#### Abstract

Relativistic basis sets of double-zeta, triplezeta, and quadruple-zeta quality have been optimized for the lanthanide elements La-Lu. The basis sets include SCF exponents for the occupied spinors and for the $6 p$ shell, exponents of correlating functions for the valence shells ( $4 \mathrm{f}, 5 \mathrm{~d}$ and 6 s ) and the outer core shells ( $4 \mathrm{~d}, 5 \mathrm{~s}$ and 5 p ), and diffuse functions, including functions for dipole polarization of the 4 f shell. A finite nuclear size was used in all optimizations. The basis sets are illustrated by calculations on YbF . Prescriptions are given for constructing contracted basis sets. The basis sets are available as an internet archive and from the Dirac program web site, http://dirac.chem.sdu.dk.

Electronic supplementary material The online version of this article (doi:10.1007/s00214-009-0725-7) contains supplementary material, which is available to authorized users.

## 1 Introduction

The increasing use of all-electron four-component methodology for relativistic effects in molecular structure calculations brings with it a need for high-quality basis sets. Several other authors have generated basis sets at the SCF level for part or all of the periodic table, either with the Dirac Hamiltonian or with the Douglas-Kroll-Hess Hamiltonian [1-19]. While some of these basis sets include correlating functions, a number of them lack the functions needed for valence and outer core correlation and polarization of the SCF sets. In a series of papers [20-27], Dyall has focused on providing consistent basis sets of doublezeta (dz), triple-zeta (tz), and quadruple-zeta (qz) quality for the heavy elements, including correlating functions for the valence and outer core orbitals in the style of the correlation consistent basis sets [28-31]. So far these basis sets have covered the $4 \mathrm{~s}, 5 \mathrm{~s}, 6 \mathrm{~s}$, and 7 s blocks; the $4 \mathrm{p}, 5 \mathrm{p}$, and 6 p blocks; the 4 d and 5d transition series; and the actinides. This paper continues the series by presenting basis sets for the lanthanides. Work is in progress on the 3 d and 6 d transition series and the 7 p block.

The lanthanides have similar challenges to the actinides, but also have some unique features, as far as basis sets are concerned. As for the actinides, the 5d orbital is occupied for several members of the series ( $\mathrm{La}, \mathrm{Ce}, \mathrm{Gd}$, and Lu ), and is low-lying for many of the early members of the series. It is in fact doubly occupied in some excited states early in the series. It must therefore be included in the basis set
optimization. The $6 p$ orbital is not occupied, but is needed for polarization of the 5 d and 6 s orbitals. However, unlike the actinides, this orbital must be doubly occupied in the exponent optimization to prevent it from becoming too tight and thus not serve its purpose as a polarization orbital. Correlation of the 5 s and 5 p shells is critical as it is for the actinides. Obviously, correlation of the 4 f is critical, but since the 4 f is the first shell of its symmetry, it does not have the orthogonality constraint that the 5 f has in the actinides, and so is much more compact relative to the other shells. This influences the extent to which the ranges of the correlating functions can overlap. Because of the compactness of the 4 f , correlation of the 4 d is also important.

## 2 SCF basis sets

The methods used for the SCF basis set optimization have been described previously [20, 22, 32, 33]. The basis sets were optimized in Dirac-Hartree-Fock calculations using the Dirac-Coulomb Hamiltonian with the standard Gaussian nuclear charge distribution [34] for the most abundant (or stable) isotope. As for previous basis sets in this series, $\ell$-optimization was employed. In the SCF optimizations, the exponents are varied only within a given angular space, i.e. for a given $\ell$ value, with all other exponents fixed. This is because the exponents in each angular space are to a large degree independent of those in the other angular spaces. The angular spaces are cycled through the optimization process until there is no significant change in the total energy and the gradient with respect to the logarithms of the exponents.

The electron configuration used for the basis set optimization was as follows. For the elements in which the 5d is occupied ( $\mathrm{La}, \mathrm{Ce}, \mathrm{Gd}, \mathrm{Lu}$ ), the ground configuration was used for all angular symmetries. For the remaining elements, the ground $4 \mathrm{f}^{n} 6 \mathrm{~s}^{2}$ configuration was used for all symmetries except d, where the $4 \mathrm{f}^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$ configuration was used. For the optimization of the $6 p$ function, the configuration in which $6 \mathrm{~s}^{2}$ was replaced with $6 \mathrm{p}^{2}$ in the ground configuration was used.

The size of the basis sets was determined for consistency with basis sets across the row, taking into account the basis set sizes of the $6 \mathrm{~s}, 6 \mathrm{p}$ and 5 d blocks, and for the quality of the representation of the outermost maxima. As a consequence of this consistency criterion, some revisions were deemed necessary for the 5d block: these revisions are described elsewhere [35].

The size of the dz basis set optimized for Ba [27] is 24 s 16 p 10 d , and the revised 5 d basis set size is 24 s 17 p 12 d 7 f [35]. The s set size was therefore chosen to be 24s. For the p set, the choices are 16 p or 17 p. Optimization of both 16 p
and 17 p sets across the lanthanide series revealed that the $16 p$ sets were too tight by the end of the block, so the larger 17 p sets were selected. Because the 5 d is more diffuse for the lanthanides than for the 5 d transition series, the d set size chosen for the lanthanides was 13d. These choices yielded a 24 s 17 p 13 d 7 f dz basis set. Two p functions were then added for the 6 p , and the outermost 9 functions were reoptimized. These functions describe the outermost maxima of the $3 p$ through 6p orbitals. The final SCF basis set size including the 6 p functions is 24 s 19 p 13 d 7 f .

For triple-zeta, the size of the basis set for Ba is 30 s 21 p 13 d , the revised 5 d set size is 30 s 21 p 15 d 10 f , and the $6 p$ set size is 30 s 26 p 16 d 10 f . The s and p set sizes were therefore taken to be 30 s and 21 p . As for the dz basis sets, an extra $d$ function was added for the lanthanides relative to the 5 d series because the 5 d is more diffuse in the lanthanides. These choices yielded a basis set size of 30s21p16d10f. Three p functions were added for the 6 p , and the outermost 12 exponents were reoptimized. The final SCF basis set size including the 6 p functions is 30 s 24 p 16 d 10 f .

For quadruple-zeta, the basis set size for Ba is 35 s 26 p 17 d , and the 5 d basis set size is 34 s 26 p 19 d 12 f , with 34 s 31 p 20 d 12 f for the 6 p series. After optimizing both a 34 s and a 35 s set, the 35 s set was chosen for the lanthanides. Addition of an extra $d$ function to make a 20 d set was found to yield 6 functions for the 5d. For reasonable balance, 5 functions are required, which was obtained with a 19 d set. For the p set, 4 functions were added to the 26 p set for the $6 p$, and the outermost 14 functions were reoptimized. The final SCF basis set size including the 6 p functions is 35 s 30 p 19 d 12 f .

Total energies for the ground configuration are given in Table 1. The basis sets used in these calculation include the $6 p$ set and the $f$ functions added for $5 d$ and $6 s$ correlation in the double-zeta and triple-zeta basis sets, as described below. The energies for the quadruple-zeta basis sets fall below the numerical energy, due to the phenomenon of "prolapse" in relativistic basis set calculations [3].

## 3 Correlating and dipole polarizing functions

Correlating functions for the $4 \mathrm{~d}, 4 \mathrm{f}, 5 \mathrm{~s}, 5 \mathrm{p}, 5 \mathrm{~d}$, and 6 s shells were optimized in MR-SDCI calculations, using the RAMCI program [33] modified for basis set optimization. All exponents are fully optimized. Exponents for the double-zeta basis sets are given in Table 2. Exponents for the triple-zeta basis sets are given in Tables 3, 4, 5, 6, 7. The f functions reported for 5 d 6 s correlation are the outermost SCF f function and the even-tempered extension. Exponents for the quadruple-zeta basis sets are given in Tables $8,9,10,11$. The procedure for the various shells is described below.

### 3.1 4f correlation

In the basis set optimizations for other blocks, including the $5 f$, it has been assumed that it is sufficient to add a single function with one unit higher in angular momentum to correlate the main shell for the dz basis set, then increase the maximum correlating angular momentum by one and add one function for each correlating angular momentum, going up the basis set series to tz and qz. Owing to the nodeless nature of the 4 f shell, this assumption was tested in a series of calculations. These tests assessed the effect of adding functions in a single symmetry ( $\mathrm{g}, \mathrm{h}, \mathrm{i}, \mathrm{k}$ ) in CI calculations involving double excitations from the 4 f shell into shells of
that symmetry. The tests showed that the 1 g and 2 g 1 h sets are fairly well balanced. The first i function has about the same energy gain as the fourth $g$ function and the third $h$ function, making 4 g 3 h 1 i fairly well balanced. The next well-balanced set is 5 g 4 h 3 i 2 k ( k was the highest angular momentum in the study). Balance between the symmetries is not the only consideration, however: it is also important to be able to extrapolate the basis sets smoothly within symmetries. It was considered that the additional $g$ and $h$ functions in the 4 g 3 h 1 i set might unduly perturb the series used for extrapolation. Therefore, a 3 g 2 h 1 i set was chosen for the qz basis set, and the scheme used for other basis sets is deemed appropriate for the 4 f shell.

For the 4 f shell the functions were optimized on the ground $\mathrm{f}^{n} \mathrm{~s}^{2}$ or $\mathrm{f}^{n-1} \mathrm{~d}^{1} \mathrm{~s}^{2}$ configuration. The configuration space included all double excitations from the 4 f shell into the correlating space, which consisted of 1 g for the doublezeta basis sets, 2 g 1 h for triple-zeta, and 3 g 2 h 1 i for qua-druple-zeta. Only configuration state functions (CSF) coupling to the ground state $J$ value were included in the optimization, mainly due to the large number of such CSF. Due to the number of CSF generated for elements in the middle of the block with the quadruple-zeta basis sets, it was necessary to perform separate CI calculations, splitting the correlating set into a 3 g set and a 2 h 1 i set. Since the

angular spaces are fairly well decoupled, this is not a serious approximation.

### 3.25 d and 6 s correlation

For the 5 d and 6 s shells, correlating functions were optimized on the $\mathrm{f}^{n-1} \mathrm{~d}^{1} \mathrm{~s}^{2}$ configuration. The configuration space included all double excitations from these two shells into the correlating space, which consisted of 1 f for the double-zeta basis sets, 2 f 1 g for triple-zeta, and 3 f 2 g 1 h for quadruple-zeta. For the double-zeta and triple-zeta sets, the

energy was averaged over all possible coupled angular momenta for the CSF. For the quadruple-zeta basis sets, the 4f shell was coupled to the highest possible angular momentum to reduce the number of configurations to a minimum, and the average taken over all possible couplings to this angular momentum. Since the $f$ shell is frozen in these optimizations, this approximation has little impact on the results.

Because the f functions have some overlap with the SCF functions, it is only necessary to add to the basis set those functions that are not already represented. For the doublezeta basis sets, the f function was added to the SCF f set. For the quadruple-zeta basis sets, the SCF set covers the range of the correlating $f$ functions, so the optimized
functions are not needed. The choice for the triple-zeta sets was more involved, and is discussed next.

As for the 5 f block, two minima were found for the outer d correlating 2 f 1 g functions in the triple-zeta basis sets: one in which the f functions were tighter and one in which the f functions were more diffuse. The $g$ functions in both sets were about the same. The tighter set exists for all elements except Pm; the looser set exists from Pm through Lu. It is likely that the orthogonalization to the 4 f influences the optimization. The exponents in both sets are only partly covered by the outer SCF f functions, but an even-tempered extension of one function serves to cover both the correlating f space and a reasonable representation of the dipole polarizing f space, so the even-tempered extension has been used to supplement the SCF f set instead.

### 3.35 s and 5 p correlation

Correlating functions for the 5 s and 5 p shells were optimized in MR-SDCI calculations on the ground configuration, for the state with the maximum $J$ value. Single and double excitations out of the 5 s and 5 p shells into the correlating space were coupled to $J=0$, to ensure that only configurations representing 5 s and 5 p correlation were included. The correlating space consisted of $1 d$ for the double-zeta basis sets, 2d1f for triple-zeta, and 3 d 2 f 1 g for quadruple-zeta. These optimizations are not strictly necessary for the dz and tz basis sets, because the range of correlating functions is covered by the SCF occupied set. However, they are a useful guide to the functions that need to be uncontracted. The d and f functions are not included in the final basis set.

For the qz basis sets, it is necessary to at least examine the $g$ function to see if it is covered by any of the other

correlating sets. It turns out that the the $g$ function has a fair overlap with the outer $g$ for $4 f$ correlation, but the gradient with $Z$ is quite different. A compromise must therefore be made in the selection to avoid linear dependence. Some of the options are to use the outer $g$ from the $4 f$ correlating set for the 5 s 5 p correlation, and to substitute the outer g from the 4 f correlating set with the g from the 5 s 5 p correlating set, with or without reoptimization of the other $g$ functions. All of these options result in a loss of correlation energy of a few millihartrees, so none of them is to be preferred. The final choice was to use the outer $g$ from the $4 f$ correlating set for the 5 s 5 p correlation.

### 3.44 d correlation

Correlating functions for the 4 d shell were optimized on the ground configuration for the state with the maximum $J$ value, with single and double excitations out of the 4d shell into the correlating space coupled to $J=0$. The correlating space consisted of 1 f for the double-zeta basis sets, 2 f 1 g for triple-zeta, and 3 f 2 g 1 h for quadruple-zeta. Again, the f functions are not strictly necessary and are not included in the basis set, but serve as a guide to the contraction pattern. The 4 d correlating set is needed for La , but for the other elements, 4 d correlation is

adequately covered by the SCF f functions and the 4 f correlating functions.

### 3.5 Dipole polarization

Functions for dipole polarization of the 4 f shell were determined as follows. For the double-zeta basis sets, a single $g$ function was determined for the $4 f$ dipole polarization by maximizing the polarizability calculated by second-order perturbation theory. The basis states for the perturbation theory consisted of the eigenfunctions of the Dirac Hamiltonian for the configurations generated by a single $\mathrm{f} \rightarrow \mathrm{g}$ excitation from the ground configuration. For the triple-zeta and quadruple-zeta basis sets, the exponents of the dipole polarization functions were determined by multiplying the outermost correlating exponent for each angular momentum by a factor obtained from the double-zeta results. This factor is the exponent of the double-zeta dipole polarizing $g$ function divided by the exponent of the double-zeta correlating $g$ function. In this way 1 g 1 h and g g1h1i sets for 4 f dipole polarization were generated for the triple-zeta and qua-druple-zeta basis sets.

For the 5 d dipole polarization, a single f function was determined for the dz basis sets in the same manner, using the eigenfunctions of the Dirac Hamiltonian for the configurations generated by a single $d \rightarrow f$ excitation from the $f^{n-1} d^{1} s^{2}$ configuration for the perturbation basis. The functions so generated for the dipole polarization were sufficiently similar to the correlating functions that it was not considered necessary to generate functions for the triple-zeta and quadruple-zeta basis sets.

Table 12 Configuration average total SCF energies in $E_{\mathrm{h}}$ for uncontracted basis set calculations on the weighted average of the configurations used for the contractions

## 4 Contraction patterns

Contraction coefficients for the occupied spinors, including the 5 d and 6 p , were taken from SCF calculations on a weighted average of the valence configurations, as follows:

- For $\mathrm{La}, \mathrm{Ce}, \mathrm{Gd}$, and Lu , where the 5 d is occupied in the ground state, the $4 \mathrm{f}^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$ and $4 \mathrm{f}^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{p}^{2}$ configurations were used with a $9: 1$ weight ratio ( $90 \%$ s, $10 \%$ p). Note that for La the 4 f is empty: this element is treated as a transition metal.
- For the rest $(\mathrm{Pr}-\mathrm{Eu}, \mathrm{Tb}-\mathrm{Yb})$, the $4 \mathrm{f}^{n} 6 \mathrm{~s}^{2}, 4 \mathrm{f}^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$, and $4 \mathrm{f}^{n-1} 6 \mathrm{p}^{1} 6 \mathrm{~s}^{2}$ configurations were used with a weight ratio of 6:3:1.

These ratios were chosen so that the primary configuration is not greatly perturbed by the inclusion of orbitals that are empty in the ground state, but still give a reasonable representation of these orbitals. Thus, a weight of $10 \%$ was chosen for $6 p$ configurations, and a $2: 1$ ratio was chosen for the $4 \mathrm{f}^{n} 6 \mathrm{~s}^{2}$ and $4 \mathrm{f}^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$ configurations. These choices are somewhat arbitrary. The higher weight of the $4 f^{n-1} 5 \mathrm{~d}^{1} 6 \mathrm{~s}^{2}$ configuration reflects the greater importance of the 5 d than the 6 p .

The f functions that were added for 5 d and 6 s correlation have been included in the SCF set, and therefore in the contraction calculations. References to the SCF set include these functions.

The total energies for the weighted average used for generating the basis sets are given in Table 12.

To determine which primitive functions should be uncontracted, a sequence of MR-SDCI calculations was
performed on several of the elements across the row, in which different primitive functions were included in the correlating space. For each basis set size, the appropriate number of primitive functions was used in the MRCI calculations. For example, for 5 s 5 p correlation in the triplezeta basis sets, the correlating set was 2 s 2 p 2 d 1 f . Excitations into the 4 f shell were not considered in these calculations. The large and small component coefficients of these correlating functions were determined by diagonalizing the Fock matrix in the space that consists of the DHF occupied spinors used as contracted functions and the additional primitive functions that are to be used for correlation. The virtual functions from this diagonalization were then orthogonalized to the original DHF occupied functions, to ensure strict orthogonality. (This procedure also allows the elimination of any linearly dependent functions, but no linear dependence was observed in this work.)

The contraction pattern is described first for the outer valence shells, then the additional functions required for the inner valence are described, and finally the functions for correlation of the 4 d . To any of these contractions, the relevant polarization functions listed in Tables 2, 7 and 11 can be added. In the descriptions, functions are counted by increasing exponent size, from the smallest. In cases where linear dependence might be a problem, alternative prescriptions are given.

### 4.1 Double-zeta basis sets

- Outer valence $5 d / 6 s / 6 p$ To the SCF functions, add the second $s$ primitive, the second $p$ primitive, the first $d$ primitive, and the first f primitive (the $5 \mathrm{~d} / 6$ s correlating f function for La ).
- Inner valence $4 f / 5 s / 5 p$ To the outer valence set, add the fourth s primitive, the third p primitive, the third d primitives, the second and third f primitives, and the correlating g function for the 4 f shell.
- Core $4 d$ To the inner valence set, add the fifth s primtive, the fifth $p$ primitive, the sixth d primitive, and the fifth f primitive.

### 4.2 Triple-zeta basis sets

- Outer valence $5 d / 6 s / 6 p$ To the SCF functions, add the first and third $s$ and $p$ primitives, and the first and second $d$ primitives. For La add the correlating $2 f 1 \mathrm{~g}$ functions for the $5 \mathrm{~d} / 6 \mathrm{~s}$ shells; for $\mathrm{Ce}-\mathrm{Lu}$ add the first and third f primitives and the $5 \mathrm{~d} / 6 \mathrm{~s}$ correlating $g$ function.
- Inner valence $4 f / 5 s / 5 p$ To the outer valence set, add the fourth and sixth s primitives and the fifth and sixth p
primitives. For La add the fourth and fifth d primitives, and the 5 s 5 p correlating f function; for $\mathrm{Ce}-\mathrm{Lu}$ add the third through fifth $d$ and $f$ primitives, and the $4 f$ correlating 2 g 1 h set.
- Core $4 d$ To the inner valence set, add the seventh and ninth s and p primitives, and the seventh and eighth d primitives. For La, add the correlating 2 f 1 g functions for the 4 d shell; for $\mathrm{Ce}-\mathrm{Lu}$ add the sixth and seventh f primitives from the SCF set. The $g$ function for $4 d$ correlation is covered by the 4 f correlating set.

### 4.3 Quadruple-zeta basis sets

- Outer valence To the SCF functions, add the first, second, and fourth $s$ and $p$ primitives, the first through third d primitives. For La add the correlating 3 f 2 g 1 h for the 5 d and 6 s shells; for $\mathrm{Ce}-\mathrm{Lu}$ add the first through third f primitives and the correlating 2 g 1 h functions for the 5 d and 6 s shells.
- Inner valence To the outer valence set add the fifth, sixth, and eighth $s$ primitives and the sixth, seventh and eighth p primitives. For La add the the third, fourth, and fifth d primitives and the correlating 2 f 1 g set for the 5 s and 5 p shells; for $\mathrm{Ce}-\mathrm{Lu}$ add the third through sixth d and f primitives, and the 4 f correlating 3g2h1i set.
If linear dependence problems are encountered in the d space, do not include the second d primitive.
- Core $4 d$ To the inner valence set, add the tenth through 12th s and p primitives, and the seventh through ninth $d$ primitives. For La add the $4 d$ correlating 3 f 2 g 1 h set; for $\mathrm{Ce}-\mathrm{Lu}$ add the seventh and eighth f primitives. The 4 d correlating 2 g 1 h set is well enough represented by the 4 f correlating functions to be omitted.

## 5 Application

To exemplify the performance of the basis sets developed here in molecular calculations we have investigated the YbF molecule. This system has received a fair amount of theoretical attention because of its potential for the observation of parity-violating interactions [36, 37], in connection with the determination of the electric dipole moment of the electron (see, for instance, [38-42] and references therein).

YbF is an open-shell molecule with a ${ }^{2} \Sigma^{+}$ground state. Experimental [43, 44] and theoretical [45, 46] investigations indicate that the unpaired electron is located in a $\sigma$ orbital with dominant contributions from the 6 s orbital of Yb , corresponding to a $\mathrm{Yb}\left(f^{14} s \sigma\right) \mathrm{F}$ configuration.

### 5.1 Computational details

The calculations were performed with the Dirac program suite [47], using the Dirac-Coulomb Hamiltonian. The valence double-zeta, triple-zeta, and quadruple-zeta sets from the present work were used for Yb , including the correlating functions and the functions for dipole polarization of the 4 f and the 5 d . The matching augmented correlation-consistent basis sets of Dunning [28] (aug-cc$\mathrm{pVnZ}, n=2,3,4$ ) were used for F . All basis sets were kept uncontracted, with the small component basis generated by restricted kinetic balance. Furthermore, all twoelectron integrals over small component ( S ) basis sets (the so-called (SSISS)-type integrals) were replaced by a simple correction [48].

In addition to the potential energy curves for individual basis sets, we have extrapolated the points on the potential energy curves for the triple- and quadruple-zeta sets to obtain a curve for the complete basis set limit $\left(E_{\infty}\right)$, using the relation [49]
$E_{\infty}(\mathbf{R})=\frac{4^{3} E_{4}(\mathbf{R})-3^{3} E_{3}(\mathbf{R})}{4^{3}-3^{3}}$
where the subscripts denote the cardinal numbers for the basis sets and $E_{n}(\mathbf{R})$ is the potential energy for a given geometry and electronic structure method for a basis of cardinal number $n(=2,3,4, \infty)$. It is possible to extrapolate the potential energy rather than the individual energies because the expression used to fit the energy as a function of the cardinal number $n$ is linear in the parameter of the fit, $A(\mathbf{R})$ :
$E_{n}(\mathbf{R})=E_{\infty}(\mathbf{R})+A(\mathbf{R}) / n^{3}$
Any combination of energies merely produces the same combination of the fit parameters, which can then be treated as a single parameter and the combination of energies can be extrapolated.

The $E_{n}(\mathbf{R})$ energies were obtained at the SCF, MP2, $\operatorname{CCSD}$, and $\operatorname{CCSD}(\mathrm{T})$ levels of theory for the ground state [50], using as reference wave function that of the $\mathrm{Yb}\left(s \sigma_{1 / 2}\right) \mathrm{F}$ configuration. For the active occupied space, orbitals arising from the combination of the $\mathrm{Yb} 4 \mathrm{f}, 5 \mathrm{~s}, 5 \mathrm{p}, 6 \mathrm{~s}$ and the F 2s and 2 p atomic orbitals were explicitly considered in the calculations. Due to computational constraints, we have truncated the active virtual space so that 117,230 and 296 orbitals were used in the double-zeta, triple-zeta and qua-druple-zeta calculations.

Spectroscopic constants ( $r_{e}, D_{e}, \omega_{e}$ and $\omega_{e} x_{e}$ ) were determined from a fifth degree polynomial fit in the vicinity of the potential energy minima, which corresponded to bond lengths between 1.96 and $2.10 \AA$, spaced by $0.01 \AA$ between 1.98 and $2.06 \AA$, and by $0.02 \AA$ for the outer regions. In the calculation of $D_{e}$ the asymptotic
dissociation limit is calculated from the energies of the isolated neutral atoms, fluorine in the ${ }^{2} P_{3 / 2}$ state and Yb in the ${ }^{1} S$ state.

### 5.2 Results and discussion

The results of our calculations for the ${ }^{174} \mathrm{Yb}^{19} \mathrm{~F}$ isotopomer are presented in Table 13, along with the experimental results [43, 44, 51-53] and other theoretical results [39, 54-56]. The overall qualitative trend clearly shows that improvement of the basis set and correlation treatment leads to progressively better agreement with experiment for the properties under consideration, as expected from basis sets constructed in such a systematic fashion.

For the main spectroscopic constants $\left(r_{e}, \omega_{e}\right.$, and $\left.\omega_{e} x_{e}\right)$ the extrapolated CCSD results agree remarkably well with experiment: within $0.001 \AA$ for the bond length, $1 \mathrm{~cm}^{-1}$ for the harmonic frequency, and $0.1 \mathrm{~cm}^{-1}$ for the anharmonicity. The agreement is better than that of the $\operatorname{CCSD}(\mathrm{T})$ results, for which the results differ from experiment by about $0.01 \AA, 20 \mathrm{~cm}^{-1}$, and $0.3 \mathrm{~cm}^{-1}$ respectively. The agreement of the CCSD results must be considered fortuitous, however, because it is clear from the perturbative triples results that the calculations are not converged. The current calculations do not include correlation of the 4 d shell, and it is possible that $4 \mathrm{~d}-4 \mathrm{f}$ correlation is significant. Truncation of the virtual space might also contribute to the discrepancy. In addition, the size of the triples correction suggests that a better treatment of the higher-order excitations is necessary to approach the experimental results for the right reasons.

Nevertheless, the current results are comparable to or better than previous theoretical predictions. The all-electron results of Nayak and Chaudhuri [39] do not include any higher angular momentum functions and therefore are not very accurate. The all-electron results of Su et al. [56] do not include higher angular momentum functions on the Yb atom but use the aug-cc-pVQZ basis set for F , which leads to a very unbalanced, and consequently inaccurate, calculation. The remaining calculations all include $g$ functions on Yb , but no higher, and use either triple-zeta or quadruple-zeta basis sets on F. Although these calculations are also somewhat unbalanced, the bulk of the correlation of the Yb 4 f is included with the inclusion of g functions. The best of these calculations appears to be the CISD + Q calculations of Cao et al. [54], which include the correlation of the 4 d shell. However, given the size of the triples correction in our results, it is likely that these results also represent a fortuitous cancellation of errors. Our results are the only results to include angular momentum beyond $g$ on the Yb atom, and since both the triple-zeta and the qua-druple-zeta basis sets include higher angular momentum

functions, it is difficult to compare directly with the other results.

The current double-zeta results should be treated with caution. Both the Yb basis and the F basis are too small for accurate calculations, so that a large part of the correlation
is missing. This is true of double-zeta calculations in general, which are usually only suitable for qualitative work. However, for YbF there is another reason. Dolg et al. [45] found that SCF calculations pointed to an $\mathrm{f}^{13} \mathrm{~s}^{2}$ ground state for YbF whereas in MRCI calculation the
$\mathrm{f}^{14} \mathrm{~s}^{1}$ configuration was preferentially stabilized and became the ground state. The inadequate correlating space in the present double-zeta calculations could therefore lead to a poor description of the ground state. This possibility is supported by the large triples corrections for the predicted properties, not only for the double-zeta basis, but also for the larger basis sets.

The existence of a perturbing state is verified by calculations done with the triple-zeta basis set with two different virtual spaces. The first included 198 virtuals, and the second included 230 virtuals, which corresponds to an additional $\mathrm{s}, \mathrm{d}, \mathrm{f}, \mathrm{g}$, and h shell. The potential energy curves relative to the minimum for the $\operatorname{CCSD}$ and $\operatorname{CCSD}(\mathrm{T})$ calculations are shown in Fig. 1, along with the $\mathrm{T}_{1}$ diagnostic, as a function of $r$. The CCSD curve for the smaller virtual space shows an abrupt variation at around $1.9 \AA$ that indicates the presence of another state, which is manifested by the large values of the $\mathrm{T}_{1}$ diagnostic in the vicinity of this point. The $\mathrm{T}_{1}$ diagnostic for the larger virtual space at these geometries is in the normal range for a single reference. It is clear from the figures, however, that the same abrupt change in the CCSD potential observed for the smaller virtual space occurs for the larger virtual space, but at a shorter bond length (about $1.78 \AA$ ).

As this perturbation occurs relatively far from the CCSD minimum and without significantly changing the shape of the potential, there should only be a small effect on the calculated spectroscopic constants. This is not the case for $\operatorname{CCSD}(\mathrm{T})$ due to the sharp rise in energy in the repulsive region, which explains why the $\operatorname{CCSD}(\mathrm{T})$ constants are further from experiment than the CCSD constants. This observation also helps to explain the poor accuracy of other calculations, notably those of Su et al. [56], who observe a shoulder between 1.7 and $2.0 \AA$ in their pseudopotential calculations (which no doubt influences the fitting of the curve and consequently the quality of the spectroscopic constants).

These results confirm the idea that there is more than one state to consider, and that the position of these two states is strongly dependent on the degree of correlation included. The results of single-point calculations with several virtual spaces, given in Table 14, show that the bulk of the extra correlation, and the biggest change in the $\mathrm{T}_{1}$ diagnostic, comes from the addition of a d and a g shell. Moreover, it is clear that the perturbative treatment for the triple excitations is not reliable in the regions of large $\mathrm{T}_{1}$ values, and a more thorough treatment of higher excitations and of the reference space is mandated.

For the dissociation energies, the extrapolated $\operatorname{CCSD}(\mathrm{T})$ values are the closest to experiment, but are still $20-$ $30 \mathrm{~kJ} \mathrm{~mol}^{-1}$ too low. Treatment of higher-order excitations, and a better treatment of the perturbing state, are likely to increase the binding and thus bring the results into

Fig. $1 \operatorname{CCSD}$ and $\operatorname{CCSD}(\mathrm{T})$ potential energy curves (relative to the minima) and T1 diagnostic in the triple-zeta basis set, using different numbers of active virtuals (198 and 230)
better agreement with experiment. The results of Cao et al. are closer to experiment than ours, which might be due to the correlation of the 4 d shell in their calculations. However, improvements in the basis set and the correlation treatment are likely to move their results to a value that is

For CCSD the value of the $\mathrm{T}_{1}$ diagnostic is given in parenthesis; for $\operatorname{CCSD}(\mathrm{T})$ the values for the fourth and fifth order triples corrections are given in parentheses (for details see Ref. [50])
too high. The fact that the BSSE in their results is about $14 \mathrm{~kJ} \mathrm{~mol}^{-1}$ indicates that neither the 1-particle nor the $N$-particle space is saturated. Although the current calculations do not account for BSSE, the effect of BSSE on our results should be smaller than on the results of Cao et al. or of Heiberg et al. Our quadruple-zeta basis set is larger than any of the others used for Yb and includes higher angular momentum functions, which will reduce the size of the BSSE relative to calculations that lack these higher angular momentum functions. The PP values of Su and coworkers are too high and are yet another indication of the poor quality of their calculations.

The experimental numbers are, however, obtained by indirect methods: the results of Ref. [52] are derived from molecular beam chemiluminescence studies, whereas those of Ref. [53] are based on thermochemical data and a ligand-field model. They are therefore rather dependent upon assumptions and approximations in the underlying models. This, together with the variations in the theoretical values, leaves some uncertainty about the magnitude of the error in the current calculations.

## 6 Conclusion

Basis sets of double-zeta, triple-zeta, and quadruple-zeta quality have been optimized for the lanthanide elements $\mathrm{La}-\mathrm{Lu}$, including functions for correlation of the 6 s and 5 d , the 4 f , the 5 s and 5 p , and the 4 d shells. The full tables of basis sets including spin-free relativistic SCF [57] and Dirac-Fock SCF coefficients are available in ASCII format from the Dirac web site, http://dirac.chem.sdu.dk. The spin-free relativistic SCF coefficients include the Foldy-Wouthuysen transformed large component coefficients that can be used in the scalar one-electron NESC approximation [58].

These basis sets are shown to perform well in the determination of the ground-state spectroscopic constants
of YbF , and extrapolations to the basis set limit using the triple- and quadruple-zeta basis yields results close to experiment for $r_{e}, \omega_{e}$ and $\omega_{e} x_{e}$. For $D_{e}$, the results are outside the experimental limits by some tens of $\mathrm{kJ} \mathrm{mol}^{-1}$, but should be improved by the inclusion of more outer core orbitals and a better treatment of higher excitations. The double-zeta basis sets provide qualitatively correct results, but cannot be used for high accuracy calculations, especially in difficult cases such as YbF where electron correlation effects are extremely important for correctly describing the ground-state wave function.

The importance of using proper, flexible correlating basis sets in order to allow single-reference based perturbative approaches, such as $\operatorname{CCSD}(\mathrm{T})$, to work properly in cases where dynamical correlation can strongly influence the nature of the wavefunction was shown here. In light of our results, we therefore suggest the use of at least the triple-zeta basis set, and including in the virtual space all correlation functions, in order to obtain a qualitative and quantitatively correct picture.

## 7 Internet archive

This paper includes an internet archive in ASCII format. The archive contains the Dirac-Fock SCF coefficients and the spin-free relativistic SCF coefficients, including the Foldy-Wouthuysen transformed large component coefficients, and the correlating and polarizing functions. Prescriptions are given in the archive for the construction of various basis sets.
