Hydrated ZrO$_2$ thin films were prepared by reactive sputtering using H$_2$O gas, and these films were heat treated in air at temperatures from 100 to 350 °C. Absorbance peaks due to hydrogen-bonded OH groups for these samples were observed by Fourier transform infrared spectroscopy. The peak intensities were nearly the same before and after heat treatment below 200 °C, but began to decrease at 250 °C, and the absorption peak disappeared at 350 °C. Ion conductivity of the films was evaluated by AC impedance measurements and was found to be about $3 \times 10^{-6}$ S/m before and after heat treatment at 200 °C; it also decreased after heat treatment above 250 °C. From these results, we considered that protons of OH and/or H$_2$O in the films are the dominant ionic species that contribute to the ion conductivity of the films.
1. Introduction

Zirconium oxide (ZrO\textsubscript{2}) thin films have been applied in wide-ranging fields of optical and electronic industries, because ZrO\textsubscript{2} is a technologically important material with a high melting point (2670 °C),\textsuperscript{1)} excellent thermal stability, high refractive index, and low optical absorption in a broad wavelength region from near-UV (above 240 nm) to mid-IR (below 8 µm).\textsuperscript{2)} ZrO\textsubscript{2} thin films have been prepared by electron beam evaporation,\textsuperscript{3,4)} pulse laser deposition,\textsuperscript{5)} ion-assisted deposition,\textsuperscript{6)} sol-gel processing,\textsuperscript{7,8)} metal-organic chemical vapor deposition,\textsuperscript{9)} and sputtering.\textsuperscript{10,11)} In recent years, sputtering techniques have been widely used to fabricate thin films, because it is superior in its ability to form large-area films with high productivity, and it is easy to control the stoichiometry of the deposited films.\textsuperscript{12)}

Ion conductivities of hydrated ZrO\textsubscript{2} have been investigated, and England \textit{et al.}\textsuperscript{13)} reported an ion conductivity of $2 \times 10^{-5}$ S/cm at room temperature for ZrO\textsubscript{2}\cdot1.75H\textsubscript{2}O powder prepared by a sol-gel technique. Kim \textit{et al.}\textsuperscript{14)} reported a room-temperature ion conductivity of $1.67 \times 10^{-6}$ S/cm for ZrO\textsubscript{2}\cdotH\textsubscript{x} thin films with x = 1.70, deposited by reactive sputtering in Ar + H\textsubscript{2} + O\textsubscript{2} atmosphere. Furthermore, ZrO\textsubscript{2} solid electrolyte thin films have been successfully applied to all-solid-state electrochromic devices\textsuperscript{14-15)} and switchable mirrors.\textsuperscript{16-17)} In consideration of the merits of the sputtering method and safety from the explosion of hydrogen gas, as reported in a previous paper,\textsuperscript{18)} we prepared hydrated Ta\textsubscript{2}O\textsubscript{5} thin films by reactive sputtering in H\textsubscript{2}O atmosphere. In order to confirm the feasibility of this method for the formation of other hydrated oxide films, hydrated ZrO\textsubscript{2} thin films were prepared in this study. We also examined the effect of heat treatment on the ion conducting characteristics of the films to confirm the proton
2. Experimental Procedure

Hydrated ZrO$_2$ films with thicknesses of 100 nm and 1 µm were prepared by reactive RF magnetron sputtering. A 2-inch-diameter disk of the Zr target (99.9% purity) was sputtered in H$_2$O and D$_2$O gases. The sputtering gas pressure, sputtering power, and substrate temperature were maintained at 6.7 Pa, 50 W, and 10°C, respectively. These films were heat treated at temperatures from 100 to 350 °C in air atmosphere for 2 hours. Indium tin oxide (ITO)-coated glass and Si were used as substrates. Refractive index, density, crystal structure, chemical structure, and surface morphology of the deposited films were characterized by ellipsometry, X-ray reflectivity (XRR), X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR), and atomic force microscopy (AFM), respectively. The plasma state during sputtering was characterized by plasma emission spectroscopy. Ion conductivity was measured for the sample with the Au/ZrO$_2$/ITO structure shown in Fig. 1(a) by AC impedance measurements at frequencies from 10 mHz to 1 MHz at room temperature in air. The conductivity of the thin films was estimated by assuming the equivalent circuit shown in Fig. 1(b), where $R_s$ is the resistance of the ITO electrode, $R_p$ is the ionic resistance of the ZrO$_2$ film, $C_d$ is the double-layer capacitance, and $C_p$ is the capacitance of the ZrO$_2$ film. A Au film was deposited by vacuum evaporation on the ZrO$_2$ films as a top electrode, and ITO was used as a bottom electrode. The ZrO$_2$ films were removed from the sputtering chamber and kept in a desiccator before measurements.
Figure 2 shows the plasma emission spectra obtained during sputtering in H\textsubscript{2}O gas. Emission peaks due to OH radicals, O\textsuperscript{2+} ions, H and O atoms are clearly observed\textsuperscript{19-20).} H atoms and OH radicals are considered to be formed by the dissociation of H\textsubscript{2}O molecules in the plasma. These active species are expected to be incorporated into the films, and hydrated ZrO\textsubscript{2} thin films are expected to be formed in the atmosphere of H\textsubscript{2}O gas.

XRD patterns of the films with a thickness of 1 µm deposited on Si substrates are shown in Fig. 3, and peaks due to monoclinic-ZrO\textsubscript{2}\textsuperscript{21)} are observed. Although these peaks are broad and weak, no other crystalline phases are found to be formed. These peaks slightly shift to a higher angle with increasing heat treatment temperature, which indicates the decrease of the lattice constant. It is known that monoclinic-ZrO\textsubscript{2} is formed above 650 °C\textsuperscript{1)}, however, monoclinic-ZrO\textsubscript{2} films were formed at a substrate temperature of 10 °C in this study. The nonequilibrium formation process by the deposition of high-energy sputtered particles is thought to be the reason for the formation of the monoclinic-ZrO\textsubscript{2} films.

AFM is used to study the surface topography of the films before and after heat treatment. The root mean square roughness was 2.9–3.5 nm and no marked change was observed after heat treatment up to 350 °C.

FTIR spectra of the films before and after heat treatment at different temperatures are shown in Fig. 4. As shown in Fig. 4(a), the films deposited in H\textsubscript{2}O atmosphere have absorption peaks at approximately 740 cm\textsuperscript{-1} corresponding to Zr-O groups\textsuperscript{22,23)}, which indicates the formation of ZrO\textsubscript{2}. The absorption peaks due to hydrogen-bonded OH
groups$^{24}$ are clearly seen in the region of 2800–3700 cm$^{-1}$ for the films before and after heat treatment below 300 °C. The peak intensity decreases slightly at 250°C, and disappears completely at 350 °C. Figure 4(b) shows FTIR spectra of the films prepared in D$_2$O atmosphere. The wave-number region is changed to 1000–7000 cm$^{-1}$ in this figure to clearly indicate the OH and OD peaks and the influence of interference. The absorption peaks due to hydrogen-bonded OD groups$^{25}$ are observed in the region of 2000–2600 cm$^{-1}$. This clearly indicates that water molecules were introduced into the film during the reactive sputtering process. However, the intensity of the absorption peaks due to OD groups decreased gradually, and the peaks due to OH groups increased when the films were kept in air. It is thought that the exchange of D$_2$O molecules in the film and H$_2$O molecules in air progresses even at room temperature. With increasing heat treatment temperature, the absorption peaks due to OD groups decreased greatly. The absorption peaks due to OH groups increased abruptly after heat treatment at 100 °C and then decreased slightly with the increase of heat treatment temperature. The increase in the intensity of the peak due to OH groups indicates that a large part of OH and/or H$_2$O in the films originate from H$_2$O molecules in ambient atmosphere.

We estimated the molar concentration of water in the films using Lambert-Beer’s law,

$$A = \log \left( \frac{1}{T} \right) = \varepsilon c d ,$$

where $A$, $T$, $\varepsilon$, $c$, and $d$ represent the absorbance, transmittance, molar absorption coefficient, molar concentration of the medium, and thickness, respectively. The molar absorption coefficient of water in the films was assumed to be the same as that of pure water, $\varepsilon = 93.7 \text{ l/(mol} \cdot \text{cm})$, which is calculated from
where \( k \) and \( \lambda \) are the extinction coefficient of water (0.2804 at 3404 cm\(^{-1}\))\(^{26}\) and wavelength, respectively. The molar concentration of pure water is 55.5 mol/l.

Film density estimated from the XRR measurement is shown in Fig. 5. The film density becomes higher with increasing heat treatment temperature, however, it is still lower than the bulk value of 5.85 g/cm\(^3\) for monoclinic-ZrO\(_2\).\(^{1)}\) Figure 6 shows the change in the refractive index after heat treatment measured with an ellipsometer at a wavelength of 633 nm. The refractive index increases from 1.90 to 1.92 with the increase of heat treatment temperature, and the values are small compared with the value of 2.15 for bulk monoclinic-ZrO\(_2\).\(^{1)}\) The low refractive index corresponds to the low film density.

From the results above, it is thought that the low film density of the ZrO\(_2\) films is due to the introduction of H\(_2\)O molecules into and/or between ZrO\(_2\) grains and the porous structure of the film. Therefore, we assumed the film density \( \rho_{\text{film}} \) to be given by

\[
\rho_{\text{film}} = q_{\text{ZrO}_2} \rho_{\text{ZrO}_2} + q_{\text{H}_2\text{O}} \rho_{\text{H}_2\text{O}} + q_{\text{void}} \rho_{\text{void}},
\]

where \( \rho_{\text{ZrO}_2} \) is the density of bulk monoclinic-ZrO\(_2\) (5.85 g/cm\(^3\)) and \( \rho_{\text{H}_2\text{O}} \) is the density of water (0.997 g/cm\(^3\) at 25 °C), and \( q_{\text{ZrO}_2} \), \( q_{\text{H}_2\text{O}} \), and \( q_{\text{void}} \) are the volume fractions of bulk ZrO\(_2\), H\(_2\)O, and voids, respectively. \( q_{\text{H}_2\text{O}} \) is calculated from eq. (1). The density of voids \( \rho_{\text{void}} \) is ignored (\( \rho_{\text{void}} = 0 \)), and the sum of the volume fractions is assumed to be unity (\( q_{\text{ZrO}_2} + q_{\text{H}_2\text{O}} + q_{\text{void}} = 1 \)). The refractive index of the film \( n_{\text{film}} \) is
also assumed to be given by the following equation (Drude theory): 
\[ n_{\text{film}}^2 - 1 = q_{\text{ZrO}_2} \left( n_{\text{ZrO}_2}^2 - 1 \right) + q_{\text{H}_2\text{O}} \left( n_{\text{H}_2\text{O}}^2 - 1 \right) + q_{\text{void}} \left( n_{\text{void}}^2 - 1 \right), \]  
(4)

where \( n_{\text{ZrO}_2} \), \( n_{\text{H}_2\text{O}} \), and \( n_{\text{void}} \) represent refractive indexes of \( \text{ZrO}_2 \), \( \text{H}_2\text{O} \), and voids, respectively. The values of \( n_{\text{ZrO}_2} \), \( n_{\text{H}_2\text{O}} \), and \( n_{\text{void}} \) are assumed to be 2.15, 1.33, and 0, respectively. The results of the volume fractions are shown in Fig. 7. Although the volume fractions calculated from the density and refractive index differ slightly, it is clearly seen that the volume fractions of monoclinic-\( \text{ZrO}_2 \) and void increase slightly with increasing heat treatment temperature owing to the loss of \( \text{H}_2\text{O} \) molecules. From the volume fractions of \( \text{ZrO}_2 \) and \( \text{H}_2\text{O} \), molar ratio \( n \) of \( \text{H}_2\text{O} \) in the \( \text{ZrO}_2 \cdot n\text{H}_2\text{O} \) film was estimated to be approximately 0.2 for the as-deposited film.

Cole-Cole plots of complex impedance (R and X are the real and imaginary parts of complex impedance, respectively) are shown in Fig. 8. The resistances \( R_p \) due to ion conduction are obtained from the diameters of the semicircles in the Cole-Cole plots. \(^{28}\) The resistances of the films before and after heat treatment at 100–200 °C were in the order of \( 10^4 \) Ω; however, they began to increase after heat treatment at 250 °C. The ionic conductivity of the films \( \sigma_i \) was calculated using

\[ \sigma_i = \frac{d}{R_p S}, \]  
(5)

where \( d \), \( R_p \), and \( S \) are the film thickness, the film resistance estimated from the Cole-Cole plots, and the area of the electrodes, respectively. Figure 9 shows the change in the ion conductivity of the films before and after heat treatment. High ion conductivity of \( 3 \times 10^{-6} \) S/m was obtained for the as-deposited \( \text{ZrO}_2 \) films. The lower conductivity compared with those of \( \text{ZrO}_2 \cdot 1.75\text{H}_2\text{O} \) powders \(^{13}\) and \( \text{ZrO}_2 \cdot \text{H}_{1.70} \) thin
films\textsuperscript{14} are thought to be caused by the lower H\textsubscript{2}O content in our films, as described above. The ion conductivity was maintained high even after heat treatment at 200 °C, however, it began to decrease after heat treatment above 250 °C. Even though some of H\textsubscript{2}O molecules are desorbed from the film during heat treatment, H\textsubscript{2}O molecules are absorbed by the films again at room temperature, owing to the low film density and porous structure of the ZrO\textsubscript{2} films. This result indicates that protons in the hydrated ZrO\textsubscript{2} films contribute to the ion conduction. The ion conductivity of the ZrO\textsubscript{2} films is similar to that (4 × 10\textsuperscript{-6} S/m) of the Ta\textsubscript{2}O\textsubscript{5} films reported in our previous paper\textsuperscript{18} and the ion conductivity of the ZrO\textsubscript{2} films remains high after heat treatment at higher temperatures than that of the Ta\textsubscript{2}O\textsubscript{5} films. These results suggest that the hydrated ZrO\textsubscript{2} films are a promising candidate for solid electrolyte thin films.

4. Conclusions
Hydrated ZrO\textsubscript{2} thin films were fabricated by reactive sputtering using H\textsubscript{2}O gas, and ion conductivity of 3 × 10\textsuperscript{-6} S/m was obtained for the as-deposited film. It was indicated that protons in the hydrated ZrO\textsubscript{2} films contribute to the ion conduction, and the ion conductivity was confirmed to be stable after heat treatment up to 200 °C. Because of these results, the hydrated ZrO\textsubscript{2} film is considered to be a promising candidate for proton-conducting solid electrolyte thin films.
