mu z}. \quad (2)$$

Here the term $\Lambda(E)$ is the efficiency function of the XEOL for the substrate used, which must be measured and accounted for prior to any further analysis. The other terms, I_0 and μ , represent the incident intensity and the absorption coefficient, respectively. The substrate is thick enough to absorb the entire transmitted x-ray beam (the x-ray attenuation length of MgO at these energies is between 0.3 and 0.7 μm). We therefore assume that the measured signal is entirely XEOL. Figure 8 presents raw uncorrected XEOL spectra around the Co L edges, taken from our CCO sample using circularly polarized incoming light of both helicities. Clear circular dichroism is observed.

We now detail the application of sum rules analysis to the XEOL data, mainly following Chen *et al.* [38]. The sample was oriented such that the x-ray beam was 30° from the $[001]$ axis. Before measurements, the sample was cooled from 150 to 2 K in a 2 T field along the beam direction. Figure 9 presents data taken at 15.5 K. Figures 9(a) and 9(b) present the XAS

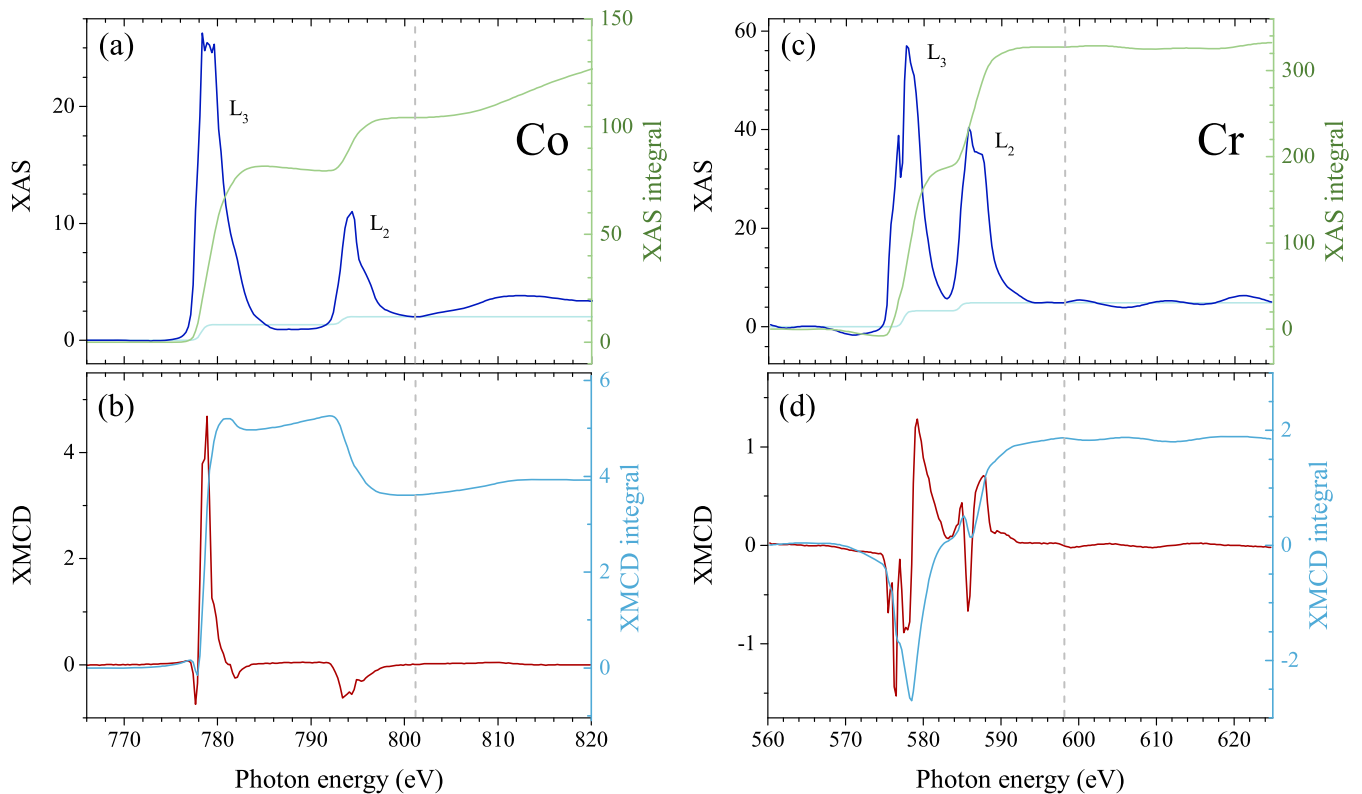

FIG. 9. XAS and XMCD spectra from CCO, taken around the Co and Cr $L_{2,3}$ edges at 15.5 K. (a) and (c) XAS spectra ($\mu_+ + \mu_-$) around the Co and Cr L edges, respectively. The calculated two-step function is also shown (see main text). The right-hand axes represent the integral over the XAS, after the two-step function is subtracted. (b) and (d) XMCD spectra ($\mu_+ - \mu_-$) around the Co and Cr L edges, respectively. The right-hand axes represent the integral over the XMCD spectra. Vertical dashed lines indicate the cutoff energies at which the integrals are evaluated (see main text).

($\mu_+ + \mu_-$) and XMCD ($\mu_+ - \mu_-$) spectra taken around the Co $L_{2,3}$ edges. The absorption coefficients from either helicity (μ_{\pm}) were corrected for $\Lambda(E)$ before addition/subtraction. The right-hand axes represent integrals over these spectra. Figures 9(c) and 9(d) present the same spectra, taken around the Cr $L_{2,3}$ edges.

For determining moment sizes, the integrals are evaluated at an energy above the L_2 edge in which their profile flattens out (energies chosen for Co and Cr were 801 and 598 eV, respectively, marked as dashed lines in all panels). Beyond these energies pronounced EXAFS oscillations appear in the XAS spectra in Figs. 9(a) and 9(c). These can be reproduced using *ab initio* simulation code such as FDMNES [39] without considering any magnetic order (not shown). The integral over the XAS spectrum was taken after a two-step function is subtracted, which represents the continuum contribution to the $2p \rightarrow nd$ $E1$ transitions at the $L_{2,3}$ edges. The nominal 2:1 branching ratio was used to define the relative height of each step. This is the ratio between the probability of excitation at the L_3 and at the L_2 , which reflects the higher degeneracy of the core state with $j = 3/2$ (L_3) with respect to that with $j = 1/2$ (L_2). The energy at the center of each step was chosen as the maxima of the XAS derivative around each edge, and the width of the steps was taken as the bin size (0.25 eV). This is slightly narrower than the core-hole lifetime of the Co L_3 , which is tabulated at 0.43 eV ($\pm 25\%$) [40].

Integrating over the XMCD spectrum allows determining the orbital moment. However, to determine the spin moment, the XMCD integral must also be evaluated over the spin-orbit split edges separately. This is problematic in the case of Cr, because the L_2 and L_3 are so close in energy that their overlap leads to errors of up to 100% [41]. We will therefore not present spin moments for Cr. This overlap is not a severe problem for Co because the L_2 and L_3 edges are well separated, so this effect is accounted for by dividing $m_{S,\text{eff}}$ of Co by 0.92 [41]. However, choosing the correct cutoff energy between the edges can have a significant effect also on the estimate of the Co spin moment. This is demonstrated in Fig. 10, which presents the calculated Co spin moment at 15.5 K as a function of the cutoff energy. Also shown is the derivative of the XMCD spectrum. We choose the cutoff energy at which this derivative is zero (marked by a solid vertical line).

Zero-field measurements such as those in Fig. 11 were taken at different temperatures, following field cooling (described above). The results of sum rules analysis of these data are presented in Fig. 11, and were calculated following the analysis of Chen *et al.* in Ref. [38]. The number of d holes was set in the calculations to seven for Cr^{3+} and three for Co^{2+} . Due to the field cooling procedure, we assume a single domain state along the [001] magnetic easy axis. Therefore, to account for the $\theta = 30^\circ$ incidence angle, a factor of $\cos 30^\circ$ was corrected for in the vertical axis. We find that the Co orbital and effective

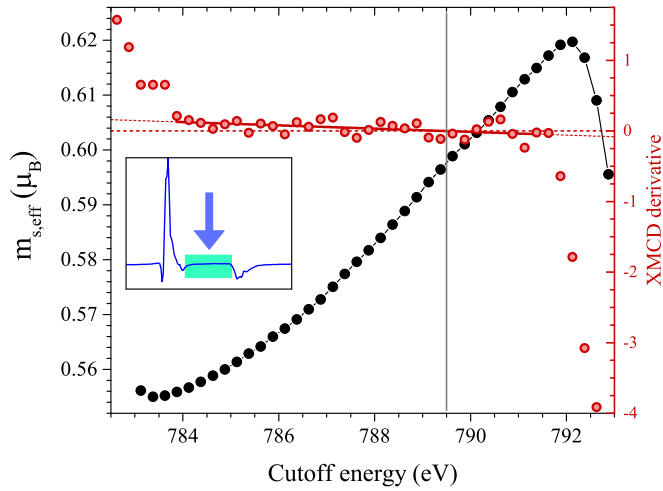

FIG. 10. Effective Co spin moment size at 15.5 K, as function of the cutoff energy between the L_2 and L_3 edges. The open circles and the right-hand axis indicate the derivative of the XMCD spectrum [Fig. 11(c)]. The derivative can be described by a linear function, and the diagonal line represents the best fit. The vertical line indicates the energy at which the derivative crosses zero. The inset shows the Co XMCD spectrum, highlighting the energy range shown in the main figure.

spin moments acquire the same sign. For the case of Cr these moments acquire opposite signs ($m_{S,eff}$ values are not shown for Cr). All of the moments remain roughly constant below 60 K, consistent with the temperature dependence of XMCD in scattering. The ratio $m_L/m_{S,eff}$ for Co remains around 0.3, but a slight decrease appears to occur within the multiferroic conical phase at low temperatures.

The same data were taken under a magnetic field of 6.8 T, applied parallel to the beam. The results of sum rules

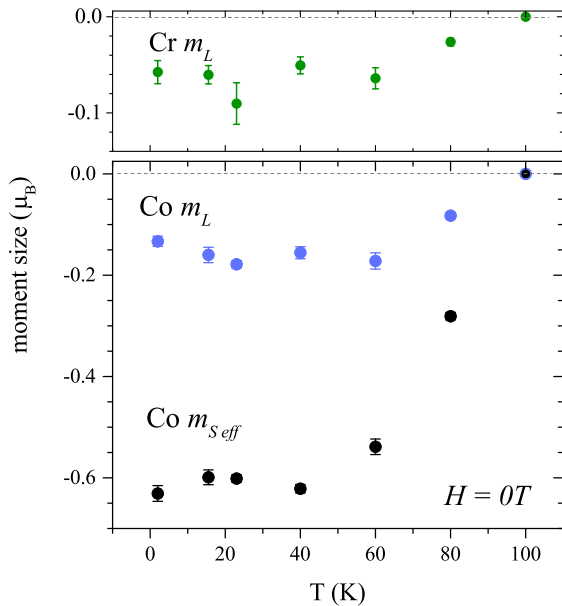

FIG. 11. Average effective spin and orbital moments ($m_{S,eff}$ and m_L) at various temperatures, in zero field. The vertical axis is corrected for a factor of $\cos 30^\circ$, to account for the angle between the beam and the [001] magnetic easy axis.

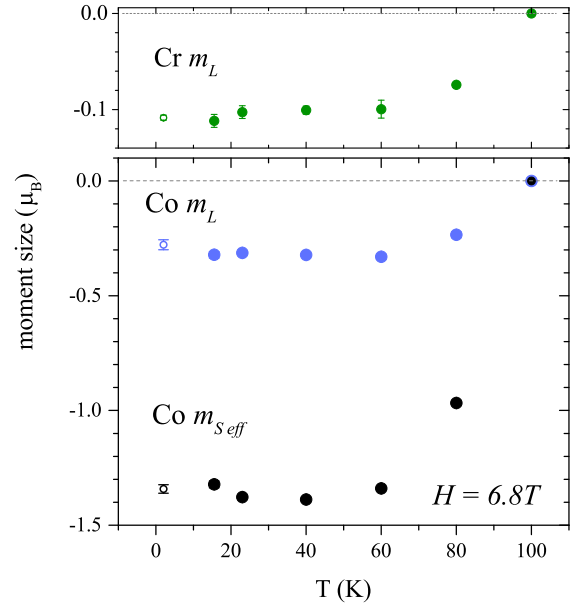

FIG. 12. Average effective spin and orbital moments ($m_{S,eff}$ and m_L) at various temperatures, under 6.8 T applied along the beam direction. The data points at 2 K were taken under 6 T, and are therefore shown as open circles.

analysis of these data are presented in Fig. 12. In this case it is unclear if the moments are still fully along the [001] or along the field direction, so the $\cos 30^\circ$ correction was not applied in this figure (note also that the 2 K data set was taken at 6 T, not 6.8 T). Nevertheless, the moments grow by over 100%. As before, the moments appear mostly saturated below 60 K, and the ratio $m_L/m_{S,eff}$ for Co remains approximately 0.26.

Due to the high coercivity observed in magnetization measurements, XMCD contrast was also collected as a function of magnetic field at the Co and Cr L_3 edges. This allows disentangling the contribution to the hysteresis curve of magnetization from the Co and the Cr ions. For every applied field, a measurement was taken at the L_3 edge (576.3 and 778.9 eV) for both incoming circular polarizations. Measurements were also taken off resonance at an energy well below the edge (574 and 776 eV), to correctly extract μ from Eq. (2). The Co and Cr data are presented on the same scale. As before, the beam was at a 30° angle with respect to the [001] axis, and 60° from [110]. No correction was made to account for the 30° incidence, because from these data one cannot distinguish whether the magnetization rotates or not. From the results in Figs. 12(a)–12(e) it appears that the sign of hysteresis for the Co and the Cr signals is reversed, and they appear to exhibit the same coercive field.

The lower row of panels in Fig. 13 presents hysteresis curves of magnetization taken with the MPMS device at selected temperatures, as previously described. A linear term has been removed from all magnetization data above 6 T (approximately the saturation field at the lowest measured temperature). This term can arise both from impurities in the substrate, as well as from nonhysteretic contributions to magnetization in the sample. The magnetization data exhibit a jump around 0 T. This cannot be reproduced by the sum of the XMCD data,

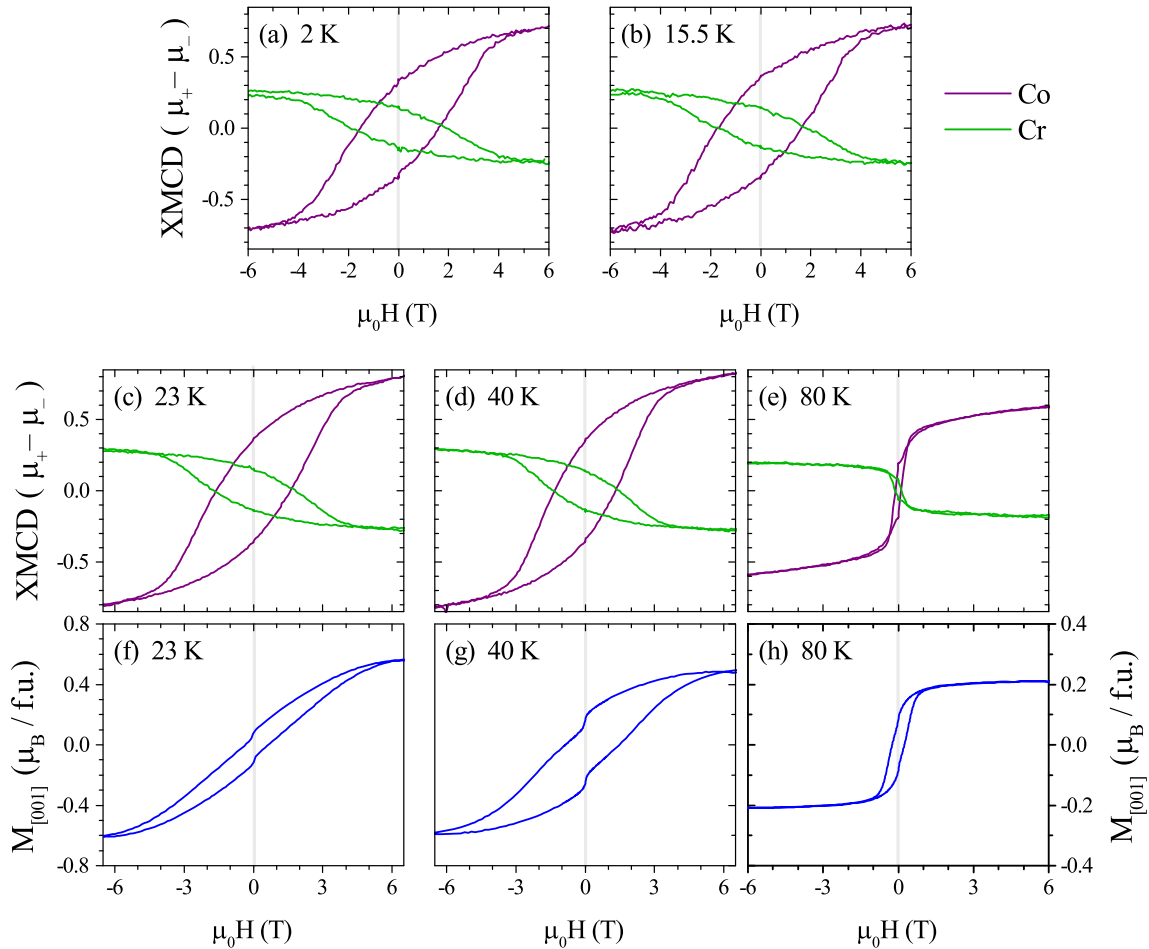

FIG. 13. Magnetic hysteresis of CCO. (a)–(e) XMCD as function of magnetic field measured with photons energies at the Co and the Cr L_3 edges (see main text). Data are shown for five different temperatures, and have been corrected using Eq. (2). All XMCD data are on the same scale. (f)–(h) Total magnetization as function of magnetic field, measured at a number of different temperatures. (f) has a vertical scale larger than that of (g) and (h), which have the same scale. Note that comparison between magnetization and XMCD is not straightforward because the magnetization was measured along [001], while XMCD was measured at an angle of 30° from the [001] axis.

because the Co and Cr signals exhibit the same coercive field. However such a comparison is only qualitative. The data from the two experiments cannot be directly compared, because the XMCD experiment was conducted at a 30° angle of incidence from the [001] axis, and magnetization measurements were taken along [001]. This also means that in the XMCD experiment the field component along [001] is weaker because it is applied along the beam direction. The discrepancy around 0 T could be explained by an unstrained fraction of the sample, which would have a low saturation field, as in bulk. This is possible because the magnetization measurement probes the whole sample, but the x-ray experiments probe only the volume beneath the $30 \times 220 \mu\text{m}^2$ beam.

D. Resonant soft x-ray diffraction

Resonant soft x-ray diffraction has been frequently employed in recent years to study antiferromagnetic structures of thin films [42,43], and particularly multiferroic films [44–46]. This is because the large resonant enhancement of magnetic diffraction even from very small sample volumes [47].

A signature of the low-temperature multiferroic phase in CCO is the appearance of a spiral component in the magnetic structure below $T_S = 27$ K. Combined with the high-temperature ferrimagnetic arrangement, this results in a conical magnetic structure [3]. The spiral is described by a magnetic wave vector of $\mathbf{Q} = (q q 0)$, with $q \approx 2/3$. We now aim to observe the spiral using RXD by fulfilling Bragg's law at the Co L_3 edge. This cannot be done at the Cr L edges, because they are too low in energy. Since the [110] direction is perpendicular to the sample surface, the same experimental conditions of the Sec. III B can be kept, except the incident angle is now changed to the Bragg angle $\theta = \sin^{-1}(hc|\mathbf{Q}|/2E)$, in which E is the incoming photon energy, h is Planck's constant, and c is the speed of light, and \mathbf{Q} is in units of rad \AA^{-1} . Scattering is now expected to arise solely from the second term in Eq. (1). Summing up all individual contributions from moments in the magnetic super cell, one can write the magnetic structure factor as

$$F_{E_1E_1}(\Psi) \propto (\hat{\varepsilon}'^* \times \hat{\varepsilon}) \cdot \sum_i \hat{m}_i(\Psi) e^{2\pi i \mathbf{Q} \cdot \mathbf{r}_i}, \quad (3)$$

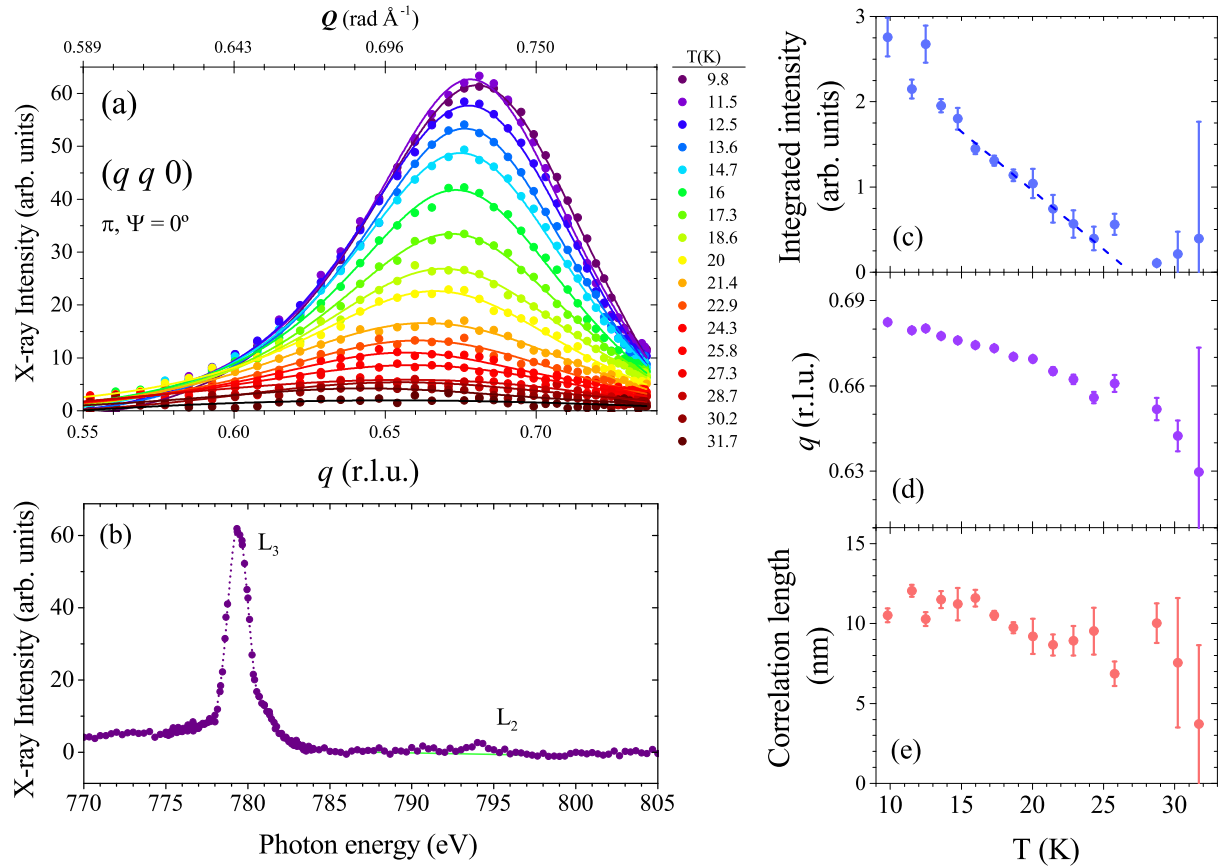

FIG. 14. Temperature dependence of the $(q q 0)$ reflection from a $[110]$ -oriented CoCr_2O_4 film. (a) Data taken upon warming, using incoming π polarized linear light with an energy of 779.2 eV ($\text{Co } L_3$) with the sample at an azimuth of $\Psi = 0^\circ$ ($[001]$ axis in the scattering plane). Lines are best fits of the data to Voigt profiles. Scans were conducted along the $[110]$ (specular) direction, so the horizontal axis is the corresponding q value in $(q q 0)$. The upper horizontal axis presents the actual magnitude of the momentum transfer Q . (b) Energy dependence of the integrated intensity of the $(q q 0)$ reflection, taken using incoming π polarized linear light with the sample at 10 K and at an azimuth of $\Psi = 0^\circ$. (c), (d), and (e) The temperature dependence of the integrated intensity, the modulation parameter q , and the correlation length, respectively. The lines in (b) and (c) are guides for the eye.

in which r_i is the position of the ion carrying moment \hat{m}_i . Ψ is the azimuthal angle [see Fig. 2(a)], which is defined as 0° when $[001]$ is in the scattering plane.

Figure 14 presents the temperature dependence of scattered intensity from the $(q q 0)$ reflection at the $\text{Co } L_3$ edge, measured upon warming with the sample oriented such that the $[001]$ direction is in the scattering plane ($\Psi = 0^\circ$). The appearance of this reflection indicates that the film exhibits the low temperature (multiferroic) phase despite the high strain. Values of q in reciprocal lattice units (r.l.u.) are calculated using the lattice constants measured at room temperature and the size of the momentum transfer, shown in the top horizontal axis. The right-hand edge of the data is limited by the edge of accessible reciprocal space at this energy. The magnetic intensity continuously changes within the accessible temperature range, and disappears near the expected value of T_S . The energy dependence of this reflection is presented in Fig. 14(b). The simple energy profile that emerges suggests that most of the intensity is from a few dominant multiplet transitions around the $\text{Co } L_3$ edge.

Figure 14(c) presents the integrated intensity of the reflection, which continuously decays upon warming. Linear extrapolation of the curve suggests $T_S \approx 27$ K, as seen in

bulk [3]. Short range correlations are found also above this temperature. The modulation parameter q , presented in Fig. 14(d), changes in the range 0.63–0.69 r.l.u., which includes all previously reported q values: 0.63 [3], 0.67 [7], and $2/3$ [8]. Unlike other reports on bulk samples, here q does not lock-in to a constant value [7,8], so no indication of the first-order transition around 14.5 K is observed. The correlation length of the spiral, presented in Fig. 14(e) and calculated as $\zeta = 2/\text{FWHM}$ (FWHM indicates the full width at half maximum), does not change considerably throughout the measured temperature range, and remains at around 10–12 nm, approximately 3 times longer than in a single crystal [5]. For comparison, the correlation length calculated from the (220) structural reflection, measured at room temperature using 10.8 keV x rays, is 25 nm. The large range of q in Fig. 14(d) and the broad width of the reflection may indicate that the observed reflection overshadows weaker reflections, such as those which would indicate the existence of the 14.5 K transition. Lastly, no $(\delta \delta 0)$ -type reflections with $\delta = 1 - q$ have been observed at the Co or Cr edges, although these were predicted in Ref. [48].

To further study the spin structure, an azimuthal dependence of the $(q q 0)$ reflection was conducted at 10 K by rotating the sample by an angle Ψ around the $[110]$ axis. The azimuthal

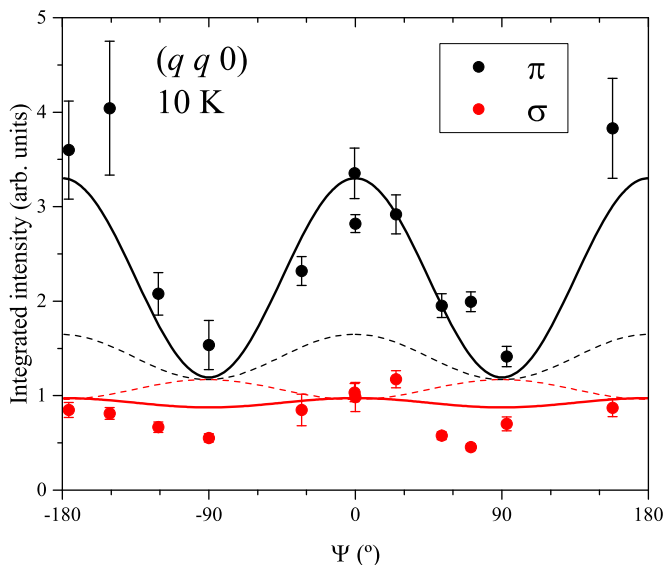

FIG. 15. Azimuthal dependence of the $(q q 0)$ reflection in CCO, measured at 10 K using incoming light with either σ or π linear polarization. Solid lines are calculations with a phase of $\pi/4$ between the Co sublattices. The dashed lines are a calculation with 0° phase, as in LKDM theory. Calculations assumed $q = 2/3$ and used Eq. (3) to calculate the structure factor.

dependence of the integrated intensity is presented in Fig. 15 for incoming π and σ linearly polarized light.

To describe the observed azimuthal dependence, we follow LKDM theory [4] as it successfully reproduces many observations. The theory describes the system as six magnetic fcc sublattices, numbered by $\nu = 1-6$. (two A fcc sublattices at the 8a diamond sites, four B fcc sublattices at the 16d pyrochlore sites). The i th moment in the sublattice is described [8] as

$$\mathbf{S}_{i\nu} = \sin\varphi[\hat{x}\cos(\boldsymbol{\tau}\cdot\mathbf{r}_{i\nu} + \gamma_\nu) + \hat{y}\sin(\boldsymbol{\tau}\cdot\mathbf{r}_{i\nu} + \gamma_\nu)] + \hat{z}\cos\varphi. \quad (4)$$

This represents a spiral in the ab plane, plus a constant moment along c . Here $\boldsymbol{\tau}$ is the ordering wave vector, $\mathbf{r}_{i\nu}$ is the position of the i th atom in sublattice number ν , γ_ν is the phase of the spiral on sublattice ν , and φ is half the opening angle of the cone (i.e., the canting angle away from the \hat{z} axis that the spiral causes). Since our data were taken at the Co L_3 edge, we calculate the expected azimuthal dependence from this magnetic motif by plugging only the two Co sublattices into Eq. (3). The results are presented as dashed lines in Fig. 15. Clearly this model does not agree with the measured data.

A possible reason for this discrepancy was recently suggested by Macke *et al.* [49], who demonstrated that dynamical diffraction effects can account for discrepancies between measured data and expected azimuthal dependences calculated in the kinematic limit. However, given that the present system is a thin film with a limited probed volume measured in specular geometry (implying that the azimuthal rotation does not affect the beam's path length in the sample), we believe this is not the case here.

To reconcile the LKDM model and the data, we find that only one parameter needs to be modified. LKDM theory [4]

defines that the two Co sublattices have the same γ_ν phase in their spiral components. The solid line in Fig. 15 represents a calculation for the same model, but with a phase of $\pi/4$ between the two Co sublattices. A reasonable agreement with experimental data is reached, and we conclude that the spiral state is not entirely the same as in the bulk picture presented by LKDM theory. A possible explanation for the change can be the temperature (10 K), which is below the anomalous ~ 14.5 K magnetic transition. This transition is known to affect the magnetic structure, and is not described by LKDM theory.

IV. DISCUSSION

The interest in CCO is mainly due to the macroscopically observed \mathbf{M} and \mathbf{P} , and the strong magnetoelectric coupling between the different magnetic sublattices. Our results provide important details about the magnetic behavior of the Co and the Cr sublattices. Even though the focus of our study is on a strained film and not bulk CCO, much of the behavior is qualitatively similar to bulk. For example, the T_S value is at the exact temperature as in bulk, and T_N is a few Kelvin lower than bulk.

The XMCD results describe the behavior of the Co and Cr ions' average uncompensated moment. They exhibit the exact same coercive field at all temperatures, indicating that these sublattices are closely coupled to each other. Indeed the exchange coupling between them (j_{AB}) is understood to be either the strongest, or among the strongest interactions in CCO [50]. On the other hand, we observe opposite behaviors at the two edges: they exhibit opposite XMCD contrast as function of magnetic field (both in the sign of their hysteresis curves and in field cooling), and they have opposite signs of their spin moment (for Co^{2+} the m_L and $m_{S,\text{eff}}$ have the same sign, for Cr^{3+} they are opposite). This is in agreement with the expected antiferro-type coupling between Co and Cr.

We must emphasize here that while XMCD is element selective, it does not directly distinguish between different magnetic sublattices of the same ion species. According to LKDM theory, CCO possesses six magnetic sublattices (two of Co ions, four of Cr). This means that values obtained for either ion species represents an average over the magnetic sublattices of that species.

The shape and opposite sign of the temperature dependences of XMCD for Co and Cr can explain the temperature dependence of macroscopic magnetization in CCO. Our data are in particularly good agreement with the simple model of Ref. [13], in which the two sublattices are described by modified Brillouin functions. This model estimated a coupling constant of -18 K (-1.5 meV), which is in reasonable agreement with the calculated j_{AB} values of ~ -3.5 to ~ -4.4 meV in Refs. [50] and [48]. Given that the Co ions order at $T_C \approx 94$ K, the model also predicted ordering of the Cr ions at 49 K, in agreement with T_{kink} . However, this model requires the Co sublattice to order at T_C for *any* magnetization to appear. Once magnetization of the Co sublattice exists, the model works because the Co couples to Cr. This is in contrast to the prediction that j_{AA} (Co-Co coupling) is weaker than j_{AB} and j_{BB} .

LKDM theory is a more reliable foundation to describe CCO, as it successfully reproduces many observations of

AB_2O_4 magnetic spinels. Unfortunately, this model does not correctly describe the azimuthal dependence of the $(q\ q\ 0)$ reflection. For it to do so, a modification in the relation between the Co sublattices is required: a phase of $\pi/4$ between their γ_ν values must be introduced. This may be due to the strained state of the system. It may also underline the main shortcoming of LKDM theory, namely that it does not take into account the A - A (Co-Co) interaction. This disagreement with theory can also be the case for bulk CCO, and not due to strain. Indeed even for bulk CCO, a stability parameter value of $u = 2$ is required to reproduce the experimental results, which is outside of the expected tolerance range [9]. In addition to LKDM theory, new computational studies have been conducted on CCO, using both LSDA+ U [50] and Monte Carlo simulations [51]. First-principles calculations aimed at studying the introduction of Fe ions into CCO were also conducted [48]. The magnetic interactions, as well as the magnetic ordering wave vector, were found to be directly connected to the magnitude of polarization. Most important was the finding that the effect of changing the magnitudes of the intrasublattice couplings j_{BB} and j_{AA} are not negligible compared to the intersublattice coupling j_{AB} . This agrees with the observation that XMCD signals of Co and Cr appear at the same ordering temperature T_C , and that they exhibit the exact same coercive field at all temperatures.

The second major point in our study is the effect of strain on the system. Already from LKDM theory, the parameter u was defined to quantify the level of distortion in the system. It was argued that by altering exchange paths, the Néel state destabilizes. Clearly the same idea applies for strain. Based on the notion that the u parameter controls the ground state, one can intuitively realize that since u depends linearly on exchange terms, strain will alter it by varying the bond lengths (and thus changing exchange paths).

Our film was grown along [110], a direction which keeps both macroscopic observables in-plane. This allows applying strain directly along these directions. The first observation in relation to strain is that the multiferroic conical phase is still present (indicated by the appearance of the Co magnetic spiral), and its onset temperature remains $T_S = 27$ K, as in bulk. In our case the $[1\bar{1}0]$ direction of P remained virtually unstrained (0.02% compressive). Since the spin spiral and P are linked to the same transition, this may explain why the spiral appears unaffected by strain.

The second observation in the context of strain is that the coercive field grows by 2 orders of magnitude compared to bulk. This is already implied by the nonzero α term in the spin rotation energy (a consequence of a lowering of crystal symmetry from cubic), as it predicts a deepening of the energy landscape. Furthermore, it is reasonable to assume that strain along a principal axis will affect the anisotropy of octahedral sites (Cr). The effect of strain on the tetrahedral sites (Co) is discussed in more detail in Ref. [17]. The sum rules analysis of the XMCD data indicates a large Co^{2+} orbital moment (m_L). This suggests a strong magnetic anisotropy at the ionic level. The Co^{2+} m_L moment is not only much larger than the Cr^{3+} m_L , is it also $\sim 30\%$ of the Co^{2+} effective spin moment. Unfortunately, no literature data are available to compare to these to bulk values, so a relation between these results and the enlarged coercivity is not directly proven here.

The possibility of an exchange bias in the system is suggested by the scattering XMCD data. This is not supported by other data sets, and is not clearly observed in the hysteresis curves of magnetization. Also, the less-understood features of magnetization in bulk do not appear in our strained sample. The T_L transition is notably absent in RXD, and no clear lock-in of q is observed. Strain has recently been shown to alter the lock-in transition of magnetic order in other multiferroic films [45]. Nevertheless, the observed order produces a broad diffraction peak due to its short correlation length. If this phase is only at the surface of the sample, other behaviors may be buried below, but their signal is masked by the broad signal observed.

No evidence of T_{kink} is observed either (both in RXD and in XMCD), indicating that it is perhaps absent due to the strained state of our lattice. This is noteworthy because this feature is expected to relate to the Cr-Cr interaction. Such B - B interactions were understood as the main driving force behind the frustration that destabilizes the Néel state. However, the Néel state is indeed destabilized, evidenced by the appearance of the Co spiral, as in bulk. This discrepancy may be due to LKDM theory's inaccurate description of CCO. Alternatively, the Co and Cr ions may depend differently on strain directions.

Many of the present findings cannot be directly compared to bulk CCO values because of the absence of soft x-ray studies in literature. Literature on XMCD and sum rules analysis on bulk CCO would be of value, as would linear dichroism experiments. These would provide insight on the ions' local environments and on variations between differently strained states. The RXD literature on bulk CCO does not describe the azimuthal dependence of $(q\ q\ 0)$, so one cannot conclude that the disagreement with theory is a result of strain.

V. SUMMARY

Using resonant soft x-ray techniques, we observed the magnetic behavior of a strained [110]-oriented film of $CoCr_2O_4$. We used XMCD in scattering and in transmission modes to separately follow the magnetic moments of the Co and Cr ions as functions of temperature and magnetic field. Transmission measurements were facilitated by x-ray excited optical luminescence from the substrate, which allowed us to apply sum rules analysis. Resonant soft x-ray diffraction was used to follow the conical order in the multiferroic phase.

Many of the observed behaviors are close to bulk behavior, even though the system is strained. For example, the sign of the effective spin moments ($m_{S,\text{eff}}$) of Co^{2+} and Cr^{3+} is opposite, as expected to occur also in bulk. The XMCD signal of the two sublattices is always of opposite sign. The temperature dependence of XMCD from the two sublattices is qualitatively different, also as predicted for bulk.

Two major effects of strain are observed: the first is that the coercive magnetic field is 2 orders of magnitude higher than in bulk. This is well described by a quadratic term (α) in the spin rotation energy, which appears due to symmetry lowering. Sum rules analysis of the XMCD data indicates a large Co^{2+} orbital moment (m_L), which suggests a strong single-ion magnetic anisotropy. The second observation is that the conical magnetic structure appears at the same T_S temperature as in bulk, demonstrating that the low temperature

phase is not suppressed by the strain. This order is strongly coupled to the electric polarization, so its appearance is a strong indication that this phase is multiferroic despite the applied strain. The conical order differs from bulk because the lock-in transition at $T_L \approx 14.5$ K is not observed, and because the azimuthal dependence of the $(q\ q\ 0)$ reflection cannot be described by LKDM theory. The azimuthal dependence of $(q\ q\ 0)$ can be described by slightly modifying the Co spin motif in the LKDM model.

The present work serves to underline the prospect of manipulating ferrimagnetic multiferroics using strain. We have demonstrated that the high degree of magnetic frustration can be manipulated to alter the functionality of M . It remains to be seen whether or not P can be manipulated in a similar

fashion, because measurements of P in CCO films have not been reported to date.
