General introduction

Anna Carrano

Alzheimer's disease

Alzheimer's disease (AD) is the most common form of dementia in the elderly population in the occidental world. Because of the ongoing increase in life expectancy, we can expect approximately 25% of people living in the Western hemisphere to be over 65 years of age by 2050. One third of these elderly people will likely develop AD and become affected with or will suffer from the consequences of this severe, disabling disorder, for which no cure exists yet. The first AD case was described by the German psychiatrist and neuropathologist Alois Alzheimer in 1907 (Alzheimer, 1907). Upon histopathological examination of the brain he described the common neuropathological hallmarks of the disease, which are to date still used to confirm the definite diagnosis of AD.

AD is clinically characterized by a gradual decline in memory and cognition that makes patients in the final stage of the disease bedridden and completely care dependent. Clinical symptoms begin with short term memory loss, and progress to more extensive cognitive and emotional dysfunction. Death occurs on average 9 years after clinical diagnosis, but the characteristic neuropathological changes that will eventually result in dementia occur decades before the first clinical symptoms appear. Neuroimaging and biochemical analysis of the cerebrospinal fluid, together with neuropsychological examination, are important tools to establish the diagnosis of "probable AD" during life. However, definite diagnosis of AD can only be obtained post-mortem by pathological examination of the brain, which is still the "gold standard" for AD diagnosis today.

Pathology

On a macroscopic level the main pathological hallmark of AD is severe atrophy of selective brain regions, such as the neocortex, hippocampus, amygdala and entorhinal cortex. The extensive neuronal loss results in widening of the sulci, narrowing of the gyri and enlargement of the ventricles (figure 1). Microscopically, the characteristic neuropathological lesions include senile plaques containing β -amyloid ($A\beta$) and intracellular neurofibrillary tangles (NFT) containing hyperphosphorylated-tau. Both lesions occur throughout the cerebral cortex and are commonly accompanied by deposition of $A\beta$ in the brain vasculature also known as cerebral amyloid angiopathy (CAA) (figure 2). NFTs have not only been detected in brains of AD pa-

Figure 1. Macroscopical hallmarks of AD brain. A crosswise slice shows macroscopically the differences between a healthy brain and the severely affected AD brain. In the AD brain the cortex shrivels up, damaging areas involved in thinking, planning and memory. Atrophy is especially severe in the hippocampus, an area of the cortex that plays a key role in formation of new memories. Ventricles grow larger.

tients but also in patients suffering from other types of dementia. Extensive deposition of $A\beta$ however exclusively occurs in AD pathology.

Although the pathological diagnosis of AD is based on the presence of insoluble $A\beta$ plaques and by the number and distribution of neurofibrillary changes, clinicopathological studies suggest that three features in particular correlate with clinical dementia. They are 1) the number and distribution of neurofibrillary changes (Braak, et al., 2006; Braak and Braak, 1991) ; 2) a raised level of soluble $A\beta$ in the brain (Lue, et al., 1999; McLean, et al., 1999) ; and 3) the severity of CAA (NGoM, 2001).

Neurofibrillary tangles

Neurofibrillary tangles (NFT) are formed by hyperphosphorylation of the microtubule-associated protein tau, causing it to aggregate intracellularly in an insoluble form in neurons. Under physiological conditions the primary function of tau is to bind to the microtubules and assists with their formation and stabilization in order to maintain effective axonal transport.

Under pathological conditions, an excessive disengagement of tau from the microtubules takes place due to abnormal post-translational hyperphosphorylation of tau. The detachment of tau from the microtubules leads to its intracellular accumulation compromising axonal transport and thus contributing to synaptic dysfunction and eventually neuronal death and neurodegeneration (Ballatore, et al., 2007).

The severity of NFT pathology is graded on a 0–6 scale (using Roman numerals 0–VI by convention) according to “Braak stages” (Braak and Braak, 1991), which pertain to the spread of NFTs in the brain.

NFT pathology relates to the severity of dementia, however, even though the neurofibrillary changes are closely related to dementia, they do not have a clear relationship to genetic factors in AD and they are thought to appear later in the disease progression, following A β deposition. Furthermore, NFT are also found in other neurodegenerative diseases, such as tauopathies, including progressive frontotemporal dementia subtypes, supranuclear palsy, corticobasal degeneration and Pick’s disease.

In AD pathological events, such as A β -mediated neurotoxicity, oxidative stress and inflammation may be responsible to initiate or contribute directly or indirectly to tau mediated neurodegeneration; however, their precise positioning in the cascade of events that leads to neuronal loss remains unclear.

Figure 2. Microscopical hallmarks of AD. Immunohistochemical staining of the 3 hallmarks of AD: A) neurofibrillary tangle, B) neuritic plaque and C) cerebral amyloid angiopathy.

Amyloid Plaques

Plaques are characterized by extracellular deposition of A β and can be observed throughout the brain parenchyma. Full-length A β (A β 1-40 or A β 1-42) is derived from the amyloid precursor protein (APP) by sequential proteolytic activity of the β -secretase (or β -site AAP-cleaving enzyme, BACE) and the γ -secretase/presenilin complex (presenilin-1, nicastrin, APH1A and PEN2) (De Strooper 2003). After APP cleavage, A β peptides are secreted into the brain interstitial fluid (ISF) as monomers/dimers, where they are able to further polymerize into diffusible A β oligomers. The amino acid sequences of A β 1-40 and A β 1-42 are identical with the exception that the longer peptide contains 2 extra hydrophobic amino acids at the C-terminus, which render the A β 1-42 more insoluble and prone to aggregation than A β 1-40. In soluble states, A β is passively redistributed in brain parenchyma and cleared (Hardy and Selkoe, 2002). However, under pathological conditions A β starts to accumulate and because of its fibrillogenic characteristic forms protofibrils at first and eventually mature fibrils, which will deposit as insoluble plaques. Based on the importance of A β accumulation in AD pathogenesis, the amyloid cascade hypothesis has been formulated (for more details see figure 3).

Several forms of amyloid plaques can be distinguished in the brain parenchyma; the most common being compact and diffuse plaques. Diffuse plaques consist of amorphous extracellular deposits of A β and occur in large numbers in the same brain regions as neuritic plaques. Compact amyloid plaques (also called senile plaques or neuritic plaques) are roughly spherical in shape with a dense core of aggregated A β fibrils frequently surrounded by dystrophic axons and dendrites, activated microglia and reactive astrocytes. The severity of plaque pathology is scored according to a distinct metric, which is named after the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) (Mirra, 1997). The CERAD scoring system is a four-tiered scale representing neocortical neuritic plaques density.

Amyloid plaques may also contain other proteins such as serum amyloid P component (SAP), activated complement proteins and clusterin (Eikelenboom, et al., 2011).

Cerebral Amyloid Angiopathy

CAA is defined by the deposition of a congophilic material (i.e. positive staining with a Congo-red dye) in cerebral leptomeningeal and intracortical arteries, arterioles and capillaries

and can occasionally be found in postcapillary venules and veins. CAA is caused by accumulation of A β peptide in the media and adventitia of cerebral blood vessels wall and occurs in about 98% of AD patients, with approximately 75% of these cases rated as severe CAA. Importantly, clinical studies reported a strong correlation between cognitive impairment and the severity of CAA (Attems, et al., 2011; Biffi and Greenberg, 2011; Thal, et al., 2008; Vinters, 1987).

The biologic overlap between CAA and AD is substantial as CAA is found, to some extent, in virtually all AD cases and correlated with AD severity (Thal, et al., 2008). Also genetically speaking the analogies between AD and CAA are undeniable. Mutations in the APP, PS1 and PS2 genes cause familial forms of AD and widespread CAA (Levy, et al., 2006; Mann, et al., 2001; Revesz, et al., 2003; St George-Hyslop, et al., 1987; Tanzi, et al., 1987). Most severe CAA is seen in cases with the Flemish, Iowa and Dutch mutations in the APP gene. Mutations in PS1 and PS2 genes can also lead to CAA in familial AD cases, especially those PS1-mutations beyond codon 200 (Revesz, et al., 2002).

Although non-invasive CAA diagnostic criteria have been developed and refined in the past decade, in order to both improve and standardize diagnosis during life (Boston criteria for CAA) (Knudsen, et al., 2001), a definitive CAA diagnosis can only be formulated after histological investigation of affected brain tissue, obtained at autopsy or via brain biopsy. Furthermore, positron emission tomography imaging with the A β -binding compound Pittsburgh Compound B can be used as a tool to distinguish between AD with or without CAA, as CAA generally favors occipital brain regions (Greenberg, et al., 2008) according to post mortem analysis of CAA pathology and radiographic analysis of CAA-related hemorrhages.

Common ApoE polymorphisms influence the risk of both sporadic CAA and sporadic AD (Biffi, et al., 2010). Based on localization, association to ApoE alleles and occurrence in AD patients, two types of sporadic CAA can be defined. CAA type 1 is characterized by A β accumulation in capillaries and is therefore often referred to as capillary CAA, although additional A β depositions in larger blood vessels, leptomeningeal and cortical arteries, arterioles, veins and venules can also be observed (Thal, et al., 2002). CAA type 1 has a strong association with Apolipoprotein E4 (ApoE4) genotype (46,7% allele frequency) (Richard, et al., 2010; Thal, et al., 2008) and correlates with severity of AD pathology (Attems and Jellinger, 2004). In CAA type 2, A β depositions are restricted to non-capillary blood vessels. CAA type 2 shows a higher frequency of the ApoE2 allele and is not associated with the ApoE4 genotype (Thal,

Figure 3. The amyloid cascade hypothesis. The amyloid cascade hypothesis posits that deposition of A β protein is the causative agent of AD pathology and that NFTs, neuronal cell loss, vascular damage follows as a direct result of this deposition that ultimately leads to AD dementia. The amyloid cascade hypothesis, first proposed by John Hardy in 1991, synthesizes histopathological and genetic information and has dominated AD research for the past twenty years.

The hypothesis started to take form in 1984 with the isolation of A β from leptomenigeal vessels (CAA) of an AD case and Down syndrome and later on with the identification of APP mutations as a cause of amyloid deposition in hereditary cerebral hemorrhage with amyloidosis Dutch type (a familiar form of CAA) (van Duinen et al. 1987; Levy et al. 1990; Van Broeckhoven et al. 1990). It was then clear that mutations in the APP gene (located on chromosome 21) could cause A β accumulation in some familiar cases and that these mutations likely induced an increase in A β production. We now know that mutations in APP, presenilin 1 (PS1) and presenilin 2 (PS2) are responsible for familiar forms of early onset AD (EOAD). These mutations indeed not only cause increased A β production, but, in addition, promote the release of more toxic forms of A β . Although these genetic alterations are not responsible for the more common late onset AD, accumulation of cerebral A β is still the key event in the pathogenesis of the sporadic form of the disease. Increased levels of A β can either be the result of increased production or alternatively by decreased clearance of A β . In sporadic AD A β accumulation is most likely due to an inefficient removal of A β rather than overproduction, as seen in EOAD. (Di Paolo et al., 2011).

et al., 2002). Interestingly ApoE2, which exerts a protective effect on AD risk, increases risk of intracerebral hemorrhage in CAA patients (Nicoll, et al., 1997). Based on the findings it seems that these two CAA types represent two different pathological entities. Furthermore, CAA type 1 appears to be more strictly related to AD pathology and it has even been postulated that CAA type 1 is a specific subtype of sporadic AD, defined by characteristic neuropathological features (Richard, et al., 2010) and genotype specific associations (Thal, et al., 2010).

The two types of CAA also differ with regard to the composition of A β species present in the vascular wall. The ratio between the two main forms of A β (1-40 and 1-42) has been reported to be different, with capCAA showing a ratio 1-40/1-42 significantly lower than in CAA type 2, a ratio much more similar to what found in parenchymal plaques. Thus, A β 1-40 has a greater tendency to be deposited in the larger vessel wall, whereas A β 1-42 is mainly deposited in senile plaques and CAA-affected capillaries (Attems and Jellinger, 2004; Roher, et al., 2003; Thal, et al., 2008). Nonetheless, it has to be noted that A β 1-40 is also present in capCAA and senile plaques as well and that the two A β isoforms are both present in amyloid-laden capillaries (Richard, et al., 2010).

In addition, N-terminal truncated forms of A β and other proteins including apoE are present in cerebrovascular A β depositions. A β is initially deposited in the abluminal portion of the tunica media surrounding smooth muscle cells (SMC) as well as in the adventitia. With increasing severity all layers of the vessel wall show A β depositions accompanied by a loss of SMC (Kawai, et al., 1993; Yamaguchi, et al., 1992). In capillaries, devoid of a smooth muscle cell layer, amyloid deposition also starts in the basement membrane, may extravasate into the neuropil and may also lead to capillary occlusion in severe cases (Thal, et al., 2008; Yamaguchi, et al., 1992).

In very severe stages of CAA the vascular architecture is disrupted potentially leading to microaneurysm formation, fibrinoid necrosis and A β depositions in the adjacent surrounding neuropil (i.e. dyschoric changes) (Attems, et al., 2011).

Frequently, dyschoric changes are seen surrounding capillaries as globose A β accumulation or flame like deposits and therefore some authors misleadingly use 'dyschoric CAA' as a synonym for capCAA.

The deposition of A β as CAA is probably due to the failure of two main mechanisms of A β

Historical notes

In 1907 Alois Alzheimer, a German psychiatrist, described, for the first time, the clinical symptoms and the typical plaques and tangles in a demented woman with presenile dementia (Alzheimer, 1907). In the same year, and without knowing the findings of Alzheimer, Oskar Fischer reported neuritic plaques in 12 cases of senile dementia (Fischer, 1907). These were landmark findings in the history of research in dementia because they delineated the clinicopathological entity that is now known as Alzheimer's disease.

Cerebral amyloid angiopathy was probably observed for the first time in 1909 by Oppenheim when he described metachromasia in the core of plaques, which could also be found in nearby capillaries (Oppenheim, 1909). The amyloid nature of plaques was discovered by Divry in 1927, who also observed CAA (Divry, 1927), but the first systematic study was made by Scholz in 1938 (Scholz, 1938).

The term "angiopathy dyshorique" was originally introduced by Morel in 1950 (Morel, 1950) and interpreted as congophilic angiopathy (synonymous with CAA), with parenchymal lesions by Pantelakis in 1954 (Pantelakis, 1954). This terminology was derived from translating the original German description of CAA, which used the term *Drusige Entartung*, as used by Scholz, who reported that the substance in this specific form of angiopathy was the same as the main component of senile plaques. This term already made the link with amyloid plaques, which were called *Alzheimer Drusen* at that time, and meant the occurrence of plaque-like silver and Congo red stainable material in blood vessels (Richard, et al., 2010).

In 1984 Glenner and Wong isolated A β from cerebral blood vessels (Glenner and Wong, 1984b). Glenner and Wong were the first to isolate A β (called by them, beta amyloid) from the meningeal vessels of first a late onset sporadic AD case and then, based on the universal occurrence of AD in trisomy 21, from a Down syndrome brain (Glenner and Wong, 1984a).

elimination from the brain: 1) the direct transport of A β into the blood via specific receptors at the BBB and 2) the perivascular drainage of A β with other solutes and interstitial fluid along capillary and artery walls. Deposition of A β within the perivascular space forms an obstacle and reduces the drainage capacity which can lead to CAA formation and also to increased parenchymal A β deposition (Weller, et al., 1998; Weller, et al., 2008).

Clearance of A β through the BBB is discussed in the following chapters.

The blood-brain barrier

The BBB is a complex structure within the brain and its main function is to provide and maintain a highly controlled microenvironment for neurotransmission to occur through the formation of a tight sealed barrier between the circulating blood and the CNS (figure 4). It is formed by a monolayer of brain microvascular endothelial cells, capillary basement membranes, astrocytic end feet and pericytes (Fig.2). The BBB is characterized, at least in part, by a specific phenotype of the endothelial cells, with adherens junctions as cell–cell interaction stabilizers, and tight junctions (TJ) that limit paracellular flow of water, ions and larger molecules into the brain.

TJ are domains of occluded intercellular clefts composed of protein complexes that seal the paracellular space. The sealing feature of the TJ is regulated by the expression of transmembrane proteins, such as occludin, claudins and junction adhesion molecules, anchored via accessory proteins, such as ZO-1-3 to the cytoskeleton. Occludin and the claudins consist of four transmembrane domains and two extracellular loops and form the TJ through homophilic protein-protein interactions mediated by the extracellular loops and are the most important membranous components of the junctions. The presence of intricate TJ complexes together with the lack of fenestrations are important characteristic of the BBB, which guarantee the low permeability of the barrier, impeding the entrance of plasma components, red blood cells, and leukocytes into the CNS, and conferring the high electrical resistance of the BBB. The TJ have a valuable function not only in restricting paracellular permeability (gate function), but also in segregating the apical and basal domains of the cell membrane (fence function) so that the endothelium can take on the polarized (apical–basal) properties that are more commonly found in epithelia.

The supply of necessary substances into the brain needs therefore to be mediated by active transport. Several transporters for amino acid and nucleosides are present at the BBB along with the glucose transporter 1, allowing the maintenance of cerebral homeostasis.

BBB disruption is a common feature of virtually all neurodegenerative disorders and so, along with neuroinflammation, can be viewed as a key component in the process of neurodegeneration. The main question remains whether BBB dysfunction precedes neuropathological changes such as senile plaques and NFTs. Alternatively, impaired BBB function might be a secondary event and caused by the deposition of aberrant protein aggregates and concomitant inflammatory responses.

Histopathological studies have demonstrated that BBB changes are evident in the cerebral microvasculature of AD patients (Claudio, 1996; Farkas and Luiten, 2001). These include degeneration of perivascular cells, swollen astrocytic end feet (Higuchi, et al., 1987; Yamashita, et al., 1991), reduced expression of glucose transporter-1 protein, increased pinocytotic vesicles and decreased numbers of mitochondria. In addition, prominent thickening and local disruption of capillary basement membranes have been reported by several research groups analyzing either biopsy tissue or post mortem material (Farkas, et al., 2000; Perlmutter and Chui, 1990). Furthermore, the appearance of string vessels (collapsed and acellular membrane tubes), a reduction in capillary density, accumulation of collagen and perlecan in the basement membrane, loss of tight junctions and/or adherens junctions and BBB breakdown with leakage of blood-borne molecules have also been reported in AD (Zlokovic, 2011). Taken together, there is ample evidence that microvascular pathology is a commonly observed phenomenon in AD brains.

Because in capCAA accumulation of A β occurs at the interface of the CNS and the systemic circulation, affecting those location responsible for the transport or the clearance of A β into the venous or CSF compartments, the role of capCAA in affecting BBB function and integrity and therefore the involvement in A β clearance is of particular interest to understand AD pathophysiology.

Amyloid clearance

The low paracellular permeability of the BBB implies that, in order to cross the barrier, specific transporters and carriers are needed to allow the entrance of necessary metabolites and nu-

trients and the removal of toxic substances in order to maintain cerebral homeostatic balance. The brain endothelium does not allow free exchange of peptides, and this is also true for the passage of A β . The transport of A β is strictly regulated by specific (and less specific) transporters at the BBB, which play a crucial role in the clearance of A β from the brain.

The major influx transporter for A β across the BBB is the receptor for advanced glycation endproducts (RAGE). RAGE binds to different forms of A β and mediates its pathophysiologic cellular responses: not only can it transport A β across the BBB into the brain, but A β /RAGE interaction contributes to the neurotoxic effects directly by producing oxidative damage to RAGE-expressing neurons, and indirectly, by activating microglia (Yan, et al., 1996). The A β -enriched environment in AD brains increases RAGE expression at the BBB and in neurons, amplifying A β -mediated pathogenic responses.

Low-density lipoprotein receptor related protein 1 (LRP1), a member of the LDL receptor family, is the major efflux transporter of A β (Shibata, et al., 2000) and acts as a multifunctional scavenger and signaling receptor. Binding of A β to LRP1 at the abluminal side of the BBB initiates A β clearance from the brain to the systemic circulation via transcytosis across the BBB. LRP1 binds to A β either directly or via A β chaperones such as ApoE to mediate brain A β clearance.

ApoE mediates the clearance of A β and influence risk of developing AD affecting A β clearance in an isoform-dependent manner. The ApoE4 allele is in fact the isoform less effective in clearing A β when compared to ApoE2 and ApoE3 isoforms (Kim, et al., 2009). Notably, ApoE4 is the major genetic risk factor for sporadic AD, increasing risk and decreasing age at onset of AD dose-dependently, with the homozygotes having the higher risk (Castellano, et al., 2011).

Another apolipoprotein, ApoJ, also known as clusterin, is involved in the transport of A β across the BBB. ApoJ, as well as ApoE, can cluster to A β and facilitates its binding to LRP2. LRP2 quickly transports ApoJ across the BBB and eliminates A β as well when it is bound to ApoJ. Interestingly, also ApoJ has been reported to increase the risk of developing sporadic AD, emphasizing the importance of A β clearance in the development of AD.

The ABC (ATP-binding cassette) transporters belong to another class of transporters involved in the removal of A β from the brain. These are efflux transporters that are normally expressed at the BBB and limit the penetration of many drugs into the brain. Some ABC transporters,

Figure 4. The Blood-Brain Barrier. The cerebral endothelial cells form tight junctions at their margins which seal the aqueous paracellular diffusional pathway between the cells. Pericytes are distributed discontinuously along the length of the cerebral capillaries and partially surround the endothelium. Both the cerebral endothelial cells and the pericytes are enclosed by, and contribute to, the local basement membrane which forms a distinct perivascular extracellular matrix (basal lamina 1, BL1), different in composition from the extracellular matrix of the glial endfeet bounding the brain parenchyma (BL2). Foot processes from astrocytes form a complex network surrounding the capillaries and this close cell association is important in induction and maintenance of the barrier properties. Axonal projections from neurons onto arteriolar smooth muscle contain vasoactive neurotransmitters and peptides and regulate local cerebral blood. BBB permeability may be regulated by release of vasoactive peptides and other agents from cells associated with the endothelium. Microglia are the resident immunocompetent cells of the brain. The movement of solutes across the BBB is facilitated by passive or active transporters in the endothelial cell membranes. Efflux transporters in the endothelium limit the CNS penetration of a wide variety of solutes including A β (Abbott et al., 2009).

including P-glycoprotein (P-gp), BCRP (breast cancer resistance protein) and MRP-1 (multidrug resistance-associated protein 1), are able to transport A β mediating its efflux from the brain endothelium to blood across the luminal side of the BBB.

Defective vascular clearance of A β from the brain and/or an increased re-entry of peripheral A β across the blood vessels into the brain result in elevated A β levels in the brain parenchyma and around cerebral blood vessels. At pathophysiological concentrations, A β forms neurotoxic oligomers and also self-aggregates, which leads to the development of CAA and plaques. Because of the pivotal role of A β removal in regulating the concentration of A β in the brain and therefore its accumulation, the transport of A β across the BBB might be a key event in the pathological cascade that leads to AD.

Inflammation

Inflammation and oxidative stress in the brain are concurrent with AD. Currently, there has been increasing evidence suggesting that inflammatory mechanisms are not merely bystanders in neurodegeneration but powerful pathogenetic forces in the disease process.

The innate immune response and resulting neuroinflammation appears to be responsible for local activation of microglia, astrocytes, and the complement system, the subsequent local initiating a pro-inflammatory cascade that results in the release of potentially cytotoxic molecules, cytokines, reactive oxygen species (ROS) and other related compounds, causing neurodegeneration (Yu and Tan, 2012).

Elevated levels of proinflammatory cytokines and acute phase proteins are localized around A β plaques in AD (Akiyama, et al., 2000), suggesting that the AD brain is in a chronic proinflammatory state. Oligomeric A β 1-42 can also cause oxidative stress by integrating into membranes and catalytically generating the lipid peroxidation product, 4-hydroxynonenal (HNE), and through activation of the ROS-generating enzyme NADPH oxidase in microglia. On the other hand, inflammation and/or oxidative stress can themselves cause A β accumulation in the brain. APP, from which A β is cleaved, is transcriptionally regulated similarly to heat shock proteins and is responsive to the proinflammatory cytokine IL-1. Oxidative stress, on its turn, upregulates proteins involved in A β production, such as presenilin 1 (Oda, et al., 2010).

Several studies have suggested that amyloid associated proteins, such as clusterin and heat shock proteins, are involved directly and indirectly in numerous ways related to inflammation and immunities in the brain, regulating complement activation, inhibiting NF- κ B, activating microglia and inducing release of proinflammatory cytokines (Bruinsma, et al., 2012; Erickson, et al., 2012).

Modest, transient upregulation of A β in the brain may serve as an antioxidant defense and promote clearance of damaged cells in the brain by microglia (Kontush, 2001; Neniskyte, et al., 2011). Under severe or chronic conditions of cellular stress, it is however feasible that A β accumulation could transition to pathological levels, resulting in formation of toxic oligomers that drive the AD process (Erickson, et al., 2012).

A prominent inflammatory response is found especially surrounding capCAA in which dyschoric changes are particularly severe. Furthermore CAA-related inflammation is of clinical importance since patients with this type of pathology present with cognitive decline, sei-

zures and headaches, that improve upon anti-inflammatory treatment (Chung, et al., 2011; Eng, et al., 2004; Kinnecom, et al., 2007). In addition, it has been suggested that especially capCAA dyshoric changes could contribute to a rapid clinical deterioration (Eurelings, et al., 2010), suggesting an important role of capCAA and dyshoric angiopathy, rather than plaques and CAA, in cognitive decline.

Outline of this thesis

Given the central role of the vascular and BBB compartments in the regulation of A β clearance the aim of the studies described in this thesis was to examine the role of A β transport proteins, as well as the expression of specific BBB/endothelial proteins in the AD/CAA brain and to elucidate the putative role of CAA in the evolution of AD pathology. To this end, my thesis focuses on vascular alterations presented in the capillary form of CAA and the common and not common features shared with “classical” AD, on proteins involved in A β transport across the BBB, including A β transporters and amyloid associated proteins, and a number of proteins that may play a significant role in the overall homeostasis and maintenance of the vascular endothelial and BBB compartment.

Chapter 2

This chapter describes the pathological characteristics of capCAA, the relationship between amyloid deposits in capCAA, CAA and plaques, and the distribution patterns of neurofibrillary changes, inflammatory markers, and ApoE around amyloid lesions.

Chapter 3

To investigate the differential expression of proteins between AD and capCAA brains a proteomics study was performed. We identified several proteins specifically upregulated in capCAA, the expression of which has been further validated with immunohistochemical techniques. We here investigated the expression and localization of laminin, clusterin, SAP and complement activation in capCAA and AD brains. Both laminin, clusterin, SAP and complement proteins colocalize with amyloid deposits in CAA and capCAA-affected tissue. Interestingly, we observed a more pronounced colocalization with vascular A β compared to amyloid plaques in AD brains.

Chapter 4

We investigated BBB alterations in CAA-affected capillaries with the emphasis on tight junction (TJ) changes and signs of neuroinflammation. We show that A β is toxic to brain endo-

thelial cells via binding to RAGE and concomitant ROS production, which ultimately leads to disruption of TJs and loss of BBB integrity, as shown by the leakage of fibrinogen in capCAA tissue.

Chapter 5

The expression and function of ABC transporters might be critical in the development of AD and (cap)CAA. We demonstrate that Pgp and BCRP are downregulated in capCAA, not in AD, and that A β and clusterin influence the expression level of P-gp. This might play a pivotal role in the development of the different amyloid deposits.

Chapter 6

In this chapter we summarize and discuss the results of this thesis.

Abstract

Cerebral amyloid angiopathy (CAA) affects brain parenchymal and leptomeningeal arteries and arterioles but sometimes involves capillaries (capCAA) with spread of the amyloid into the surrounding neuropil, that is, dyschoric changes. We determined the relationship between capCAA and larger vessel CAA, A amyloid (A β) plaques, neurofibrillary changes, inflammation, and apolipoprotein E (APOE) in 22 cases of dyschoric capCAA using immunohistochemistry. The dyschoric changes contained predominantly A β 1-40, whereas dense bulblike deposits adjacent to the capillary wall contained mostly A β 1-42. There was an inverse local correlation between A β plaque load and capCAA severity ($p = 0.01$), suggesting that A β transport between the neuropil and the circulation may be mechanistically involved. Deposits of hyperphosphorylated tau and ubiquitin and clusters of activated microglia, resembling the changes around A β plaques, were found around capCAA but were absent around larger vessel CAA. In 14 cases for which APOE genotype was available, there was a high APOE- ϵ 4 allele frequency (54%; 43% homozygous). The severity of CapCAA increased with the number of ϵ 4-alleles; and APOE4 seemed to colocalize with capCAA by immunohistochemistry. These results suggest that capCAA is pathologically and possibly pathogenetically distinct from larger vessel CAA, and that it is associated with a high APOE- ϵ 4 allele frequency.

Key Words: Alzheimer, Capillary cerebral amyloid angiopathy, Cerebral amyloid angiopathy, Dementia, Dyschoric, Neuroinflammation.

Introduction

Sporadic cerebral amyloid angiopathy (CAA) is characterized by deposits of A-amyloid (A β) in meningeal and parenchymal arteries, arterioles, and to a lesser extent, brain capillaries (Revesz, et al., 2003). Cerebral amyloid angiopathy is a common finding at autopsy, and its incidence increases with age and occurs in 70% to 100% of Alzheimer disease (AD) patients (Bergeron, et al., 1987; Ellis, et al., 1996). Cerebral amyloid angiopathy may occur in any region of the brain and spreads in a characteristic pattern starting in the neocortex, where the occipital lobe is a predilection site; it may involve other brain areas, including the diencephalon, striatum, and cerebellum (Alafuzoff, et al., 2009; Thal, et al., 2003). Sporadic CAA can be classified into CAA-type 1, involving cortical capillaries in addition to leptomeningeal and cortical arteries and arterioles, and CAA-type 2, not involving cortical capillaries (Thal, et al., 2002). Capillary CAA (CapCAA) can occur in any stage of CAA-type 1 and correlates with severity of AD pathology, whereas larger vessel CAA does not (Attems and Jellinger, 2004; Jellinger and Attems, 2005). A remarkably high apolipoprotein E- ϵ 4 (APOE- ϵ 4) allele frequency (46.7%) has been found in subjects with CAA-type 1 (6). Capillary CAA is relatively frequently found in subjects with advanced A β deposition in the brain, and severe capCAA in the absence of neuritic plaques has been described in a limited number of APOE- ϵ 4 homozygous subjects (Thal, et al., 2008; Vidal, et al., 2000). In capCAA-affected capillaries, more than in larger CAA-affected vessels, flame-like amyloid deposits may extend beyond the vessel wall and radiate into the neuropil, that is, “dyshoric angiopathy” (Attems, 2005).

Although many capCAA-affected vessels exhibit dyshoric changes, they are not a prerequisite for capCAA. Here, we use the term dyshoric changes in capCAA to describe plaque-like AA aggregates attached to the basement membranes of capillaries entering the pericapillary neuropil. This is based upon the description of dyshoric angiopathy by Surbek (Surbek, 1961) in 1961, which distinguished capillaries with plaque-like amyloid deposits (dyshoric angiopathy) from parenchymal plaques. The term angiopathy dyshorique was originally introduced by Morel in 1950 (Morel, 1950) and interpreted as congophilic angiopathy (synonymous with CAA), with parenchymal lesions by Pantelakis (Pantelakis, 1954) in 1954. This terminology was derived from translating the original German description of CAA, which used the term *Drusige Entartung*, as used by Scholz (Scholz, 1938), who in 1938 first systematically reported that the substance in this specific form of angiopathy was the same as the main component

of senile plaques. This term already made the link with amyloid plaques, which were called Alzheimer Drusen at that time and meant the occurrence of plaquelike silver-and Congo red-stainable material in blood vessels. The vascular changes covered by this description were those in larger vessels as well as dyschoric changes in capillaries representing electron-dense amyloid material in the affected vessel walls (Schlote, 1965; Scholz, 1938). Here we use the term capCAA for amyloid laden capillaries and dyschoric changes to denote the amyloid deposits radiating into the neuropil. Some previous studies of capCAA report that A β 1-42 is the most prominent isoform in globular deposits and that both A β 1-40 and A β 1-42 are present in the capillary wall; A β 1-40 is mainly found in larger vessel CAA (Attems, et al., 2004; Jeynes and Provias, 2006; Oshima, et al., 2006). Little is known about the precise composition of the dyschoric changes. The presence of A β 1-40 in capCAA has been reported to correlate with the amount of A β 1-40 in plaques, but there are conflicting results for the correlation between capillary A β 1-42 and plaque A β 1-42 (i.e. some have found a positive correlation (Attems, et al., 2004), whereas this correlation was negative in other studies (Jeynes and Provias, 2006; Oshima, et al., 2006).

Neurofibrillary changes have been observed around A β -laden arteries and arterioles in CAA (Delacourte, et al., 1987; Williams, et al., 2005). Interestingly, the presence of tau-positive structures is correlated with perivascular A β deposits, but not with A β in the vessel wall, suggesting that parenchymal A β might trigger the tau pathology (Attems and Jellinger, 2004; Delacourte, et al., 1987; Oshima, et al., 2006; Oshima, et al., 2008; Rozemuller, et al., 1989; Williams, et al., 2005).

A neuroinflammatory response, as can be seen around classical plaques, is absent around larger vessel CAA (Akiyama, et al., 2000; Eikelenboom, et al., 2008; Yamada, et al., 1997). Whether dyschoric capCAA is accompanied by inflammatory changes has not been systematically investigated, but in addition to the parenchymal A β , perivascular tau deposits might elicit an inflammatory reaction similar to that observed around plaques. This study aims to further investigate the differences between dyschoric capCAA and larger vessel CAA, with respect to the distribution of different A β -isoforms, the relationship with plaques, the surrounding neurofibrillary changes, signs of inflammation, and the correlation with the APOE- ϵ 4 allele.

Materials and Methods

Subjects and Clinical Data

Patient selection was based on neuropathologic findings at autopsy; collection of clinical data was performed retrospectively. Subjects with extensive capCAA and dyschoric changes were collected from 4 neuropathologic databases that contain autopsies between 2000 and 2007. The databases contain subjects with different types of dementia (mostly AD), and Parkinson disease (PD) and related disorders; subjects without dementia who donated their brains to the Netherlands Brain Bank; and subjects who died of a variety of nonneurological diseases in 1 academic hospital. Inclusion criteria were based on the neuropathologic finding of capCAA and not on clinical characteristics. Both subjects with and without dementia were included if there was marked capCAA. Subjects with very mild capCAA, with small number of A β -positive capillaries in some of the microscopic fields were excluded because this is a rather common finding in an aged population. All subjects or their legal representatives had signed an informed consent form for use of clinical data and tissue for scientific purposes before the information was added to the databases. In total, 22 patients with capCAA were included, with an average age of 77.9 years (SD, 7.7 years; range, 65-95 years); of these, 10 (46%) were men.

Neuropathologic Assessment

The brain specimens were obtained at autopsy with postmortem intervals of less than 15 hours. For neuropathologic diagnoses, blocks of 5 cortical areas, basal nuclei (including nucleus accumbens), thalamus, hippocampus, amygdala, mesencephalon, pons and medulla oblongata, and cerebellum were examined with routine stains (hematoxylin and eosin, periodic acid Schiff-Luxol fast blue). Hippocampus and cortical areas were also stained with methenamine silver and/or an antibody against A β 1-17, and either Gallyas or tau (AT8). All additional neuropathologic evaluations for this study were performed on formalin-fixed paraffin-embedded tissue from occipital pole cortex (Brodmann area 18/19).

Staging of neurofibrillary changes was done according to Braak and Braak (Braak, et al., 2006; Braak and Braak, 1991). To determine the CAA stage, temporal pole cortex, hippocampus (essentially CA1 and entorhinal area of the parahippocampal gyrus), cerebellum (vermis), and striatum (pallidum and caudatum), were analyzed, as described (Thal, et al., 2003).

Immunohistochemistry

Examinations were performed on 5- μ m-thick sections of formalin-fixed (4%, 24 hours) par-

affin-embedded tissue. To quench endogenous peroxidase activity, sections were treated with 0.3% H₂O₂ in methanol for 30 minutes. Antigen retrieval was performed in either 10 mmol/L pH 6.0 sodium citrate buffer heated by microwave for 10 minutes and cooled to room temperature or formic acid for 15 minutes at room temperature and subsequently rinsed in water and PBS. Sections were stained using the avidin-biotin-peroxidase complex method, EnVision method, or Power Vision method, as described (Copani, et al., 2006; Hoozemans, et al., 2009). The primary antibodies, dilutions, and manufacturers of the antibodies are listed in Table 1. The sections stained for AT8 (anti-paired helical filament tau), ubiquitin, glial fibrillary acidic protein (GFAP), and HLA-DR (LN3) were costained with Congo red to visualize the relationship between these changes and the capCAA.

Immunofluorescent double staining for A β 1-40 (mouse IgG2b) and A β 1-42 (mouse IgG1) was performed by means of goat anti-mouse isotype-specific secondary antibodies to visualize the distribution of the different isoforms around the capillaries as previously described

Morphological Analysis and Quantification

Morphological analysis of capCAA and larger vessel CAA scores were determined in sections stained with antibodies against A β 1-17, A β 1-40, and A β 1-42. Vessels smaller than 10 μ m were defined as capillaries. Microscopic fields (n = 4) (capillaries, magnification 10 \times ; larger vessels, magnification 2.5 \times) were analyzed. The A β -positive vessels were scored as follows: 0, none; 1, occasional positive vessel (<20%); 2, several positive vessels scattered throughout the field (20%-60%); 3, most vessels affected (>60%). The presence of A β plaques (plaque severity) was quantified in the same manner as the number of A β -positive larger vessels (0, none; 1, occasional plaque; 2, several plaques scattered throughout the field; 3, abundant presence of plaques).

The AT8 and ubiquitin immunostains were scored as follows: 0, none; 1, mild (occasional immunoreactivity [IR]); 2, moderate (scattered throughout the field); and 3, severe (surrounding most capillaries). All scoring was done by 2 raters (Edo Richard and Anna Carrano). Both raters assigned a score to every section, taking into account the whole section; the definite score was then assigned in consensus. The observers were blinded to the clinical diagnosis and any patient information.

Sections double stained with the primary antibodies and Congo red and for A β 1-40/1-42 were evaluated in a qualitative way. Adjacent sections were stained for determination of colocalization of APOE4 and A β 1-17.

Statistical Analysis

Because of the relatively small number of subjects in the study, and the use of ordinal scales to grade neuropathologic changes, nonparametric tests were used for all analyses. Spearman's rank correlation coefficients were calculated. Mann-Whitney U statistics was used for analyzing dichotomized variables.

Results

Subjects

Of the 22 patients with capCAA identified from the 4 databases based on the description of capCAA in the neuropathologic reports, 4 cases were found among 89 cases in a database of

subjects who were clinically suspected of having Creutzfeldt-Jakob disease (CJD), which was not confirmed at autopsy; 10 cases were from the database of the Netherlands Brain Bank (containing 380 subjects); 8 of these were diagnosed as AD and 2 had no neurological disease; 4 of 110 cases were from the database with PD and related disorders; and 2 cases were from the general pathology database of an academic hospital-one of these was diagnosed as AD, and one had no dementia (Table 2).

Neuropathologic Findings

All clinically diagnosed AD patients and 4 of 6 CJD-suspected cases fulfilled neuropathologic criteria for AD with respect to tau pathology, Braak tangle stage of IV, or higher. All clinically diagnosed PD cases had Lewy body pathology, in addition to moderate tau pathology. The 3 cases without dementia had Braak tangle scores of I to III.

A β Deposition

Dyshoric changes were mainly observed around the capillaries and only rarely around larger vessels. Both A β 1-40 and A β 1-42 were detected around the capillaries, and they were highly correlated (Spearman ρ 0.855, $p < 0.001$), but their distributions differed. A β 1-40 was the main component of the dyshoric changes; in addition to its main component in the vessel wall, it completely surrounded the capillary with extensive spread into the neuropil (Figs. 1A, C). On the other hand, A β 1-42 was mainly present in dense bulblike deposits directly adjacent to and to a lesser extent in the capillary wall. To a much lesser degree than A β 1-40, there were flame-like deposits radiating into the neuropil (Figs. 1B, C). This is the reverse of the distribution in plaques with a dense core consisting of A β 1-40 and a diffuse spread around consisting of mainly A β 1-42 (Figs. 1E, F).

The severity of capCAA correlated with the severity of larger vessel CAA (Spearman ρ 0.71, $p < 0.001$). Capillary CAA occurred in any stage of CAA, and no subjects had capCAA without any larger vessel CAA. There was a significant inverse correlation between capCAA severity and plaque density, with relatively few plaques in subjects with the most extensive capCAA (Spearman [rho] -0.52, $p = 0.013$; Fig. 2). When A β 1-40 and A β 1-42 were analyzed separately, this correlation was the same for both isoforms (Spearman [rho] -0.59, $p = 0.004$ vs -0.53, $p = 0.011$; Fig. 2). No significant correlation was found between larger vessel CAA and plaque load (Spearman [rho] -0.39, $p = 0.076$).

Figure 1. (A-F) Immunofluorescent double staining for β -amyloid ($A\beta$) 1-40 (green) and $A\beta$ 1-42 (red), illustrating the distribution of the 2 isoforms in capillaries with the surrounding dyschoric changes (A-C) and plaques (D-F).

Figure 2. (A-C) Correlation between capillary cerebral amyloid angiopathy (capCAA) severity and plaque severity (scored as 0-3) analyzed for β -amyloid ($A\beta$) 1-17 (A), $A\beta$ 1-40 (B), and $A\beta$ 1-42 (C). Scale bars = mean \pm SEM. * $p < 0.05$, *** $p < 0.001$.

Tau and Ubiquitin

Few or no neurofibrillary tangles were observed in the occipital cortex of any of the subjects, although they were present in other brain regions, particularly in the AD cases (Table 2, Braak tangle score). AT8 IR was observed surrounding Congo red-positive dyschoric capillaries and was virtually absent around the larger Congo red-positive vessels (Figs. 3J, K). Similarly, ubiquitin

ubiquitin-positive neuritic dystrophy was found around capCAA, but not around larger Congo red-positive vessels (Figs. 3M, N).

The extent of AT8 immunoreactivity correlated with the severity of ubiquitin reactivity (Spearman ρ 0.527, $p = 0.03$). The cases with little ubiquitin (score ≤ 2) had significantly less AT8 IR than the cases with abundant ubiquitin (>2) (0.8 vs 2.4, $p = 0.001$). No cases had tau pathology in the absence of ubiquitin IR; whereas in 2 cases, ubiquitin IR without any tau pathology was observed around the dyschoric capCAA-affected vessels.

Glia Activation

Double staining for GFAP and Congo red demonstrated the presence of astrocytes around virtually all A β -laden vessels, albeit strongest around capillaries, in particular, in the presence of dyschoric changes, which were surrounded by clusters of GFAP-immunoreactive astrocytes (Figs. 3G, H). Clusters of HLA-DR-positive microglia were strongly associated with A β -laden capillaries with dyschoric changes but were only sporadically observed around larger vessels harboring CAA (Figs. 3D, E). Clusters of activated microglia and astrocytes were found around the classical plaques in the same region. In the control subjects, some GFAP IR was present, but no HLA-DR-positive microglia were seen.

APOE

The APOE genotype was available for 14 of 22 cases. The APOE $\epsilon 4$ allele frequency in this cohort was 54%; 6 (43%) of 14 patients were homozygous for the APOE $\epsilon 4$ allele. Of the 8 subjects in whom the APOE genotype was not determined, 7 had APOE4 IR compatible with the presence of at least 1 $\epsilon 4$ allele. When stratified for APOE genotype, subjects with at least 1 APOE $\epsilon 4$ allele had higher scores for capillary A β 1-17 (2.4 vs 2.0), A β 1-40 (2.1 vs 1.4), and A β 1-42 (2.3 vs 2.0) than subjects without an $\epsilon 4$ allele. In these small groups, none of these differences reached significance, but there was a trend (particularly for A β 1-40) toward more severe capCAA depending on the number of $\epsilon 4$ alleles (Fig. 4). Subjects homozygous for the $\epsilon 4$ allele had the strongest association with capillary A β , as shown on adjacent sections stained for APOE4 and A β 1-17 (Fig. 5).

Discussion

We describe neuropathologic changes accompanying the parenchymal A β surrounding capCAA with dyschoric changes in a series of 22 cases. Because different neuropathologic databases tend to contain disproportionate numbers of patients with specific diseases, subjects were selected from 4 different databases to obtain a sample with as little bias toward a specific category of subjects as possible. Despite this, selection bias might have contributed to an overrepresentation of subjects with dementia in our sample as a result of the relative overrepresentation of subjects with dementia in these databases. Therefore, clinical data of these subjects in relation to the neuropathologic findings should be interpreted with caution. The cases with clinical diagnosis of AD and PD were confirmed on neuropathologic analyses. All of the cases suspected of having CJD had rapidly progressive dementia, and at autopsy were found to have significant tangle pathology; in 4 cases, this fulfilled neuropathologic criteria for AD.

We found several neuropathologic differences between capCAA and larger vessel CAA. Consistent with previous reports, we demonstrated that in capCAA-affected vessels, A β 1-42 is present within the walls of A β -laden capillaries and in dense bulblike deposits adjacent to the capillary wall (Attems, et al., 2004; Jaynes and Provias, 2006; Oshima, et al., 2006). In previous studies, A β 1-42 was found to be the main isoform in capCAA as opposed to A β 1-40 in larger vessel CAA. In capCAA in our cases, A β 1-40 was mainly as dyschoric deposits spreading into the neuropil and to a relatively lesser degree in the vessel wall, whereas A β 1-40 deposits were in the larger vessel wall CAA. A possible explanation for this difference with previous reports could be that few patients in previous series had abundant dyschoric changes (i.e. in which A β 1-40 is the most prominent isoform); therefore, A β 1-42 was described as the main isoform in capCAA.

The high APOE ϵ 4 allele frequency (54%) is similar to that found by Thal et al (Thal, et al., 2002) in their series of capCAA (46.7%). This frequency is much higher than that in the general population (14%) and in late-onset sporadic AD (37%) (Slooter and van Duijn, 1997). Moreover, the incidence of ϵ 4/ ϵ 4 homozygous subjects of 43% is extraordinarily higher than that in the general population (3%) and in AD cases (13%) (Poirier, et al., 1993). It is also much higher than in the series of Thal et al (Thal, et al., 2002), in which 3 (20%) of 15 genotyped type 1 CAA subjects had the ϵ 4/ ϵ 4 genotype. Taken together, these findings indicate that this specific genotype might represent a strong risk factor for the occurrence of capCAA, specifi-

Figure 3. Immunoreactivity in capillary cerebral amyloid angiopathy (capCAA) (left column of panels), CAA (middle column of panels), and plaques (right column of panels). (D-O) Panels show double staining with Congo red. (A-C) β -Amyloid ($A\beta$) 1-17 staining. The dyschoric changes are found around the capillaries, and not the larger vessels. (D-F) Microglial activation (LN3 staining) around the capillaries, particularly when there are dyschoric changes. (G-I) Glial fibrillary acidic protein-positive reactive astrocytes are seen around both capillaries and larger vessels, mostly when there is a dyschoric component. (J-L) Hyperphosphorylated tau (AT8 staining) is seen only around the $A\beta$ -laden capillaries and hardly around the larger vessels. (M-O) Ubiquitin is found around the $A\beta$ -laden capillaries, mainly when there are dyschoric changes, and not around the larger vessels.

cally with concomitant dyschoric changes (Vidal, et al., 2000). The very high percentage of $\epsilon 4/\epsilon 4$ genotype might be explained by the fact that the subjects in our study were selected based on the recognition of widespread capCAA, thereby probably including more severe cases. The importance of the $\epsilon 4$ allele in the pathogenesis of capCAA is illustrated by the colocalization of APOE4 with capillary A β and the increasing severity of capCAA with increasing number of $\epsilon 4$ alleles. Although a strong genetic risk factor for dyschoric capCAA, the presence of an $\epsilon 4$ allele is not required because 5 (36%) of 14 genotyped subjects did not carry an $\epsilon 4$ allele. The observation of tau pathology and ubiquitin IR around the capCAA-affected vessels in the occipital lobe, an area where few tangles are found (even in advanced AD), is remarkable. This supports the hypothesis that the tau pathology may be secondary to the A β deposits around the capillaries (Delacourte, et al., 1987; Oshima, et al., 2006; Oshima, et al., 2008; Williams, et al., 2005). Whether this relationship with tau-IR is different in other regions of the brain (e.g. with more neurofibrillary tangles) or whether capCAA in different regions can occur without any tau IR was not investigated. The presence of ubiquitin and tau close to the dyschoric changes closely resembles the changes that occur around classical plaques in AD. The fact that some cases exhibit ubiquitin without any tau pathology, but no cases exhibit tau pathology without any ubiquitin, suggests a sequence of events similar to what happens around A β plaques, where ubiquitin IR can be found before tau.

Also similar to the changes around A β plaques in AD are the clusters of activated microglia around the dyschoric A β -laden capillaries, indicating a strong inflammatory response, which is absent around larger A β -laden vessels (Arends, et al., 2000; Rozemuller, et al., 2005). The inflammatory reaction associated with A β plaques is thought to play a role in the pathogenesis of AD and likely contributes to the symptoms of cognitive decline (Arends, et al., 2000; Rozemuller, et al., 2005). Whereas larger vessel CAA is generally considered not to contribute to the development of cognitive decline, we hypothesize that the parenchymal A β in dyschoric capCAA with the associated deposits of tau and neuroinflammatory response, resembling the changes around A β plaques in AD, could contribute to cognitive decline.

The inverse local correlation between capCAA severity and plaque density around the capillaries is striking and provides a semiquantitative support for the speculation made by Surbek (Surbek, 1961) in 1961. Previous studies that have addressed this issue are contradictory, but this might be explained by different definitions of capCAA and by the fact that no clear distinction was made between capCAA with and without dyschoric changes (Attems and Jellinger,

2004; Jeynes and Provias, 2006; Oshima, et al., 2006). The inverse local correlation between plaques and capCAA is compatible with the hypothesis of A β transport between the neuropil and the circulation, that is, increased A β in and around capillaries might be accompanied by a decrease of A β plaques. This is consistent with the findings in a recent A β vaccination trial in AD patients, in which it was shown that a decrease in plaque load was accompanied by an increase in CAA severity (Boche, et al., 2008). Subsequently, CAA severity decreases again, suggesting that A β removal from plaques and clearance via the vascular system can occur and is a dynamic process (Boche, et al., 2008).

Several possible mechanisms of A β clearance have been hypothesized. There is clearance of A β via receptor-mediated transport across the blood-brain barrier (Deane and Zlokovic, 2007; Shibata, et al., 2000; Tanzi, et al., 2004) and another possible route of A β elimination is perivascular drainage of A β . Impaired clearance along this route might explain greater amounts of A β deposition in the brain that could ultimately lead to cognitive decline (Weller, et al., 2008). Our findings might be compatible with such a faulty blood-brain barrier clearance mechanism, resulting in accumulating deposits in and around the capillaries and leading to dyschoric angiopathy. They could also be consistent with obstruction of the perivascular route that would result in accumulation of A β as CAA and finally capCAA. However, Cap-CAA can occur with relatively little larger vessel CAA, suggesting that the problem does not necessarily start downstream from the capillaries, but rather with insufficient clearance at the blood-brain barrier in the capillaries.

Taken together, the pathological hallmarks of capCAA with dyschoric changes clearly differ from larger vessel CAA. This underscores the concept that CAA types 1 and 2 represent dis-

Figure 4. (A-C) Capillary cerebral amyloid angiopathy (capCAA) and plaque severity stratified for apolipoprotein E4 (APOE) genotype analyzed in the β -amyloid (A β) 1-17 (A), A β 1-40 (B), and A β 1-42 (C) stains show an apparent correlation between capCAA severity and APOE genotype. Values are presented as mean \pm SEM.

Figure 5. (A-F) Adjacent sections (10x) stained for β -amyloid ($A\beta$) 1-17 (A, C, E) and apolipoprotein E4 (APOE4) (B, D, F) in a patient with no $\epsilon 4$ allele (A, B), $\epsilon 4$ heterozygous (C, D), and $\epsilon 4$ homozygous (E, F). The dyschoric capillary cerebral amyloid angiopathy severity is low in the $\epsilon 4$ -negative subject, intermediate in the heterozygous subject, and high in the homozygous subject.

tinct neuropathologic entities. Several novel findings from the current study support this difference. We describe for the first time that $A\beta_{1-42}$ is the main isoform in capCAA, as opposed to $A\beta_{1-40}$ in larger vessel CAA. Although absent around larger vessel CAA without dyschoric changes, we show that capCAA is associated with tau deposits and clusters of activated microglia, closely resembling the hallmarks of parenchymal neuritic plaques in AD. In view of these

parenchymal changes, we hypothesize that dyschoric capCAA could possibly contribute to cognitive decline. We found a strong association with the APOE- ϵ 4 allele, and the increasing capCAA severity with increasing number of ϵ 4 alleles is remarkable and novel. Although the negative correlation between dyschoric capCAA and local plaque load was suggested as early as 1961, we confirm this finding based on a semiquantitative analysis. The strong association with APOE- ϵ 4 and the negative correlation between dyschoric capCAA severity and the local plaque load suggest a role for faulty A β transport between the parenchyma and the capillary system in the pathogenesis of accumulation of A β in the neuropil surrounding the capillaries. Future studies on expression of proteins involved in transendothelial A β transport in subjects with capCAA with dyschoric changes may help clarify the underlying mechanisms.

Acknowledgments

The authors thank Dr. R.A.I. de Vos (Enschede, The Netherlands) and E. Ghebremedhin (University of Queensland, Brisbane, Australia), who contributed to the neuropathology and APOE genotyping of the subjects in this study from the Laboratory for Neuropathology East Netherlands, Enschede, The Netherlands.

Supplementary Data

ELISA A β 40 and A β 42 (in collaboration with Alex Roher)

Immunoassays for A β 40 and A β 42 were performed on capCAA and AD cases, as illustrated in Fig. 1. In conformity with the neuropathological observations, quantitation of soluble and insoluble A β peptides demonstrated statistical differences between capCAA and AD, with respect to the ratio and amount of A β species. In the Tris-soluble samples (Fig. 1A) the capCAA cases demonstrated a strikingly greater mean value of both A β 40 (capCAA = 1466 pg/mg total protein; AD = 112 pg/mg total protein; $p = 0.0002$) and A β 42 (capCAA = 218 pg/mg total protein; AD = 70 pg/mg total protein; $p = 0.0114$). A similar difference between capCAA and AD was observed in the Guanidine-HCl soluble samples (Fig. 1B) for levels of A β 40 (capCAA = 205632 pg/mg total protein; AD = 16973 pg/mg total protein; $p = 0.0524$) and A β 42 (capCAA = 270840 pg/mg total protein; AD = 91606 pg/mg total protein; $p = 0.0213$).

Supplementary Figure 1. Elisa quantification of A β 40 and A β 42 in capCAA and comparison with AD. A. Trizma soluble A β levels shows a striking increase of A β 40 in capCAA respect to AD, with a ratio A β 40:A β 42 4.2 times higher in capCAA. A similar ratio A β 40:A β 42 is observed in the Guanidine-HCl fractions (4.09 times higher in capCAA respect to AD). All values are adjusted for total protein. The statistical analysis used was an unpaired, 2-tailed t-test. capCAA= capillary cerebral amyloid angiopathy, AD= Alzheimer's disease

All steps were performed at 4°C. Occipital lobe tissue pieces (100 mg) were homogenized in 6 volumes (600 μ l) of 20 mM Tris-HCl, 5 mM EDTA, pH 7.8, protease inhibitor cocktail (PIC, Roche Diagnostics, Mannheim, Germany) with a Teflon tissue grinder. The homogenate was centrifuged in a TLA 120.2 rotor (Beckman) for 20 min at 435,000 \times g. The Tris-HCl-soluble supernatant was collected and total protein measured with the Micro BCA protein assay kit

from Pierce (Rockford, IL). The remaining pellet was dissolved in 600 μ l of 90% glass distilled formic acid (GDFA) with an electric grinder (Omni TH, Kennesaw, GA) and incubated for 1 h. The GDFA homogenates were then centrifuged at $435,000 \times g$ in a TLA 120.2 rotor for 20 min. The supernatant was collected and dialyzed 3 times, 30 min each against deionized water then twice for 1 h against 0.1 M ammonium bicarbonate and lyophilized. The lyophilized material was reconstituted in 500 μ l 5 M guanidine hydrochloride (GHCl), 50 mM Tris-HCl, pH 8.0, PIC (Roche), shaken for 3 h, centrifuged at $435,000 \times g$ in a TLA 120.2 rotor for 20 min, the supernatant collected and total protein determined with Pierce's Micro BCA protein assay kit. A β 40 and A β 42 were quantified with ELISA kits from Invitrogen according to the manufacturers' instructions.

Supplementary Figure 2. Microglia activation around diverse dyschoric A β deposits: flames vs. bulbs. A, C depict adjacent tissue slices of a capCAA case showing severe flame-like vascular A β deposits. B, D present a case with severe bulb-like vascular A β . A β staining is visible in brown in A and B. In C and D activated microglia are shown in brown around capCAA microvessels loaded with A β (in pink, stained with Congo red)

Microglia activation

Microglia are strongly activated around dyschoric changes. Especially the flame-like A β deposits evoke a severe inflammatory reaction, when compared to the mild glia activation in response to the more compact and contained bulb-like deposits as shown in Fig. 2.

Activated microglia surrounding capCAA lack the expression of microglia marker CD45 (Fig. 3). CD45, also known as leukocyte common antigen (LCA), is expressed constitutively by resting microglia and it is further inducible at the cell surface during activation (Carson, et al., 1998; Sedgwick, et al., 1991). CD45 negative microglia have a proinflammatory phenotype (release more cytokines) and have less phagocytic abilities in an AD mouse model (Zhu, et al., 2011).

Supplementary Figure 3. CD45 expression in activated microglia. A, B, C, D show in brown A β staining. E, F, G, H, show in brown CR3/43 (a MHC class II marker) positive activated microglia. I, J, K, M show in brown CD45 positive activated microglia. In control cases glia activation is absent or negligible (A, E, I). In non demented cases that presents with plaques glia activation is already present (B, F, J) although is not as strong as in full blown AD (C, G, K) or capCAA (D, H, M). Also notice the striking lack of CD45 positivity in activated microglia around capCAA (M). LCA (leukocyte common antigen) = CD45

Abstract

Alzheimer's disease (AD) is characterized by progressive cognitive impairment associated with accumulation of amyloid β ($A\beta$) in the brain parenchyma such as plaques and in cerebral blood vessels as cerebral amyloid angiopathy (CAA). Over half of the number of AD cases show presence of $A\beta$ accumulation in and around cortical capillaries, which is referred to as capillary CAA (capCAA). CapCAA cases exhibit a compromised blood-brain barrier (BBB), which might contribute to impaired $A\beta$ clearance observed in AD cases. With this exploratory proteomic analysis using human *post-mortem* brain tissue we aimed to identify differentially expressed proteins in cases with profound capCAA pathology compared to AD, in order to reveal specific insight in underlying molecular mechanisms resulting in disturbed clearance of $A\beta$ across the BBB. Furthermore, by profiling the proteomes of capCAA patients and comparing them with AD cases, we aimed to identify proteins and (patho-)biological processes that are involved in the pathogenesis of capCAA and novel biomarkers for the differential diagnosis of capCAA and AD. Using mass-spectrometry we identified 1547 proteins in total, of which 29 were differentially regulated in capCAA compared to AD and controls, including clusterin (ApoJ), serum amyloid P component (SAP) and laminin β 2. Immunohistochemical evaluation revealed that these proteins co-localized with $A\beta$ deposits, predominantly microvascular over parenchymal. Interestingly, previous studies have demonstrated that these proteins are involved in $A\beta$ aggregation and clearance from the brain, implying the involvement of altered clearance mechanisms in the pathophysiology of capCAA.

Introduction

Alzheimer's disease (AD) is the most common form of dementia in the elderly affecting 10% of the population aged over 65 years (de Jong, et al., 2007). AD is characterized by accumulation of amyloid β ($A\beta$) protein in the brain parenchyma and in the cerebrovasculature. Excessive deposition of $A\beta$ is thought to be the result of an imbalance between $A\beta$ production and $A\beta$ removal and increasing evidence suggests that in sporadic late-onset AD this process is driven by an impaired clearance of $A\beta$ (Goos, et al., 2012).

The blood-brain-barrier (BBB) plays an essential role in the clearance of $A\beta$ from the brain to periphery. A disturbance in $A\beta$ clearance across the BBB is illustrated in cases that exhibit deposition of $A\beta$ in and around cortical capillaries, also referred to as capillary cerebral amyloid angiopathy (capCAA). CapCAA is observed in up to 51% of AD cases and is associated with the clinical progression of AD (Thal, et al., 2008). Little is known about the molecular mechanism leading to capCAA in AD pathogenesis and how amyloid deposition in the vessel wall affects disease development. Considerable effort has been made in understanding the pathogenesis of AD and the development of novel therapeutic approaches. However to date, there is no effective treatment that can prevent, delay or cure the disease and most of the latest clinical trials focusing on decreasing $A\beta$ load in the brain have been failing. Interestingly, anti- $A\beta$ immunization therapies while able to reduce the amount of plaque in the brain parenchyma led, in some patients, to increased accumulation in the vasculature and consequent vasogenic edema (Alzheimer, 1907; Dierksen, et al., 2010). Clinical diagnosis of "probable AD" is based on neuropsychological examination together with neuroimaging and biochemical analysis of the cerebrospinal fluid. Although guidelines to diagnose CAA during life exist (Boston criteria) (Fischer, 1907), these are not specific for capCAA. Hence currently, it is not possible to clinically define whether an AD case has signs of ongoing or progressive capCAA. Recently, we neuropathologically defined clinical AD cases which show extensive capCAA pathology without presence of senile plaques and only minor tau depositions as tangles (Richard, et al., 2010). These cases are characterized by extensive activated NOX-positive glia recruited around vascular $A\beta$ deposits and a damaged BBB showing a reduced expression of tight junction proteins (Carrano, et al., 2011a; Carrano, et al., 2012). Identification of differentially expressed proteins in cases that only show capCAA pathology might reveal insight in the underlying molecular mechanism resulting in the disturbed clearance of $A\beta$ across the

BBB and the identification of specific biomarker for capCAA.

The use of proteomics gives information about changes in the total protein network of a tissue or cell and in the recent years it has become extremely useful to study complex diseases, such as AD.

Proteomics studies focusing on the identification of AD biomarkers for early diagnosis or disease progression and for the validation of new targets for treatment are reviewed by Juhasz (Juhasz, et al., 2011). Although proteomics analysis of AD brain and AD animal models are rather abundant, to date there is no study that analyzed the capCAA proteome. Hence, we used a proteomic approach to identify differential changes in the proteome of *post-mortem* brain tissue of patients with exclusive capCAA pathology and compared these findings with AD and age-matched non-demented controls.

Analysis of the mass spectrometry data resulted in the identification of 1547 proteins in total. A number of proteins that are known to have an altered expression profile in AD compared to controls were identified, indicating the value of this approach. Interestingly, we could identify and validate proteins that were differentially upregulated in capCAA compared to AD, including clusterin (ApoJ), serum amyloid P component (SAP) and laminin β 2.

This is the first proteomic analysis on human *post-mortem* capCAA tissue to date. By profiling the proteomes of capCAA patients and comparing them with AD and control cases, we identified proteins and processes that are involved in the pathogenesis of capCAA. More research is needed to confirm our findings and to demonstrate whether differentially expressed proteins can be used as possible candidate biomarkers for the differential diagnosis of capCAA.

Material and Methods

Post-mortem tissue

Two patients with neuropathologically diagnosed pure capCAA without senile plaques, 2 AD cases without capCAA and 2 age-matched nondemented controls were selected for the proteomics analysis. These cases were also analyzed by immunohistochemical staining. A total of 5 patients with neuropathologically diagnosed capCAA, 5 AD cases without capCAA and 2 age-matched nondemented controls were selected for the validation of differentially ex-

pressed proteins by immunohistochemistry. Cases were selected on the basis of the clinical and neuropathological diagnosis and immunohistochemical characterization of A β aggregates. Human brain specimens were obtained at autopsy with a short post-mortem interval (The Netherlands Brain Bank, Amsterdam, The Netherlands and University Medical Centre in Utrecht, The Netherlands). Neuropathological evaluation was performed on frozen tissue and formalin-fixed, paraffin-embedded tissue from occipital pole cortex. capCAA score was defined as follows: severe (+++), moderate (++) , mild (+). Staging of AD was evaluated on thin paraffin embedded routine slices according to Braak and Braak (Braak, et al., 2006; Braak and Braak, 1991) and CERAD (Mirra, et al., 1991). Age, gender, post-mortem delay (PMD), Braak, CERAD and capCAA scores and cause of death are listed in Table 1.

Tissue Homogenization and Fractionation Using Gel Electrophoresis

Tissue from the occipital pole cortex was used for proteomics analysis. For homogenization, we cut a cortical piece of ~20 mg in a bath of liquid nitrogen in smaller parts. The proteins in the tissue were solubilized in 800 μ l of 1 \times reducing SDS sample buffer (containing 62.5 mM Tris-HCl, 2% w/v SDS, 10% v/v glycerol, and 0.0025% bromphenol blue, 100 mM DTT, pH 6.8) using a Pellet Pestles microgrinder system (Kontes glassware, Vineland, NJ). Subsequently, proteins were denatured by heating at 100 $^{\circ}$ C for 10 min. Any insoluble debris was removed by centrifuging for 15 min at maximum speed (16.1 relative centrifugal force) in a benchtop centrifuge.

Proteins were fractionated using one-dimensional SDS-PAGE. 25 μ l of each homogenized sample (containing about 50 μ g of protein) was loaded on a well of a precast NuPAGE 4–12% w/v Bis-Tris 1.5-mm minigel (Invitrogen). The stacking gel contained 4% (w/v) acrylamide/Bis-Tris. Electrophoresis was carried out at 200 V in NuPAGE MES SDS running buffer (50 mM Tris base, 50 mM MES, 0.1% w/v SDS, 1 mM EDTA, pH 7.3) until the dye front reached the end of the gel. Following electrophoresis, the gels were fixed with a solution of 50% ethanol and 3% phosphoric acid. Staining was carried out in a solution of 34% methanol, 3% phosphoric acid, 15% ammonium sulfate, and 0.1% Coomassie Blue G-250 (Bio-Rad) with subsequent destaining in MilliQ water.

In-gel Digestion

The gel lanes were cut in 10 bands, and each band was processed for in-gel digestion as previ-

ously described (Piersma, et al., 2010). Briefly, the bands were washed and dehydrated three times in 50 mM ammonium bicarbonate, pH 7.9, 50 mM ammonium bicarbonate, and 50% ACN. Subsequently, cysteine bonds were reduced with 10 mM DTT for 1 h at 56 °C and alkylated with 50 mM iodoacetamide for 45 min at room temperature in the dark. After two subsequent wash/dehydration cycles, bands were dried for 10 min in a vacuum centrifuge and incubated overnight with 0.06 µg/µl trypsin at 25 °C. The peptides were extracted once in 1% formic acid and subsequently twice in 50% ACN in 5% formic acid. The volume was reduced to 50 µl in a vacuum centrifuge prior to LC-MS analysis.

Table 1. Patients details

Patient #	Age (years)	sex	PMD (hrs:min)	Braak	CERAD	capCAA	cause of death
capCAA 1	71	F	< 24	IV	B	+++	pneumonia
capCAA 2	75	F	6:00	V	0	+++	dehydration
capCAA 3	65	M	7:00	V	C	++/+++	pneumonia
capCAA 4	89	F	6:55	V	B	++/+++	cachexia, pneumonia
capCAA 5	74	M	3:25	V	C	+++	died suddenly
AD 1	90	F	3:50	VI	C	-	cachexia/dehydration
AD 2	44	M	4:25	VI	C	-	unknown
AD 3	86	F	5:00	VI	C	-	uremia based on pneumonia
AD 4	83	F	7:20	VI	C	-	cachexia/dehydration
AD 5	70	F	4:20	VI	C	-	cachexia/dehydration
Control 1	75	M	n.d.	0	A	-	myocardial infarct
Control 2	72	F	n.d.	0	A	-	lung cancer, broncho-pneumonia

n.d. : no date, F: female, M: male

Note: CERAD classification can be mistaken in capCAA cases, as neuritic changes around amyloid are not necessarily neuritic plaques but can be neurofibrillary degeneration around capCAA. This is probably the case in classification CERAD A, B and C in severe capCAA cases.

Nano-LC-MS/MS

Peptides were separated by an Ultimate 3000 nano-LC system (Dionex LC-Packings, Amsterdam, The Netherlands) equipped with a 20-cm × 75-µm inner diameter fused silica column custom packed with 3-µm 100 Å ReproSil Pur C18 aqua (Dr. Maisch GMBH, Ammer-

buch-Entringen, Germany) as described before (Bergeron, et al., 1987). After injection, the peptides were trapped at 30 μ l/min on a 0.5-cm \times 300- μ m inner diameter Pepmap C18 cartridge (Dionex LC-Packings, Amsterdam, The Netherlands) at 2% buffer B (buffer A, 0.05% formic acid in MQ; buffer B, 80% ACN and 0.05% formic acid in MQ) and separated at 300 nl/min in a 10–40% buffer B gradient in 60 min. Eluting peptides were ionized at 1.7 kV in a Nanomate Triversa chip-based nanospray source using a Triversa LC coupler (Advion, Ithaca, NJ). Intact peptide mass spectra and fragmentation spectra were acquired on a LTQ-FT hybrid mass spectrometer (Thermo Fisher, Bremen, Germany). Intact masses were measured at resolution 50,000 in the ICR cell using a target value of 1×10^6 charges. In parallel, following an FT prescan, the top five peptide signals (charge states 2+ and higher) were submitted to MS/MS in the linear ion trap (3-atomic mass unit isolation width, 30-ms activation, 35% normalized activation energy, Q value of 0.25, and a threshold of 5,000 counts). Dynamic exclusion was applied with a repeat count of 1 and an exclusion time of 30 s.

Table 1. Antibodies

Primary Antibody	species raised in	Isotype	dilution	source
Laminin β 2 clone C4	mouse	IgG1	1:1000	R&D systems
SAP	mouse	-	1:200	SSI Diagnostica
Factor VIII	rabbit	-	1:50	DAKO
Clusterin clone G7	mouse	IgG1	1:100	Dept of Clinical Chemistry, Vumc Amsterdam
Anti A β 4G8	mouse	IgG2b	1:200	Signet

Database Searching

MS/MS spectra were searched against the human IPI database 3.31 using Sequest (version 27, rev 12), which is part of the BioWorks 3.3 data analysis package (Thermo Fisher, San Jose, CA). MS/MS spectra were searched with a maximum allowed deviation of 10 ppm for the precursor mass and 1 amu for fragment masses. Methionine oxidation and cysteine carboxamidomethylation were allowed as variable modifications, two missed cleavages were allowed and the minimum number of tryptic termini was 1. After database searching, the DTA and OUT files were imported into Scaffold (versions 1.07 and 2.01) (Proteome software, Portland, OR). Scaffold was used to organize the data and to validate peptide identifications using the PeptideProphet algorithm, and only identifications with a probability >95% were retained.

Subsequently, the ProteinProphet algorithm was applied and protein identifications with a probability of >99% with 2 peptides or more in at least one of the samples were retained (Alafuzoff, et al., 2009; Ellis, et al., 1996). Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped. For each protein identified, the number of spectral counts (the number of MS/MS associated with an identified protein) was exported to Excel. For quantitative analysis across samples, spectral counts were normalized on the sum of the spectral counts per biological sample.

Each sample was separated in 10 fractions that were subjected to nano LC-MS/MS. Spectral counts for identified proteins in a sample were summed across all fractions for each sample and were normalized on the total sum of spectral counts for that sample (a similar approach has been used in (Jellinger and Attems, 2005)). This gives the relative spectral count (SpC) contribution of protein i to all spectral counts in the sample (Vidal, et al., 2000). When comparing different data sets, these normalized spectral counts are used to calculate fold changes.

Spectral Count Normalization and Statistics

Normalization was performed as described previously (Pham, et al., 2010; Surbek, 1961). The spectral counts of each protein were divided by the total spectral counts of all proteins within a sample. This number was multiplied with a constant equal to the average of total spectral counts of all samples to obtain a normalized spectral count value in the same range as the non-normalized spectral counts. The beta-binomial test (Pham, et al., 2010) was applied to find proteins that show significant differences in spectral count numbers between the diseased group and the reference group. Proteins with a p value less than 0.05 were designated as being significant.

Unsupervised and supervised cluster analysis of identified proteins was performed using hierarchical clustering in R. The protein abundances were normalized to zero mean and unit variance for each individual protein. Subsequently, the Euclidean distance measure was used for protein clustering.

Network analysis

To gain insight into the possible interactions of differentially expressed proteins in capCAA tissue we used the database STRING (Pantelakis, 1954) to retrieve functional and physical interaction. First, a general network of all identified proteins was created using medium strin-

gency settings and experimental, database, and co-expression interactions, with a number of maximum interactors for each node of 100. Text mining interactions were excluded. Network data were exported to a text file and loaded in Cytoscape v 2.8.3 for network visualization and analysis. The proteins showing differential expression in the three groups comparison were selected together with their first interactors, limiting the selection to the interactors which showed at least a fold change of 2 for the comparisons capCAA vs controls or capCAA vs AD. Proteins for which interactions were not present in the STRING database were excluded from the analysis. Clustering of the final network was obtained with the clusterMaker plugin v 1.1 (Morris, et al., 2011) using the Markov Cluster (MCL) algorithm (Enright, et al., 2002), while ontologies for each cluster were obtained using BINGO plug-in (Schlote, 1965).

Immunohistochemistry analysis for validation of differentially expressed proteins

5 µm cryosections were mounted on coated glass slides (Menzel Gläser super frost PLUS, Brainschweig, Germany) and dried O/N. Sections were incubated in thioflavin S solution (100 mg/ml) for 5 minutes to stain Aβ fibrils and washed subsequently 3 times in ethanol 70%. Sections were preincubated with normal goat serum 1:10 for 10 minutes and overnight with a mix of primary antibodies (see table 2) diluted in PBS containing 1% bovine serum albumin. Next, sections were incubated with secondary antibodies for 30 minutes.

In some cases an incubation step of 1 h with Streptavidine-Alexa633 followed. For all stainings peroxidase labelling was visualized by reaction with rhodamine-tyramide (1:3000) in the presence of 0.01% H₂O₂ for 5 minutes. After washing, slides were covered with Vectashield (Vector laboratories, Burlington, CA, USA). Between all incubation steps, sections were extensively washed with PBS (pH 7.4). Fluorescent analysis was performed with a Leica TCS SP2 AOBS confocal laser-scanning microscope (Leica Microsystem, Heidelberg, Germany). Quantification of fluorescent signal was performed by ImageJ software. Four 100 times magnified fields per slides were quantified and an average was calculated.

Table 3. (Page 72) Three group comparison. List of differentially expressed proteins (p< 0.05) in the occipital cortex of capCAA patients compared with Alzheimer's disease cases and controls ranked on fold change (capCAA versus controls). Abbreviations: CAA = capillary cerebral amyloid angiopathy; AD = Alzheimer's disease; C = control; nc= normalized spectral counts; fc = fold change

Results

Differential protein expression in capCAA, AD and controls

Our primary goal was to determine the differences in protein expression profiles between capCAA, AD and control brain tissue in a small scale feasibility study with very well documented material. For comparative protein profiling, we employed a label-free workflow based on protein fractionation by gel electrophoresis coupled to nano-LC-MS/MS of in-gel digested proteins and spectral counting that has shown its validity for candidate biomarkers discovery (Albrechtsen, et al., 2010) (van Dijk, et al., 2012).

To identify proteins associated with capCAA and AD, we compared the protein expression profiles in 2 severe capCAA cases with 2 AD cases and 2 age-matched controls. The protein band patterns obtained after gel electrophoresis of the 6 brain lysates and Coomassie staining were similar in terms of overall pattern and intensity (Fig.1a), thereby ensuring reliable label free comparison.

In total 1546 proteins were identified across all 6 samples (Fig. 1b) (see supplementary table 1 for the full list of identified proteins). The number of proteins identified in the capCAA brain samples was 1487, with 1235 identified in both samples, indicating acceptable reproducibility of protein identification and quantification across different biological samples. Similar values were obtained for the AD and control brain samples (see Fig. 1b).

44 proteins were not identified in the controls samples; most of these proteins are shared between the capCAA and AD group, 8 proteins are unique to capCAA, while 10 are found only in AD cases.

To obtain a global overview of the data set, we performed unsupervised hierarchical clustering using the normalized spectral count data from the identified proteins that were significantly differentially expressed in the 3 groups (capCAA, AD and controls, p value < 0.05) (Fig. 1 c). Supervised hierarchical clustering using 29 differentially expressed proteins clearly showed 2 different groups that clustered according to their pathological status as diseased (capCAA and AD) and non-diseased (controls). The diseased cluster further separated in capCAA and AD. (Fig. 1d)

Identification of known markers for AD and related diseases

A β was significantly upregulated in both AD and capCAA brain lysates, with a fold change of

1.9 and 5.0 respectively, whereas tau protein was only significantly up-regulated in AD brains (fold change 2.3) not in capCAA samples (fold change 1.7, p value: 0.15).

ApoE, the most important genetic risk factor for the sporadic form of AD and CAA, was also identified in our data set. ApoE was found significantly up-regulated in the capCAA brains and in 1 of the AD cases (fold change 3.1 and 3.6 respectively). These findings underscore the validity of our proteomics approach to identify proteins associated with AD and related pathology.

Differentially expressed proteins in capCAA cases.

We identified 29 proteins that were differentially expressed in capCAA cases compared to AD and control cases (table 3). In addition, we conducted a GO enrichment analysis to identify functions, cellular localization and pathways that are differently activated between two different proteomes. The 29 significant proteins were compared to the whole list of proteins in our dataset for the GO enrichment analysis (Fig. 2).

Of the 29 proteins that were significantly different between the 3 groups, 10 were found to be upregulated and 19 downregulated in capCAA compared to controls (table 3). Because of our interest in discovering proteins specifically and differentially expressed in capCAA and AD, we also compared the expression rate between capCAA and AD samples. Of the proteins upregulated in capCAA respect to controls, only 5 revealed higher spectral counts when we compared capCAA to AD. These five proteins include amyloid precursor protein (APP), clusterin, serum amyloid P component, laminin β 2, and HUWE1. Interestingly, HUWE1 was only expressed in capCAA cases and absent in the other samples.

Of the 19 proteins downregulated in capCAA respect to controls, the expression levels of 10 were also lower when we compared them to AD profile. In this class of proteins we identified 2 dehydrogenases, aldehyde dehydrogenase 9A1 (ALDH91A) and L-lactate dehydrogenase (LDHA) (fold change -2.3 and -1.4 versus control); and 3 cytoskeleton proteins, actin-related protein 3 (ACTR3), alpha-actinin-2 (ACTN2) and microtubule-associated proteins 1A/1B light chain 3A (MAP1LC3A) (fold change -3.0, 6.4 and 4.0 versus control).

Network and pathway analysis

To obtain an interaction network of the differentially expressed proteins in the three groups

Figure 1. (a) SDS gel showing protein band patterns of the 6 brain lysates. A,D: controls; B,E: AD cases; C,F: capCAA cases. (b) Numbers of proteins identified in proteomics analysis of capCAA, AD and controls brain samples. (c) Unsupervised cluster analysis of the entire data set. (d) Supervised cluster analysis of the 29 proteins significantly differentially expressed in the 3 group comparison.

we used different tools and databases. First a total interaction network of all identified proteins was built using the online database STRING. Network visualization and analysis was carried out with the Cytoscape software. The total network of interactions consisted of 1212 nodes, representing proteins and 9017 edges representing experimental or functional interactions. To gain insight into the possible co-modulation of neighboring proteins for the differentially expressed proteins in capCAA we built a subnetwork of proteins which showed differential regulation in capCAA patients with respect to AD and control subjects with their first interactors. This subnetwork included 65 proteins and 132 interactions (figure 2). Of the 65 proteins, 12 proteins showed differential expression in capCAA vs control subjects while 10 were differential when compared to AD patients. APP was one of the most interconnected nodes in the network, showing experimental interaction with APOE and clusterin (CLU). These three proteins were all significantly up-regulated in capCAA patients with respect to controls (figure 2a) while only CLU was up-regulated significantly in capCAA when compared to AD (figure 2b). APP showed experimental interactions also with annexin 1 (ANXA1) which was

significantly up-regulated in capCAA vs AD comparison (figure 2b, fold change 7.9) and with alpha actinin 1 (ACTN1) which was decreased in capCAA patients with respect to controls (fold change -6.3).

Using cluster analysis we found 12 modules of proteins showing high interconnection. To verify if these modules were involved in specific pathways we searched for enrichment of biological processes for each of the subnetworks. The subnetwork which included the majority of differentially expressed proteins was the one with APP, CLU and APOE, mainly involved in lipid transport (figure 2c), followed by negative regulation of ubiquitin-protein ligase activity. The third sub-network, for which gene ontology analysis evidenced enrichment in cell-substrate adhesion processes, included laminin β 2 (LAMB2) and serum amyloid P component (SAP or APCS) proteins both differentially regulated in capCAA. Subnetwork number 4, involved in cell signaling and protein phosphorylation, included CAMK2D, which was significantly reduced in capCAA with respect to both AD and controls subjects (fold change = -100 for both the comparisons), but also STAT1, increased significantly in capCAA vs AD comparison (fold change = 100). The complete gene ontology enrichment analysis of the 12 clusters is reported in supplementary table 2.

Validation by immunohistochemical staining

To verify the expression of proteins upregulated in the occipital cortex of capCAA cases, immunohistochemical staining for clusterin, SAP (serum amyloid P component) and LAMB2 (laminin β 2) was performed on brain tissue slices from occipital pole cortex of capCAA, AD and controls. Protein selection was based on significances (pvalue lower than 0.05), fold change (higher than 2) and readily availability of antibodies. Furthermore these proteins, interestingly, have the ability to bind A β and modulate A β aggregation and clearance at the BBB.

To demonstrate the relationships between the mass spectrometry expression and the expression observed for the same proteins by immunostaining, we compared the fold change expression measured in the two analyses. Immunohistochemical analysis showed that clusterin, SAP and laminin β 2 were abundantly expressed in capCAA cases and colocalized with microvascular amyloid deposits. Laminin β 2, which is normally expressed in the vascular basal lamina, was predominantly increased in capCAA cases, specifically around A β -laden vessels, where the structure of the basal lamina was altered and appeared as a double barrel. In contrast,

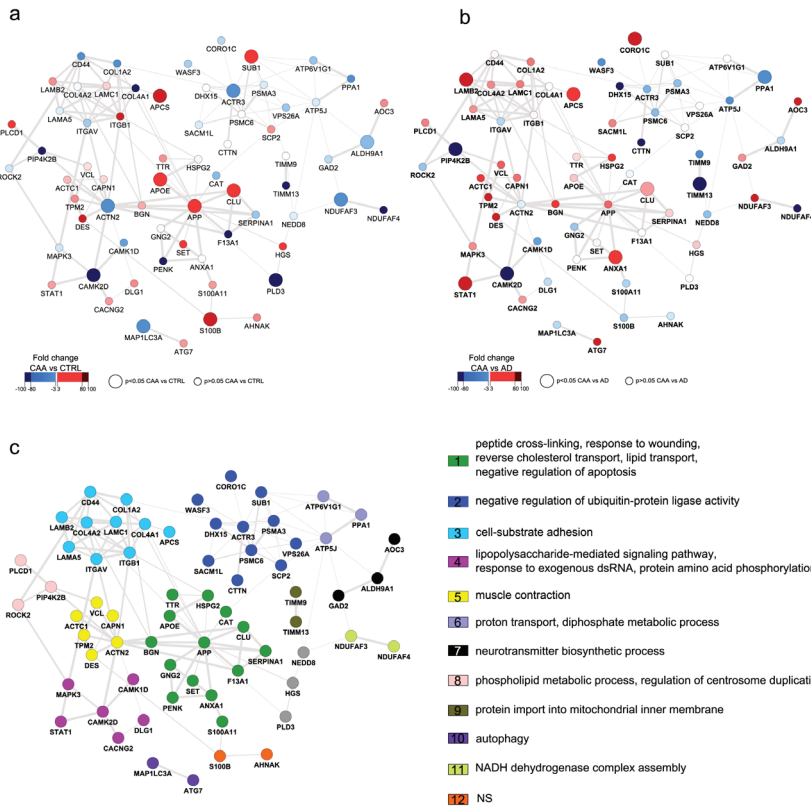

Figure 2. Interaction network of differentially expressed proteins in capCAA patients. Functional and experimental interactions were retrieved from STRING database and the proteins which showed differential expression in the 3 groups comparison were selected with their first interactors. a) fold change capCAA vs controls b) fold change capCAA vs AD, c) cluster analysis of the network. Twelve clusters were identified including a maximum of 14 proteins and a minimum of 2 proteins. On the right the most significant biological process for each cluster is reported. NS = not significant.

in AD tissue laminin expression was severely reduced, especially in the microvasculature.

SAP immunostaining revealed that this protein clearly colocalized with vascular amyloid in capCAA cases, whereas SAP was weakly expressed in and around classical plaques of AD cases and absent in control cases.

Clusterin markedly accumulated in capCAA-affected vessels and colocalized with amyloid deposits in capCAA and AD cases. However, in capCAA the expression was significantly increased compared to AD cases as clusterin not only localized to vascular amyloid deposits but also accumulated as a halo around A β -laden microvessels. Clusterin immunoreactivity was lacking in control cases.

Discussion

In the present study, we aimed to identify proteins that are associated with capCAA pathology. Because some capCAA is observed in up to 51% of AD cases (Thal, et al., 2008), we were specifically interested in proteins differently expressed between AD cases without capCAA and pure capCAA without amyloid plaques. Clinically pure capCAA cases can mimic Creutzfeldt-Jakob disease (CJD) (Eurelings, et al., 2010). Identification of differently expressed proteins might reveal novel biomarkers or targets for therapeutic intervention. To this end, we analyzed protein profiles of pure capCAA, AD and control brain samples using a high resolution tandem mass spectrometry-based proteomics approach. We identified 1547 proteins, of which 29 were significantly differentially regulated between the 3 groups. To our knowledge, this is the first proteomics analysis of capCAA and comparison with AD cases lacking microvascular amyloid deposition. We here showed that the protein expression profiles of AD and capCAA are significantly different, and particularly that such differentially expressed proteins might reveal distinct pathogenic pathways leading to these 2 subtypes of AD. Furthermore, we have demonstrated that our method based on the selection of pure severe cases is a valid approach for the identification of proteins and pathological processes important for the characterization of diverse A β -related diseases.

Classical AD markers

Although accumulation of hyperphosphorylated tau in dystrophic neurites is commonly seen surrounding A β -laden capillaries (Richard, et al., 2010), the lower Braak stage (tau pathology) and the low frequency of tau tangles in our capCAA cases might explain why tau expression is not significantly altered in capCAA cases.

ApoE is strongly associated with AD and capCAA and ApoE4 is a major genetic risk factor for AD, increasing risk and decreasing age at onset of AD dose-dependently, with the homozygotes having a higher risk (Glenner and Wong, 1984), and an even higher frequency in capCAA cases (Richard, et al., 2010; Thal, et al., 2008). ApoE is an amyloid associated protein found in all types of A β deposits. The apoE levels measured with our proteomic analysis reflected A β expression and, although up-regulated compared to controls, were not significantly different between capCAA and AD. Our small case selection was not based on ApoE genotype, but considering the influence of ApoE4 allele on AD and capCAA, this can be an interesting

approach for future studies.

Disturbed amyloid clearance

In the present study we observed specifically in capCAA an upregulation of proteins affecting the clearance of A β , a process thought to be severely compromised in AD and capCAA. Alterations in the mechanisms regulating A β clearance would, in fact, lead to a misbalance situation in which accumulated cerebral A β start aggregating and depositing as plaques or vascular CAA (Weller, et al., 2008).

Laminin β 2, SAP and clusterin were all strongly upregulated in capCAA cases, even when we compared it to AD.

Laminin, among other proteins, is present at the cerebrovascular basement membrane (Mirra, et al., 1991) and it has been suggested that basement membrane alterations may play a role

Figure 3. Validation - Laminin β 2 immunostaining (a) and quantification (b) show that laminin β 2 expression is increased in capCAA cases specifically in and around blood vessels affected by A β deposition. Laminin β 2 is expressed on the abluminal side of the vasculature where the basement membrane is located and can colocalize with vascular A β in capCAA and CAA, but does not colocalize with parenchymal plaques.

Figure 4. Validation - SAP immunostaining (a) and quantification (b) show control cases. SAP is significantly more abundant in capCAA, where it colocalizes with vascular A β , whereas it is only moderately expressed in parenchymal plaques.

Figure 5. Validation - Clusterin immunostaining (a) and quantification (b) show that clusterin is present in virtually all A β deposits both in capCAA and AD. Immunoreactivity was lacking in control cases. Clustering expression is significantly higher in capCAA compared to AD. In capCAA cases, clusterin is found colocalizing with vascular A β and accumulating as a halo around A β -laden microvessels.

in the aetiology of CAA (Juhász, et al., 2011). Changes in the basal membrane structure, such as thickening, reduplication and vacuolization, have been reported in AD brains (Carrano, et al., 2011b; Sedgwick, et al., 1991). Basal membrane proteins have been shown to interact directly with A β influencing its aggregation. Laminin, for instance, is capable of preventing A β aggregation and promoting disaggregation of pre-formed fibrils (Carson, et al., 1998; Verbeek, et al., 1998; Zhu, et al., 2011).

The expression pattern that we observed for the β 2 subunit of laminin is of particular interest, since not only laminin β 2 is upregulated in capCAA but it appears to be decreased in the vasculature of AD brains. A diagnostic marker with such characteristics might be useful to discriminate capCAA from AD and could potentially find clinical use since change in brain laminin levels could be reflected in the CSF (Matsuda, et al., 2002).

SAP is a plasma glycoprotein that can bind a variety of ligands, including A β (Hartz, et al., 2012) and is a universal component of amyloid deposits (Menon and Kidwell, 2009; Verbeek, et al., 1998). SAP levels are elevated in AD brain (Raposo, et al., 2011; Zipfel, et al., 2009) and it has been suggested that SAP plays a role in AD pathogenesis by binding to A β , accelerating fibril formation and inhibiting A β proteolysis (Eurelings, et al., 2010; C. Mulder, et al., 2010). (Raposo, et al., 2011; Ryu and McLarnon, 2009; Zipfel, et al., 2009). On the other hand SAP, in combination with A β and complement proteins, in particular C1q, promotes the release of pro-inflammatory cytokines enhancing inflammation around A β deposits (Veerhuis, et al., 2003). SAP was strongly upregulated in capCAA cases respect to AD, as measured by our proteomics analysis. Immunohistochemistry revealed that microvascular A β deposits harbour significantly more SAP than parenchymal plaques, which might initiate or, at least, contribute to severe glial activation associated with capCAA (Carrano, et al., 2011a; Richard, et al., 2010). Furthermore, as for laminin, SAP levels can be monitored in CSF. Although no differences in CSF SAP levels have been reported between AD and controls (S.D. Mulder, et al., 2010), it is possible, considering the higher degree of SAP positivity detected in capCAA versus AD, that capCAA cases would show significant changes in CSF SAP levels compared to controls.

Clusterin is a well-known amyloid associated protein present in amyloid plaques and we here show that its expression is significantly increased in capCAA cases. Clusterin is a glycoprotein involved in the clearance of A β peptides and fibrils by binding to megalin receptors and en-

hancing endocytosis of fibrils into glial cells. The binding of A β to clusterin should promote its clearance and the overexpression of clusterin could be a compensatory mechanism to the high abundance of cerebral A β . On the other hand the presence of clusterin can alter the aggregation of the amyloid, this results in the formation of slowly sedimenting, non-fibrillar A β complexes that are highly toxic to neurons (Bibl, et al., 2008; Goos, et al., 2009). Increase in clusterin might be beneficial in the initial stage of the disease, however when the disease progresses it might promote accumulation of toxic A β complexes.

Laminin, SAP and clusterin were found to co-localize with A β deposits, predominantly microvascular over parenchymal. Although, these proteins can be defined as A β -associated proteins, the levels measured in our proteomics analysis were not directly reflective of total A β levels. It appears that they strongly colocalize with fibrillar amyloid deposits, thioflavin-S positive, which are the main component of capCAA and CAA. This might suggest that laminin, SAP and clusterin are not directly related to the abundance of cerebral A β in general, but they might contribute to the formation of highly fibrillar vascular A β deposits (capCAA), instead of parenchymal plaques. Taken together the differential expression of proteins such as laminin, SAP and clusterin, might represent a crucial step in the pathogenesis of capCAA, affecting A β fibrilization, A β transport across the BBB and A β -driven neuroinflammation. Whether these A β -associated proteins can be used in a clinical setting as diagnostic markers remains to be investigated and warrants further studies.

Other potential candidate markers

In addition to clusterin, SAP and laminin β 2, we observed reduced expression of various other proteins, including proprotein convertase subtilisin/kexin type 1 (proSAAS), lactate dehydrogenase A (LDHA), aldehyde dehydrogenase 9A (ALDH9A1), specific cytoskeleton proteins, calcium/calmodulin-dependent protein kinase type II delta chain (CAMK2D) and phosphatidylinositol-5-phosphate 4-kinase type-2 beta (PIP4K2B). ProSAAS is a prohormone expressed in synaptic vesicles (Delacourte, et al., 1987) and it has been shown that proSAAS fragments accumulate in tau-positive Pick bodies and other tauopathies (Oshima, et al., 2008; Williams, et al., 2005). ProSAAS was repeatedly identified as a potential AD marker and found upregulated in AD CSF (Braak, et al., 2006; Eikelenboom, et al., 2008; Yamada, et al., 1997). Interestingly, we showed that proSAAS is upregulated in AD brains, but markedly

downregulated in capCAA cases. This might be explained by the low frequency of tau tangles in capCAA cases and might imply that the pathological processes leading to tau pathology in AD are likely not involved in capCAA, where the disease is, instead, centred on the compromised A β clearance at the BBB.

The dehydrogenases LDHA and ALDH9A1 are both specifically downregulated in capCAA, not in AD. LDHA is a mediator of aerobic glycolysis, an enzyme responsible for the conversion of pyruvate to lactate (Poirier, et al., 1993). Changes in LDHA levels have been associated to amyloid pathology as its expression is decreased in AD transgenic mice and in primary cortical neurons exposed to A β (Boche, et al., 2008). Remarkably, we found no alterations in LDHA expression in AD brains, whereas LDHA expression was significantly decreased in capCAA. When LDHA expression decreases, glycolytic metabolism is taken over by the mitochondria leading to increased free radical production, consequent oxidative stress and cell death, and ultimately cognitive impairment (Boche, et al., 2008). ALDH9A1 is a detoxification enzyme participating in the oxidation of aldehydes and in the metabolism of gamma-aminobutyric acid (GABA) and dopamine. Lack of ALDH would lead to increased accumulation of toxic aldehydes (Tanzi, et al., 2004). Decreased function and/or expression of ALDH, as we have specifically observed in capCAA brain, may play an important role in the pathophysiology of capCAA and might promote neurotoxicity and neuronal death.

Conclusions

In this study, we are able to demonstrate the occurrence of significant differences between capCAA and AD proteomes, despite the overlap of these two pathological conditions. Impaired A β clearance, altered synaptic plasticity, accumulation of toxic metabolites appeared to be the main pathways affected in capCAA. Proteins specifically up- or downregulated in capCAA (and not in AD) might underscore altered pathogenic pathways explaining why A β accumulates around the brain vasculature instead of depositing as plaques in the brain parenchyma, as it is observed in AD. The identification of proteins that are differentially expressed comparing AD and capCAA cases offers the opportunity to diagnose the two AD subtypes and to develop differential approaches for treatment, as different therapeutic targets can be identified for the two conditions. This not only would allow optimize treatments but would help us in the designing of clinical trials and in the selection of specific (more homogenous)

patients groups minimizing the variability of clinical outcome. It is now important to continue in the direction of assessing the validity and feasibility of such proteins for use as biomarkers, for instance analysing their modulation *in vivo* during disease progression in animal models and in human cases, e.g. by extending our proteomics analysis to more cases with diverse profiles (apoE genotypes, mild versus severe cases) and by CSF analysis.

Acknowledgements

We thank Rob Veerhuis (Department of Clinical Chemistry and Pathology, VU medical center, Amsterdam, the Netherlands) for the gift of SAP and clusterin antibodies. We thank the Netherlands Brain Bank (Amsterdam, the Netherlands), especially Michiel Kooreman, for providing excellent post-mortem human brain tissue, and are grateful to all patients and controls that donated their brains.

This work was financially supported by the 'Internationale Stichting Alzheimer Onderzoek' (ISAO grants 07517 and 09506).

Disclosure Statement

There is no actual or potential conflict of interest for any author concerning this manuscript.

Supplementary Data

Supplementary Figure 1. Expression of complement proteins C1q, C3d, C5-9 in capCAA and AD. Clusterin and SAP are both amyloid associated proteins and both modulate the complement system. SAP can bind to C1q and initiate activation of the classical pathway of the complement. Clusterin is a complement inhibitor and can suppress complement activation suppressing the formation of complex C5-9.

Therefore we analyze the expression of several complement proteins located at different stages of the cascade in post-mortem occipital cortices from capCAA and AD cases. Immunohistochemistry analysis reveals that C1q, C3d and C5-9 colocalize with the most fibrillar A β deposits, showing significantly higher levels in capCAA compared to AD.

Supplementary Figure 2. Quantification of complement proteins C1q, C3d and C5-9 expression in capCAA, AD and controls. Fluorescent analysis was performed with confocal laser-scanning microscope and quantification of fluorescent intensity was performed by ImageJ software. Quantification confirmed that these complement proteins are markedly upregulated in capCAA compared to AD and controls.

Supplementary Table 1. (Page 94-130). List of identified proteins ($p < 0.05$) in the occipital cortex of capCAA patients compared with Alzheimer's disease cases and controls ranked on pvalue. Abbreviations: CAA = capillary cerebral amyloid angiopathy; AD = Alzheimer's disease; C = control; nc = normalized spectral counts; fc = fold change

Abstract

Cerebral amyloid angiopathy (CAA) is frequently observed in Alzheimer's disease (AD) and is characterized by deposition of amyloid beta (A β) in leptomeningeal and cortical brain vasculature. In 40% of AD cases, A β mainly accumulates in cortical capillaries, a phenomenon referred to as capillary CAA (capCAA). The aim of this study was to investigate blood–brain barrier (BBB) alterations in CAA-affected capillaries with the emphasis on tight junction (TJ) changes. First, capCAA brain tissue was analyzed for the distribution of TJs. Here, we show for the first time a dramatic loss of occludin, claudin-5, and ZO-1 in A β -laden capillaries surrounded by NADPH oxidase-2 (NOX-2)-positive activated microglia. Importantly, we observed abundant vascular expression of the A β transporter receptor for advanced glycation endproducts (RAGE). To unravel the underlying mechanism, a human brain endothelial cell line was stimulated with A β 1-42 to analyze the effects of A β . We observed a dose-dependent cytotoxicity and increased ROS generation, which interestingly was reversed by administration of exogenous antioxidants, NOX-2 inhibitors, and by blocking RAGE. Taken together, our data evidently show that A β is toxic to brain endothelial cells via binding to RAGE and induction of ROS production, which ultimately leads to disruption of TJs and loss of BBB integrity.

Introduction

Alzheimer's disease (AD) is the most common neurological disorder affecting elderly and is clinically characterized by a progressive cognitive decline associated with extracellular accumulation of neurotoxic amyloid β ($A\beta$) and hyperphosphorylated tau-positive neurofibrillary tangles (Deane and Zlokovic, 2007; Jeynes and Provias, 2006). Senile plaques predominantly consist of $A\beta$ deposits and can be observed throughout the cerebral cortex in advanced stages of the disease. Alternatively, $A\beta$ is able to accumulate in the cerebrovasculature, which is referred to as cerebral amyloid angiopathy (CAA). CAA is a common finding in the elderly, with an incidence up to 50% of the population (Rensink, et al., 2003). There is a strong association between AD and CAA as CAA occurs in 80%–100% of AD cases. CAA can be widespread and is usually observed in larger vessels, including leptomeningeal vessels and cortical arteries and arterioles. Remarkably, $A\beta$ depositions are also observed in cortical capillaries (Attems, 2005). Several groups support the distinction between CAA present in larger vessels (CAA type II) and $A\beta$ accumulation in both larger vessels and capillaries (CAA type I or capillary CAA (capCAA) (Thal, et al., 2002). CAA is a major cause of hemorrhagic and ischemic strokes in elderly patients, probably also involved in microbleeds (Attems, et al., 2005; van Horssen, et al., 2005), and may play a role in AD progression. Relatively little is known on the impact of capCAA in AD pathogenesis, although it is tempting to speculate that $A\beta$ accumulation in capillaries may affect blood–brain barrier (BBB) integrity. Notably, BBB dysfunction has been reported in various neurological conditions, including multiple sclerosis, cerebral ischemia, and AD (Coisne and Engelhardt, 2011; Hawkins and Davis, 2005; Zipser, et al., 2007; Zlokovic, 2008).

The BBB is a tight sealed barrier between the circulating blood and the central nervous system (CNS), consisting of brain microvascular endothelial cells that are surrounded by basement membranes, astrocytic endfeet, and pericytes. The brain microvascular endothelium is characterized by the presence of tight junctions (TJs) and lack of fenestrae, thereby limiting the entry of plasma components, red blood cells, and leukocytes into the CNS, and confer the low paracellular permeability and high electrical resistance of the BBB (Hawkins and Davis, 2005; Zlokovic, 2008). TJs are complex structures located at the apical region between endothelial cells and are composed of connecting transmembrane proteins (occludin and claudins) that form the primary seal linked via accessory cytoplasmic proteins (zona occludens family

members) to the actin cytoskeleton (Hawkins and Davis, 2005).

Occludin is a phosphoprotein with four transmembrane domains and intracellular amino and the carboxyl termini (Blasig, et al., 2011). Occludin expression is associated with increased electrical resistance and decreased paracellular transport. Claudins comprise a multigene family consisting of more than 20 members and contain two extracellular loops and four transmembrane domains and interact in both a homophilic and heterophilic way with claudins of adjacent cells. Claudin-5 is a critical component of the BBB as it prevents the passage of molecules larger than 800 Da (Overgaard, et al., 2011). Carboxyterminal parts of both occludin and claudins interact with membrane-associated recruiting proteins of the zona occludens (ZO) protein family. ZO proteins are reported to link transmembrane proteins to the actin cytoskeleton and have signaling potential (Gonzalez-Mariscal, et al., 2011).

Leakage of the BBB in AD has been suggested by the detection of plasma proteins associated with amyloid plaques (Akiyama, et al., 1992; Kalaria, 1992; Wisniewski, et al., 1997) and within AD brain parenchyma (Kalaria, 1992; Wisniewski, et al., 1997; Zipser, et al., 2007). Likewise, in CAA, an impaired barrier function was detected associated with cerebrovascular A β deposits (Wisniewski, et al., 1997). Opening of the BBB and concomitant altered TJ expression or localization has been attributed to vascular A β aggregates (Blanc, et al., 1997; Gonzalez-Velasquez, et al., 2008; Marco and Skaper, 2006; Tai, et al., 2009), which in turn are able to induce reactive oxygen species (ROS) production, mainly generated by NADPH oxidase (NOX), in neuronal and non-neuronal cell cultures (Babior, 2000; Li, et al., 2008; Zhou, et al., 2008). Both endogenous and exogenous ROS induce loss of endothelial cell-cell interactions (van Wetering, et al., 2002) and are able to modulate BBB integrity and disrupt TJs (Lehner, et al., 2011; Schreibelt, et al., 2007). However, to date, the link between A β , ROS production and TJs alterations remains elusive.

The involvement of RAGE appears to be very important in the development of the AD and CAA pathology, since RAGE mediates the influx of A β into the brain parenchyma and consequently in an unbalanced situation enhances A β accumulation. RAGE is also known to be critical regarding the effects exerted by A β through its binding to the transporter. A β /RAGE interaction has been reported to activate NOX and a cascade of effects such as NF- κ B-mediated endothelial activation resulting in secretion of proinflammatory cytokines, the expression of adhesion molecules and suppression of cerebral blood flow (Zlokovic, 2008).

In this study, we combine neuropathological findings in unique brain samples of capCAA

patients and show a dramatic loss of TJ proteins in A β -laden capillaries. Interestingly, capCAA-affected vessels are surrounded by NOX2-immunopositive activated microglia. We next investigated the link between A β toxicity and TJ changes using a human cerebral microvascular endothelial cell line and demonstrated that cytotoxic A β via production of ROS, decreased TJ proteins expression which could be rescued by exogenous antioxidants, NOX-2 inhibition, and RAGE blocking antibody.

Materials and methods

Postmortem tissue

Six patients with extensive capCAA and two age-matched non-demented controls were selected. Human brain specimens were obtained at autopsy with a short postmortem interval (The Netherlands Brain Bank, Amsterdam, The Netherlands and University Medical Centre in Utrecht, The Netherlands). Neuropathological evaluation was performed on frozen tissue and formalin-fixed, paraffin-embedded tissue from occipital pole cortex. CapCAA score was defined as follow: severe (+++), moderate (++) and mild (+). Staging of AD was evaluated according to Braak and colleagues (Braak and Braak, 1991). Age, gender, postmortem delay (PMD), Braak, CERAD, and CAA scores and cause of death of all cases used in this study are listed in Table 1.

Immunohistochemistry

For immunohistochemical staining, 5- μ m cryosections were air-dried and fixed in acetone for 10 min. Next, sections were preincubated with normal goat serum 1:10, diluted in phosphate buffered saline (PBS) containing 1% bovine serum albumin (Roche Diagnostics, Mannheim, Germany) for 10 min. Sections were incubated O/N with primary antibodies: anti-occludin (mouse, Zymed), anti-ZO1 (rabbit, Zymed) (Table 2) diluted in PBS containing 1% bovine serum albumin. Subsequently, sections were incubated with EnVision goat-anti-mouse horseradish peroxidase (HRP) or EnVision goat-anti-rabbit HRP (Dako, Glostrup, Denmark) for 60 min. Peroxidase labeling was visualized by EnVision 3,3'-diaminobenzidine 1:50 (EV-DAB; Dako). Sections were counterstained with hematoxylin. Finally, tissue sections were rinsed with 70% ethanol prior to a 20 min incubation with 50 ml saturated NaCl

solution (0.5 M NaCl in 80% ethanol) which was supplemented with 0.5 ml 1% NaOH solution. Then sections were transferred to saturated Congo Red (VWR internationaal, Leuven, the Netherlands) solution supplemented with 0.5 ml 1% NaOH solution for 20 min. Congo Red staining was used to visualize A β fibrils. Between all incubation steps, sections were extensively washed with PBS (pH 7.4). PBS served as negative control.

Paraffin sections (5 μ m) were mounted on coated glass slides (Menzel Gläser super frost PLUS, Brainschweig, Germany) and dried O/N at 37°C. Sections were deparaffinized and rehydrated by xylene and a sloping concentration of ethanol (100%, 96%, and 70%). Endogenous peroxidase was blocked by incubating the sections in methanol+0.3% H₂O₂ for 30 min. Antigen retrieval was established by boiling the sections in 1 mM EDTA buffer for 10 min. Then, sections were O/N incubated with anti-claudin-5 (mouse, Zymed) or anti-NOX2 (mouse) (see Table2) diluted in PBS supplemented with 1% BSA. Then the sections were incubated for 30 min with EnVision anti-rabbit/anti-mouse HRP. Peroxidase labeling was visualized by EVDAB 1:50. Sections were counterstained with hematoxylin. The sections were stained with Congo Red as described above. Finally sections were rinsed twice with 100% ethanol, put in xylene and covered with DePeX mounting medium (Gurr, Germany). Between all incubation steps, sections were extensively washed with PBS (pH 7.4). PBS served as negative control.

Table 1. Summary of Patient Details

Patient #	Age	Gender	PMD	Braak	CERAD	CAA	cause of death
1	75	F	6	V	0	+++	dehydration
2	65	M	7	V	C	++/+++	pneumonia
3	83	F	5	III	B	++/+++	cachexia by dementia syndrome
4	71	F	< 24	IV	B	+++	pneumonia
5	86	M	> 24	VI	B	+	pneumonia
6	78	F	-	IV	A	+++	pneumonia

Immunofluorescence

For co-localization studies, cryosections were incubated in thioflavin S solution (100 mg/ml) for 5 min to stain A β fibrils and washed subsequently three times in ethanol 70%. Sections were preincubated with normal goat serum 1:10 for 10 min and incubated O/N with a

mix of primary antibodies: anti occludin/claudin-5 and anti factor VIII or anti ZO-1/RAGE and anti CD31 diluted in PBS containing 1% bovine serum albumin. Sections were then incubated with secondary antibodies: Cy5 labeled goat-anti-rabbit 1:100, diluted in EnVision goat-anti-mouse HRP (Dako) for 30 min. Peroxidase labeling was visualized by reaction with rhodamine-tyramide (1:3000) in presence of 0.01% of H₂O₂ for 5 min. After washing, slides were covered with Vectashield (Vector laboratories, Burlington, ON, Canada). Between all incubation steps, sections were extensively washed with PBS (pH 7.4). Fluorescent analysis was performed with a Leica TCS SP2 AOBS confocal laser-scanning microscope (Leica Microsystem, Heidelberg, Germany). Quantification of TJ protein-expressing vessel was also performed normal vessels versus A β -laden vessels. Four fields per slides were counted and a ratio was calculated (magnification X10).

Table 2. Primary Antibodies Used in this Study

Primary Antibody	species raised in	dilution	method	ARS	source
Occludin	mouse	1:200	EnVision	EDTA	Zymed (Invitrogen)
Claudin-5	mouse	1:200	EnVision	Na-citrate	Zymed (Invitrogen)
ZO-1	rabbit	1:100	ABC	-	Zymed (Invitrogen)
NOX-2	mouse	1:100	EnVision	Na-citrate	Gift of D. Roos
RAGE	goat	1:500	ABC	-	Biochem
Factor VIII	rabbit	1:250	ABC	-	DAKO
CD31	mouse	1:10	ABC	-	DAKO

Cell culture

A human cerebral microvascular endothelial cell line (hCMEC/D3) (Weksler, et al., 2005) was maintained in EBM-2 medium (Clonetics, Cambrex BioScience, Wokingham, UK) supplemented with VEGF, IGF-1, EGF, basic FGF, hydrocortisone, ascorbate, gentamycin, and 2.5% fetal bovine serum (FBS) 40. T75 flasks, 96-well plates and 24-well plates were coated with type 1 collagen (Gibco HBSS, Invitrogen, Carlsbad, CA). hCMECs were detached at 37°C with 2 ml trypsin/EDTA in PBS. Cultures were grown to confluence at 37°C in 5% CO₂ until the formation of monolayers.

A β 1-42 preincubation

Synthetic A β 1-42 (Bachem, Bubendorf, Switzerland) was dissolved in 0.1% ammonium hydroxide and stored in 50 μ l, 1 mM aliquots at -80°C . 40 μM A β 1-42 was preincubated in EBM-2 medium without FBS for 3 days in order to form aggregates. Then A β 1-42 was further diluted in cell medium to obtain appropriate concentrations.

Electron microscopy

Pre-aggregated A β 1-42 was applied to formvar carbon-coated copper grids (Stork Veco BV, Eerbeek, The Netherlands) and dried for 10 min. Grids were negatively stained with uranyl acetate for 5 min and examined with a Zeiss EM109 electron microscope to visualize the formation of fibrils.

MTT assay

The cytotoxicity of synthetic A β 1-42 preparations was assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT; Sigma Aldrich, Germany) assay. hCMECs were cultured in 96-well plates until they reached 100% confluence. Cells were incubated for 24 h with different concentrations of A β 1-42 (1 nM, 10 nM, 100 nM, 1 μM , 10 μM). Antioxidants and blocking antibody anti-RAGE were applied 2 h prior A β incubation and were still present during the entire treatment. Then cells were incubated with MTT (1 mg/ml) for 3 h at 37°C . The formazan-salt generated by mitochondria of viable cells as a result of conversion of MTT was dissolved in glycin/DMSO (ratio 1:6) and the absorbance was measured at 540 nm.

Live/dead assay

Using the LIVE/DEAD Viability/Cytotoxicity Assay Kit (Molecular Probes Inc, Eugene, OR) living and dead cells can be distinguished from each other. hCMECs were cultured in 96-well plates until they reached 100% confluence. Cells were incubated for 24 h with different concentrations of A β 1-42 (1 μM , 10 μM , 20 μM). Cells were washed gently with warm PBS. Then 1 μ l calcein AM and 1.5 μ l ethidium homodimer 1 were added to warm EBM-2 medium and 100 μ l of this mixture was added per well for 20 minutes. The cell permeable calcein AM is converted into the green fluorescent calcein by intracellular esterase activity (excitation \sim 495 nm; emission \sim 515 nm). Ethidium homodimer 1 is able to enter cells with damaged membranes. It undergoes a 40-fold enhancement of fluorescence upon binding to nucleic acids and produces a red fluorescent signal in dead cells (excitation \sim 495 nm, emission \sim

635nm). Four 10 times magnified fields were counted and a ratio was calculated for live and dead cells.

Amplex Red assay

hCMECs were cultured in 96-well plates until they reached 100% confluence. Cells were treated with different concentrations of A β 1-42 (1 nM, 10 nM, 100 nM, 1 μ M, and 10 μ M) for 24 h. After incubation, A β was removed and H₂O₂ production was detected using the Amplex red fluorescent dye (Molecular Probes, Breda, the Netherlands) which reacts 1:1 with H₂O₂ in the presence of horseradish peroxidase, producing highly fluorescent resorufin. Fluorescence was detected at 37°C in a fluorimeter (Galaxy-Fluostar, BMG, Offenburg, Germany). The excitation and emission fluorescent wavelengths were 550 and 590 nm, respectively. The calibration signal was produced by addition of known amounts of H₂O₂ added to the reaction mix. The velocity whereby H₂O₂ was produced was calculated using non-linear regression.

mRNA isolation and real-time quantitative PCR

To investigate mRNA expression of TJ proteins cells were grown on a 24-well plate until they reached 100% confluency. Cells were incubated with different concentrations of A β 1-42 (10 nM, 100 nM, 1 μ M) for 24 h. mRNA was isolated by using the mRNA capture kit (Roche Applied Science, Almere, the Netherlands) following the manufacturer's protocol. mRNA was reverse transcribed using the Reverse transcription system kit (Promega, Madison, WI) according to the manufacturer's instructions using GeneAmp PCR system 9700 (Applied Biosystems, Foster City, CA). cDNA was diluted three times and quantified for mRNA levels of occludin/claudin-5/ZO-1 relative to the housekeeping gene GAPDH. The accumulation of PCR product is measured using Sybergreen II (Applied Biosystems). Primers were developed using the program Primer Express 2.0 (Applied Biosystems). The sequences of primers are as follows: human occludin: sense 5'-CCCGTTTGGATAAAGAATTGG-3'; antisense 5'-TCAAACAACCTTGGCATCAGA-3'; human ZO-1: sense 5'-CCCGAAGGAGTTGAG-CAGGAAATC-3', antisense 5'-CCACAGGCTTCAGGAACTTGAGG-3'. The PCR amplification was performed in triplicate in a 7900 HT Fast Real-Time PCRSystem (Applied Biosystems). Relative expression levels of TJ proteins in relation to the reference GAPDH were calculated using the mathematical model: $\Delta\Delta CT$. The formula is $2^{-\Delta\Delta CT}$ where $\Delta CT = CT_{target} - CT_{reference}$ and $\Delta\Delta CT = \Delta CT_{sample} - \Delta CT_{calibrator}$.

Statistical analysis

Data were analyzed statistically by Student's *t*-test or analysis of variance (ANOVA) followed by post hoc analysis with Bonferroni's method (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$).

Results

Reduced tight junction protein expression in CapCAA-affected vessels

Using Congo Red, we observed extensive A β deposits throughout the occipital cortex in capillaries and larger vessels. No A β was detected in brain vessels of control brains. To investigate the expression of TJ proteins, postmortem tissue of 6 capCAA patients and 2 non-neurological controls was stained for occludin, claudin-5, and ZO-1. We observed a normal vascular expression pattern of TJ proteins in control tissue capillaries and in vessels not affected by A β deposition in samples from capCAA patients (Figs. 1A, 1C, and 1E). Interestingly, we observed a marked reduction or even complete loss of occludin, claudin-5 and ZO-1 staining in CAA-affected capillaries (Figs. 1B, 1D, and 1F). Quantification based on triple fluorescent staining for A β , TJs and an endothelium marker confirmed significant loss of TJ proteins expression in A β -laden capillaries compared to non-affected capillaries (Figs. 2d–2f).

A β -laden capillaries are surrounded by NOX-2-positive activated microglia

A β is known to induce ROS-generating enzymes, including NOX-2 in microglia. NOX-2 is constitutively expressed by microglial cells and under physiological conditions NOX-2 activity is low. However, NOX-2 is strikingly upregulated in response to acute and chronic stimuli, including A β (Li and Shah, 2003; Park, et al., 2005). We show that NOX-2 is expressed in microglial cells in control brain tissue (Fig. 3A), however NOX-2 is abundantly and widely expressed in microglia throughout capCAA-affected tissue. Cells stained positive for NOX-2 were recognized as microglia based on their morphology (*e.g.*, characteristic long branching processes and a small cellular body). Particularly, A β -positive capillaries are engulfed by NOX2-immunoreactive microglia (Fig. 3B), strongly suggesting increased ROS production in close vicinity of A β -laden capillaries with TJ changes.

A β induces occludin and ZO-1 mRNA downregulation

Immunohistopathological findings showed reduced TJ expression in A β -laden capillaries. To

investigate the direct effects of A β on mRNA expression of TJ proteins, we examined the effects of A β 1-42 on occludin, claudin-5, and ZO-1, using a human cerebral microvascular endothelial cell line (hCMEC/D3) (Weksler, et al., 2005). Endothelial cells treated for 24h with increasing concentration of A β fibrils (Fig. 4C) showed a dose-dependent significant reduction of occludin and ZO-1 transcripts (max reduction of 55% and 45%, respectively) (Figs. 4A and 4B). Remarkably, no changes in claudin-5 mRNA were detected (data not shown). These results are in line with the loss of occludin and ZO-1 in capCAA tissue, and suggest

Figure 1. Loss of TJ proteins in capCAA. TJ proteins (brown) are normally expressed in endothelial cells of capillaries. Claudin-5 immunoreactivity was localized virtually in all the vasculature in control and unaffected tissue (A). Loss of endothelial claudin-5 was observed in A β -laden capillaries (Congo red) (arrows) (B). Occludin immunoreactivity was localized virtually in all the vasculature in control and unaffected tissue (C). Loss of occludin in endothelial cells was observed in A β -laden capillaries indicated by the arrows (D). ZO1 expression was detected in the vasculature of control and unaffected tissue (E). Loss of ZO1 in endothelial cells was observed in A β -laden capillaries indicated by the arrow (F).

that reduced TJ protein expression might be caused by A β deposits in the microvasculature.

A β is toxic to brain endothelial cells via enhanced ROS production

In order to test which concentration of A β is lethal to brain endothelial cells, we performed a live/dead assay. Here, cells were incubated for 4 h and 24 h with different concentrations of A β 1-42. Cells treated for 4 h with A β 1-42 did not show any sign of cell death (data not shown), however after 24 h of A β treatment, we observed cell death using A β concentration of 10 μ M and higher. No significant cytotoxicity was detected upon 1 μ M A β treatment when compared to vehicle-treated cells (Fig. 5A).

To evaluate the cytotoxic effect of A β on hCMECs, we assessed the effect on mitochondrial function as a measure of cell viability. We showed a dose-dependent decrease in brain endothelial cell viability after 24 and 48 h of A β 1-42 treatment. After 24 h, a dose-dependent effect of A β on mitochondrial function was observed with a maximum effect at 1 μ M A β 1-42 with a decline of mitochondrial function around 50% (Fig. 5B). Dose-dependent toxicity was also present at 48 h (data not shown).

We observed cell death and impaired mitochondrial function, which can both be related to ROS production (Hsu, et al., 2010; Turrens, 2003). In order to investigate whether A β 1-42 induces production of ROS, hCMECs were treated with A β 1-42 for 24 h. Using an Amplex Red assay, we showed that A β 1-42 induced a dose-dependent increase in H₂O₂ production compared to vehicle-treated cells (Fig. 5C).

Antioxidants/ROS scavengers rescue endothelial cells from A β 1-42 toxicity

Since we detected hydrogen peroxide production in response to A β incubation, we further elucidated the involvement of NADPH oxidase and xanthine oxidase in A β -mediated ROS production using specific inhibitors such as diphenylene iodonium (DPI) and allopurinol. Alpha-lipoic acid (alpha-LA) was used as general ROS scavenger. Endothelial cells preincubated with DPI, allopurinol, and alpha-LA for 2 h were then treated with different concentrations of A β 1-42 (10 nM and 100 nM) in presence of the different compounds for 24 h. Cell viability was measured by MTT assay. DPI, allopurinol, and LA were all able to rescue hCMECs from A β -mediated toxicity (Fig. 6), indicating that A β -mediated cytotoxicity is mainly due to A β -induced ROS production.

Figure 2. Loss of TJ proteins in capCAA: co-localization study. Triple immunofluorescence analysis confirmed loss of TJs in endothelial cells affected by A β deposition; (a), (b), and (c) represent respectively analysis for TJ proteins claudin-5, occludin, and ZO1. A β was detected by Thioflavin S (green). Claudin-5, occludin, and ZO1 (red) were downregulated in capillaries detected by endothelial markers factor VIII and CD31 (blue). (A, B, C, D) A β -laden capillaries; (E, F, G, H) normal capillaries. Quantification of claudin-5 (d), occludin (e), and ZO-1 (f) expressing capillaries in CAA and non-CAA microvasculature is shown in the graphs. * $p < 0.05$, by Student t test.

Antioxidants rescue A β -dependent downregulation of TJ proteins

We proved that A β 1-42 fibrils induce ROS generation in our cell system and it has been previously shown that ROS can affect TJs integrity (Schreibelt, et al., 2007; van Wetering, et al., 2002). We hypothesized that the downregulation of TJ proteins observed upon A β 1-42 fibrils treatment is due to the A β -dependent ROS production. To elucidate the link between A β , ROS, and TJs expression changes, we incubated hCMEC with allopurinol for 2 h prior to A β treatment; we then measured the expression of occludin and ZO-1 mRNA levels. As allopurinol was able to rescue cells from A β -mediated cytotoxicity, it was also capable of restoring TJ mRNA levels, confirming that indeed A β -driven ROS production is responsible for major TJ alterations (Fig. 7).

Upregulation of RAGE in capCAA

RAGE is the most important influx transporter for A β across the BBB and is expressed at relatively low levels in the microvasculature under physiological conditions. We show by means

Figure 3. NOX2 expression in capCAA. NOX2 is normally detected in microglia of control brains (A, white arrows). No immunoreactivity is detected in endothelial cells. In capCAA tissue, NOX2 immunoreactivity is increased in microglia (white arrows) and endothelial cells of A β -laden vasculature (black arrows) (B).

of immunohistochemical analysis a striking increase in RAGE expression in capCAA-affected capillaries compared to control and nonaffected capillaries. These results confirm, as previously reported (Donahue, et al., 2006), that A β induces a local upregulation of RAGE (Fig. 8).

RAGE mediates A β -induced cytotoxicity

In order to determine the involvement of RAGE in the A β cytotoxic effects, we treated hC-MEC with a blocking antibody against RAGE. Cells were treated with the blocking antibody for 2 h and for 24 h together with A β 1-42 fibrils. MTT assay showed that blocking RAGE rescued cells from A β -induced toxicity, demonstrating that A β effects on endothelial cells are exerted at least partially by its binding to RAGE (Fig. 9).

Figure 4. A β induces downregulation of TJ proteins. Occludin (A) and ZO1 (B) mRNA expression was assessed by q-PCR on hCMEC upon 24 h A β treatment. Cells were treated with increasing concentration of A β 1-42 (10 nM, 100 nM, 1 μ M). TJs expression was normalized to the expression of house-keeping gene GAPDH. Data were represented as the mean \pm SEM; n = at least three experiments with triplicate samples. *p < 0.05, ***p < 0.001 by Student t test. A β fibrils were characterized by electron microscopy. (C) shows electron micrographs of A β 1-42 incubated 3 days at 37 $^{\circ}$ C prior to being added to the cell cultures.

Figure 5. A β cytotoxicity and ROS production. HCMEC/D3 were incubated with increasing concentrations of A β 1-42. Cells incubated for 24 h with 1 μ M A β 1-42 or less looked morphologically normal and appeared fluorescently green at the live/ dead assay, no significant cells death was detected. At 10 μ M or higher concentration, A β 1-42 was toxic to hCMEC, dead red fluorescent cells were detected respect to control (A). After 24 h incubation with A β 42, there was a cell viability response in a dose-dependent manner with a maximum effect of 1 μ M A β 42 and a maximum decline of mitochondrial function around 50% measured by MTT assay (B). The same treatment induced ROS production, here measured as production of H₂O₂. A dose-dependent H₂O₂ was observed after 24 h of treatment (C). Data were represented as the mean \pm SEM; n = at least three experiments with triplicate samples. **p < 0.01, ***p < 0.001 by Student t test.

Figure 6. Antioxidants rescue hCMEC from A β toxicity. HCMEC were preincubated for 2 h with antioxidants, allopurinol, DPI, and lipoic acid, before A β treatment. After preincubation, cells were treated with 10 nM, 100 nM, or vehicle in presence of the antioxidants. Antioxidants could reverse the toxic effect of A β 1-42 on endothelial cells. Data were represented as the mean \pm SEM; n = at least three. *p < 0.05, **p < 0.01, ***p < 0.001 by two-way ANOVA, followed by post hoc Bonferroni test.

Discussion

For the first time, we show in this study a dramatic loss of TJ proteins in A β -laden capillaries, which are surrounded by NOX2-positive activated microglia. We demonstrated in an *in vitro* BBB system that A β is able to induce ROS formation and decrease TJ mRNA levels, which could be rescued upon pretreatment with NOX inhibitors and lipoic acid. We further demonstrate that blocking RAGE is a way to rescue cells from A β -induced toxicity.

Using our unique postmortem tissue, we here provide evidence on the loss of expression of TJ proteins in capCAA. So far, histopathological studies have demonstrated that microvascular alterations can be extensive in AD patients (Claudio, 1996; Farkas and Luiten, 2001). These alterations have been shown associated with vascular A β deposition as degeneration of perivascular cells, including pericytes and smooth muscle cells, swollen astrocytic end feet (Higuchi, et al., 1987; Yamashita, et al., 1991), reduced expression of brain endothelial glucose transporter-1 protein, increased pinocytotic vesicles, and decreased numbers of mitochondria. In addition, prominent thickening and local disruption of vascular basement membranes was reported by several research groups analyzing either biopsy tissue or postmortem AD material (Claudio, 1996; Mancardi, et al., 1980; Perlmutter and Chui, 1990). Vascular abnormalities that are associated with local amyloid accumulation suggest that impaired vascular function and thus impaired BBB integrity represents a common phenomenon in AD pathology. Although there are several studies demonstrating BBB alterations in CAA type II, comprehensive immunohistochemical studies on BBB abnormalities in A β -laden capillaries (CAA type I) are limited. *In vitro* studies support the idea that A β deposition affects BBB integrity since different A β peptides are able to increase endothelial permeability (Blanc, et al., 1997; Tai, et al., 2009) and induce altered expression and translocation of TJs proteins in human and animal ECs (Gonzalez-Velasquez, et al., 2008; Marco and Skaper, 2006). Remarkably, data on putative TJ alterations and the underlying mechanisms in CAA-affected capillaries are lacking.

To provide novel data on the BBB integrity during CAA, we selected a unique cohort of patients with abundant A β deposits in cortical capillaries. We observed a striking loss of occludin, claudin-5, and ZO-1 immunostaining in A β -laden capillaries, whereas unaffected capillaries showed a normal expression pattern, indicating that loss of TJ expression was predominantly related to microvascular A β deposition. Importantly, endothelial cells of cap-

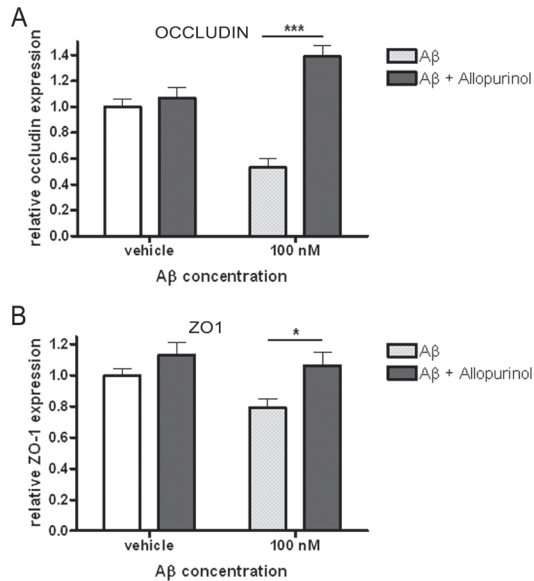

Figure 7. Antioxidants rescue Aβ-dependent downregulation of TJ proteins. Occludin (A) and ZO-1 (B) mRNA expression was assessed by q-PCR on hCMEC upon 24 h 100 μM Aβ treatment in the presence of allopurinol. TJs expression was normalized to the expression of house-keeping gene GAPDH. Co-treatment with allopurinol was able to restore normal levels of TJ transcripts. Data were represented as the mean ± SEM, n = at least three. *p < 0.05, ***p < 0.001 by two-way ANOVA followed by post hoc Bonferroni test.

CAA-affected vessels still express endothelial markers, including factor VIII and CD31, excluding brain endothelial cell death as a potential reason for the lack of TJ protein expression. Although leakage of the BBB has been supported by elevated plasma proteins associated with Aβ deposits, we here for the first time provide direct evidence of TJ proteins loss in AD brains linked to Aβ accumulation. The subsequent breakdown of the BBB may in turn disrupt normal transport of nutrients, vitamins, and electrolytes across the BBB, which are essential for proper neuronal functioning.

Interestingly, we detected enhanced expression of the ROS-generating enzyme NADPH oxidase-2 (NOX-2) in microglia surrounding Aβ-laden vessels. Previous data from our group demonstrated that deposition of Aβ throughout the brain parenchyma, especially extravascular deposition of Aβ that from the vessel wall radiates into the neuropil (named dyschoric changes), is able to induce an inflammatory response, consisting in activation of microglia and astrocytes (Richard, et al., 2010; Rozemuller, et al., 1989). Upon phagocytosis or recognition of Aβ by microglia cells, a series of responses may occur that includes the release of

Figure 8. RAGE expression in capCAA brain tissue. Expression of RAGE was detected by triple immunofluorescence analysis. A β was detected by Thioflavin S (green, A and E). No A β was detected in control tissue. RAGE (red) is strongly higher expressed in A β -laden capillaries (B) with respect to control (F). Capillaries were stained with endothelial marker CD31 (C, G). Merge show co-localization of A β and RAGE at capillary level in cap CAA (D), but no co-localization in control tissue (H).

Figure 9. Blocking RAGE rescue cell from A β cytotoxic effects. HCMEC were preincubated for 2 h with blocking antibody anti-RAGE (40 μ g/ml) prior to A β 1-42 treatment. Anti-RAGE was always present during treatment. Blocking RAGE could reverse the toxic effect of A β 1-42 on endothelial cells. Data were represented as the mean – SEM; n = at least three. *p < 0.05, by Student t test.

proinflammatory cytokines and ROS. One of the main sources of ROS under neuropathological conditions is enhanced NOX activity, together with the mitochondrial respiratory chain. In particular, NOX-2 is a well-known NADPH oxidase expressed in microglia where it is normally expressed at low levels. However, under pathological conditions, NOX-2 is upregulated and associated with a wide variety of vascular pathologies such as hypertension, diabetes, and hyperlipidemia (35). Enhanced expression of NOX-2 leads to increased ROS levels, partic-

ularly superoxide, and induces oxidative stress. In material derived from non-neurological controls, NOX-2 expression is mainly limited to microglia. Notably, the expression pattern of NOX-2 in capCAA tissue was strikingly different; revealing a stronger microglial expression, especially around capCAA-affected vessels, and NOX-2 was clearly expressed in perivascular macrophages associated with A β -laden capillaries. From these findings we conclude that A β deposition within and surrounding capillaries induces microglial activation and subsequent upregulation of NOX-2 protein expression in activated microglial cells and perivascular macrophages. These results support the idea of increased production of ROS in close proximity of capCAA-affected vessels and are in line with the observation that protein and DNA oxidative damage are increased in AD brains (Lyras, et al., 1997; Wang, et al., 2005).

To unravel pathways involved in BBB damage and A β -induced oxidative stress in brain endothelial cells, an *in vitro* approach was taken using the validated human brain endothelial cell line hCMEC/D3. We first assessed the cytotoxic effects of A β 1-42, one of the predominant A β isoforms accumulating in A β -laden capillaries. A β 1-40 is the predominant form of A β in larger CAA-affected vessels, such as arterioles and leptomeningeal vessels. However, the A β 1-40/A β 1-42 ratio of capillary A β is significantly lower than that of affected arteries and veins but equals that found in senile plaques (Richard, et al., 2010), indicating that A β 1-42 is a common A β isoforms in microvascular CAA. Furthermore, A β 1-42 is known to be the most toxic form of A β to endothelial cells (Eisenhauer, et al., 2000). Hence, we used the A β 1-42 isoform for our *in vitro* studies. We treated endothelial cells with pre-aggregated A β peptide as aggregates were reported to be more toxic to ECs (5). At standardized conditions we could observe cells death after 24 h incubation at concentrations higher than 10 μ M. Subtoxic concentrations of A β 1-42 were then used to assess the effects of amyloid on TJ expression *in vitro*. Using this set-up, we showed a significant dose-dependent downregulation of TJ proteins occludin and ZO-1 mRNA levels upon A β 1-42 incubation, but no changes in claudin-5 mRNA level, as also reported by Tai *et al.* (Tai, et al., 2009), which was in contrast to our postmortem findings. Reduced expression of occludin after 48 h of A β 1-40 incubation has been previously described in hCMEC, but no changes in claudin-5 or ZO-1 (Gonzalez-Velasquez, et al., 2008). A β 1-42 has been reported to reduce expression of claudin-5 and occludin in primary rat brain endothelial cells albeit at higher concentrations than the concentration used in this study (Marco and Skaper, 2006). Our results, together with the previous findings, confirm the

significant loss of occludin and ZO-1 in capCAA tissue and directly related these observations to A β deposit in the microvasculature. We speculate that claudin-5 protein expression may be altered by A β , as our immunohistochemical results strongly suggested. It is conceivable that prolonged exposure to A β is needed to decrease claudin-5 expression, as occurs in the patient material, or that loss of claudin-5 reported in capCAA tissue is not due to altered expression at transcriptional level but to a post-translational modification or degradation of the protein.

Our *in vitro* results showed dose-dependent decrease of mitochondrial function and increased production of ROS upon A β 1-42 stimulation of hCMEC. One consequence of impaired mitochondrial function is enhanced generation of ROS, and since dysfunctional mitochondria will produce more ROS, a feed-forward loop is set up, resulting in a vicious cycle (Wang, et al., 2007; Zhu, et al., 2006). A β is also known to increase ROS production in different cerebral cell types and we showed that both NOX inhibition and exogenous antioxidants were able to counteract the toxic effect of A β 1-42, confirming that reduced cell viability was indeed caused by ROS.

The cytotoxic effects of vascular A β might be caused by A β binding to RAGE. We observed for the first time a striking increase of RAGE expression in A β -laden capillaries. RAGE is a major influx transporter for A β across the BBB and its expression is upregulated in AD and transgenic models of amyloidosis in the affected cerebral vessels, microglia, and neurons (Zlokovic, 2008). RAGE not only imports A β into the brain, increasing A β accumulation in the cerebral parenchyma, but when bound to its ligands also induces ROS production through NADPH oxidase activation (Wautier, et al., 2001). Importantly, we showed that blocking RAGE prevents A β -induced decrease of cell viability.

Conclusion

Taken together, we show the occurrence of severe TJ alterations in A β -laden capillaries. Interestingly, affected capillaries were surrounded by NOX2-positive activated microglia. *In vitro* experiments confirmed that A β was able to decrease TJ mRNA levels and that both exogenous antioxidants as well as NOX inhibitors limit A β -mediated cellular toxicity. We further demonstrated that RAGE is the mediator of the A β -cytotoxic effects on endothelial cells. We speculate that due to increased local A β -driven ROS production, TJ protein expression is altered in the microvasculature of capCAA brains. It is plausible that extensive microvascular

A β depositions, enhanced microvascular expression of RAGE, and concomitant loss of TJ protein expression impair BBB function and consequently leads to inefficient transport of nutrients into the brain. Collectively, these pathological processes might hamper A β clearance from the brain and thereby contribute to neuronal damage.

Acknowledgments

We thank N. Hahn (Department of Pathology, VU medical center, Amsterdam, the Netherlands) and Prof. Dr. D. Roos (Sanquin Research, Amsterdam, the Netherlands) for providing the NOX-2 antibody.

Abstract

Introduction: β -Amyloid ($A\beta$) accumulation in cortical capillaries is a variant of cerebral amyloid angiopathy (CAA) referred to as capillary CAA (capCAA). CapCAA is associated with a neuroinflammatory response. In vitro studies indicate that $A\beta$ induces reactive oxygen species (ROS) production, mainly generated through NADPH oxidase (NOX), by activated microglia. ROS in turn can induce altered expression of tight junctions (TJ), which are eminent for blood brain barrier (BBB) function. Whether the function of the BBB is affected in the brains of Alzheimer's disease (AD) patients with co-morbidity capCAA remains elusive. Interestingly cases with only capCAA exist making it possible to study the capCAA independent of the AD pathology

Aim: In this study we have investigated BBB alterations in capCAA and addressed the role of the neuroinflammatory response.

Methods: Human *post mortem* brain tissue with capCAA was analyzed by immunohistochemical staining.

Results: In this study we show for the first time a dramatic loss of TJ proteins claudin-5, occludin and ZO-1 in $A\beta$ -laden capillaries. In addition, affected capillaries are associated with clusters of NOX-2-positive activated microglia. Disrupted BBB function was observed by increased presence of fibrinogen around the affected capillaries.

Conclusions: Our data provide support for early observation that the neuroinflammatory response is involved in the altered expression of TJs in endothelial cells and loss of BBB integrity in capCAA.

Key words: Alzheimer's disease, Cerebral Amyloid Angiopathy, neuroinflammation, blood-brain barrier.

Introduction

Cerebral amyloid angiopathy (CAA) is frequently observed in Alzheimer's disease (AD) and is characterized by deposition of β -amyloid ($A\beta$) in leptomeningeal and cortical brain vasculature. In 40% of AD cases, $A\beta$ mainly accumulates in cortical capillaries, a phenomenon referred to as capillary CAA (capCAA) (Richard, et al., 2010). Relatively little is known about the impact of capCAA on AD pathogenesis. Previously, we have shown that a strong neuroinflammatory response, consisting of clusters of activated microglia and astrocytes, occurs specifically around capCAA vessels with dyschoric $A\beta$ deposits, similar to the observed changes around $A\beta$ plaques in the parenchyma (Akiyama, et al., 2000; Richard, et al., 2010). The inflammatory reaction associated with $A\beta$ deposits is thought to play a role in the pathogenesis of AD and likely contributes to the symptoms of cognitive decline (Arends, et al., 2000; Roze-muller, et al., 2005). Concomitant to cognitive decline, the inflammatory reaction associated with $A\beta$ deposits is thought to play a role in the pathogenesis of AD and likely contributes to the symptoms of cognitive decline (Arends, et al., 2000; Roze-muller, et al., 2005). Concomitant to cognitive decline, the inflammatory reaction associated with $A\beta$ deposits around capillaries could impair the function of the blood-brain barrier (BBB).

Upon phagocytosis or recognition of $A\beta$ by microglia cells, a series of responses may occur, which include the release of proinflammatory cytokines and reactive oxygen species (ROS). ROS are predominantly produced by activation of NADPH oxidase (NOX) and during mitochondrial respiration and ROS generation are significantly increased under neuropathological conditions. Microglia mainly express NOX-2 and we showed that activated microglia around $A\beta$ -laden capillaries show an enhanced expression of the ROS-generating enzyme NOX-2 suggesting local ROS production (Carrano, et al., 2011).

In vitro studies have revealed that both endogenous and exogenous ROS induce loss of endothelial cell-cell interactions (van Wetering, et al., 2002) and are able to modulate BBB integrity and disrupt tight junctions (Schreibelt, et al., 2007). Tight junctions (TJs) are the main structures responsible for the barrier properties of the BBB and restrict the entry of circulating molecules and cells. These results support the idea of increased production of ROS in close proximity of capCAA-affected vessels and are in line with the observation that protein and DNA oxidative damage are increased in AD brains (Lyras, et al., 1997; Wang, et al., 2005). Opening of the BBB and concomitant altered TJs expression or localization has been attrib-

uted to vascular A β aggregates (Blanc, et al., 1997; Gonzalez-Velasquez, et al., 2008; Marco and Skaper, 2006; Tai, et al., 2009), however, comprehensive immunohistochemical studies on BBB abnormalities in A β -laden capillaries are limited. In line with previous *in vitro* data we hypothesize that the recruitment and activation of microglia due to A β deposition at the capillaries would generate ROS in proximity of the endothelium and consequently affect the expression of TJ proteins and BBB integrity.

Methods

We selected a cohort of patients with severe capCAA (n = 23). Human brain specimens were obtained at autopsy with a short postmortem interval (The Netherlands Brain Bank, Amsterdam, The Netherlands and University Medical Centre Utrecht, The Netherlands). Neuropathological evaluation was performed on frozen tissue and formalin-fixed, paraffin-embedded tissue from occipital pole cortex. Brain tissue was analyzed for expression of TJs, NOX-2, plasma proteins and A β by immunohistochemical staining.

Results

In our cohort of capCAA cases, abundant A β deposits are localized at the capillary level, as we previously described (Richard, et al., 2010). Immunohistochemical staining of brain tissue slices of capCAA cases showed a strong inflammatory response and typical intraneuronal accumulation of ubiquitin and hyperphosphorylated tau in dystrophic neurites, a sign of a severe neuronal dysfunction, localized around capCAA. Both glia activation and neuritic changes strictly correlated with the severity of microvascular A β load in the tissue. Microglia clustered around capCAA capillaries not only appeared morphologically activated but showed a strong expression of NOX-2 when compared to control situation, suggesting increased production of ROS and consequent oxidative stress around capCAA (Carrano, et al., 2011).

When analyzing TJ expression, we observed a partial loss (30–40%) of TJ proteins, occludin, claudin-5 and ZO-1 in A β -laden capillaries. Furthermore, immunohistochemical stainings revealed leakage of fibrinogen within the brain parenchyma in severe capCAA. In the cases analyzed (n = 8), fibrinogen was found as a diffuse staining within the parenchyma-surrounding vessels and in the majority of the cases (n = 7), we also found colocalization of fibrinogen with the most fibrillar capillary A β deposits. In the 3 most severe capCAA cases, the positivity for fibrinogen was virtually present around all A β -laden vessels, suggesting an ongoing dis-

ruption of BBB integrity. The measured changes (reduced TJ expression, glia activation and fibrinogen leakage) all correlated with severity of capCAA pathology.

Discussion and conclusion

In this study we showed that activated microglia express NOX-2 cluster around capCAA capillaries; this induces increased production of ROS that eventually affects TJs and BBB integrity leading to leaking of fibrinogen. The effects of vascular A β on endothelial cells and microglia are mediated, at least in part, by A β interaction with the receptor for advanced glycation end products (RAGE), which we and others found to be upregulated in capCAA, AD and transgenic mouse models of amyloidosis in the affected cerebral vessels, microglia, and neurons (Carrano, et al., 2011; Zlokovic, 2008). RAGE mediates transport of A β into the brain parenchyma. In addition, A β /RAGE interaction has been reported to activate NOX and a cascade of effects such as NF- κ B-mediated endothelial activation. Overall A β /RAGE interaction results in increased secretion of proinflammatory cytokines, expression of adhesion molecules and suppression of cerebral blood flow (Zlokovic, 2008). A β /RAGE interaction is also able to activate microglia, and consequent inflammatory response, and is thought to be involved in the clustering of microglia around A β deposits (Fang, et al., 2010). A β accumulation in the brain is a gradual process that probably involves alteration of the physiological clearance of amyloid from the brain, either through A β transport across the BBB or along perivascular spaces. A β deposits trigger the recruitment of microglia around affected capillaries. Both activated microglia and endothelium release proinflammatory cytokines and ROS which compromise not only TJs but also neuronal function. The breakdown of the BBB may disrupt the normal transport of nutrients, vitamins and electrolytes across the BBB, which are essential for proper neuronal functioning and thus contribute to the neurodegenerative process. In addition, the abnormal production of proinflammatory cytokines, chemokines and the complement system, as well as ROS, by microglia, can disrupt nerve terminals causing dysfunction and loss of synapses, which correlates with memory decline (Hensley, 2010). It appears that impairment of the BBB and a chronic neuroinflammatory response both aggravate synaptic and neuronal dysfunction, and are therefore important players in the resulting neuronal loss and dementia associated with AD.

Figure 1. Fibrinogen leakage in capCAA. Post mortem tissue of capCAA brains shows fibrinogen staining (purple) surrounding A β (pink) laden vessels. A) depicts 2 microvessels affected by A β deposition. In the left one a strong staining for fibrinogen is also present colocalizing with A β . Non affected microvessels show expression of TJ protein claudin-5 (brown). B) magnification of an A β (pink) microvessel showing reduced expression of claudin-5 (brown) and deposition of fibrinogen (purple) along the vessel walls. C) On the left, a severe leakage of fibrinogen (purple) can be observed around A β (pink) laden vessels. Fibrinogen appears as a diffuse staining in the parenchyma surrounding the vasculature, and in some instances also colocalizes with vascular A β . In the most affected area, activated glia cells show fibrinogen positivity as well.

Abstract

Alzheimer's disease (AD) is the most common form of dementia and marked by deposition of amyloid β ($A\beta$) within the brain. Alterations of $A\beta$ transporters at the blood-brain barrier may have a role in the disease process. We investigated the expression of ABC transporters P-gp and BCRP in non-neurological controls, AD, and severe capillary cerebral amyloid angiopathy (capCAA) cases, which are characterized by deposition of $A\beta$ within the structure of cerebral capillaries.

Our data show that P-gp and BCRP are profoundly downregulated in capCAA, but not in AD and control cases. *In vitro* P-gp, but not BCRP, was down-regulated in brain endothelial cells by exposure to oligomeric $A\beta_{42}$, but not fibrillar $A\beta_{42}$ or $A\beta_{40}$. Co-incubating $A\beta_{42}$ together with clusterin, an amyloid associated protein highly expressed in capCAA, strongly reduced levels of P-gp.

In conclusion, accumulation of $A\beta$, in combination with clusterin, within and around cerebral capillaries may further aggravate the disease process by affecting P-gp expression. Loss of P-gp expression or activity may serve as a selective biomarker for ongoing capCAA.

Introduction

Alzheimer's disease (AD) is the most common form of dementia and characterized by increased deposition of amyloid β ($A\beta$) within the brain. Accumulation of $A\beta$ depends on a disequilibrium between production and clearance of $A\beta$. Several pathways for $A\beta$ clearance have been described: (1) $A\beta$ endocytosis by astrocytes and microglial cells; (2) $A\beta$ enzymatic degradation (e.g., by neprilysin or the insulin-degrading enzyme); (3) $A\beta$ transport across the BBB and/or (4) $A\beta$ drainage along perivascular spaces (Thal, et al., 2008b; Weller, et al., 2008). If any of these mechanisms fail the result is an increased retention of $A\beta$ within the brain and consequently $A\beta$ aggregation and deposition.

The BBB plays a crucial role in maintaining the delicate homeostasis of the brain, including the active removal of $A\beta$. Through restrictive barrier properties and polarized expression of selective transporters, such as the ATP-binding cassette (ABC) transporters, the BBB effectively regulates movement of metabolites and nutrients between blood and brain parenchyma.

Previously, we have shown that the BBB is altered in cases with severe capillary cerebral amyloid angiopathy (capCAA), a specific subtype of CAA characterized by $A\beta$ protein accumulation in the walls of brain capillaries, which occurs in up to 51% of AD cases (Attems, 2005; Richard, et al., 2010; Thal, et al., 2002; Thal, et al., 2008b). Patients with capCAA can also present with rapidly progressive dementia disease (Eurelings, et al., 2010) or can have a diagnosis of vascular disease. In capCAA the deposition of $A\beta$ occurs at the level of the BBB and it is therefore feasible that the mechanism principally altered in capCAA patients is $A\beta$ transport across the BBB. It has been hypothesized that changes in protein expression at the BBB endothelial cells may increase the $A\beta$ load in the brain leading to the $A\beta$ accumulation as observed in AD and CAA (Zlokovic, 2011).

In recent years, the involvement of the ABC transporters in the pathogenesis of AD has been postulated. In particular, P-glycoprotein (P-gp) and breast cancer resistant protein (BCRP) are of interest in the disease process, since both transporters mediate $A\beta$ clearance from the brain (Wolf, et al., 2012). Changes in expression and function of ABC transporters at the BBB may therefore be a primary cause of increased $A\beta$ load in the brain, especially in the presence of capCAA.

In the brain, A β deposits often are associated with accumulation of other proteins, which can modulate the response of the cerebral cells to A β exposure (van Horssen, et al., 2005; Veerhuis, et al., 2005). Recently, genome-wide association studies showed that, in addition to ApoE genetic variants, single nucleotide polymorphisms in the clusterin gene may also confer risk to develop sporadic AD (Harold, et al., 2009; Lambert, et al., 2009). Therefore we hypothesized that clusterin, an amyloid associated protein (Kida, et al., 1995; McGeer, et al., 1994; Nuutinen, et al., 2009; Zhan, et al., 1994), might enhance the potential detrimental effects of A β on the brain endothelium. Clusterin also binds to and facilitates the transport of A β through the binding to LRP2 (low-density lipoprotein receptor-related protein 2) and it is actively involved in mechanisms that clear A β from the brain across the BBB (Calero, et al., 2000) (Bell, et al., 2007) (Zlokovic, 2008).

Because of the possible crucial role of P-gp and BCRP in maintaining a homeostatic level of A β and their localization at the brain capillaries, we set out to investigate the expression of the ABC transporters in AD cases, and we specifically selected cases that at the neuropathological examination presented with severe capCAA. Herein, we compared the expression profile of P-gp and BCRP to non-neurological control tissues and the differential incidence of transporter changes in AD and capCAA cases.

Accumulated A β itself can damage the BBB thereby altering the expression of several proteins, such as tight junctions (Carrano, et al., 2011b). Using an *in vitro* approach, we analysed the downstream effects of A β on the expression of P-gp and BCRP in a validated human endothelial BBB *in vitro* model accordingly to A β aggregation state (fibrillar or oligomeric) and isoform (A β 40 or A β 42).

We here describe that specifically in capCAA cases the expression of ABC transporters P-gp and BCRP is strongly reduced, in comparison with controls and AD without capCAA, and we demonstrated *in vitro* that A β reduces the expression of P-gp especially in combination with clusterin.

Material and Methods

Post-mortem tissue

Cases were selected on the basis of the neuropathological diagnosis and immunohistochemical characterisation of A β aggregates. Seven patients with neuropathologically diagnosed capCAA, 5 AD cases without capCAA and 4 age-matched non-demented controls were selected. Human brain specimens were obtained at autopsy with a short *post-mortem* interval (The Netherlands Brain Bank, Amsterdam, The Netherlands and University Medical Centre in Utrecht, The Netherlands). Neuropathological evaluation was performed on frozen tissue and formalin-fixed, paraffin-embedded tissue from occipital pole cortex. CapCAA score was defined as follow: severe (+++), moderate (++) , mild (+). AD pathology was evaluated according to Braak (Braak, et al., 2006; Braak and Braak, 1991) and CERAD (Mirra, et al., 1991). Age, gender, *post-mortem* delay (PMD), Braak, CERAD and capCAA scores and cause of death of all cases used in this study are listed in Table 1.

Table 1. Summary of Patient Details

Patient #	Age	Sex	PMD	Braak	CERAD	capCAA	cause of death
capCAA 1	76	M	< 24 h	IV	C	++/+++	pneumonia
capCAA 2	78	F	< 24 h	IV	A	+++	pneumonia
capCAA 3	95	F	< 24 h	III	B	++	peritonitis
capCAA 4	75	M	22 h	III	0	+++	pneumonia
capCAA 5	65	M	7 h	V	C	++/+++	pneumonia
capCAA 6	75	F	6 h	V	C	+++	dehydration
capCAA 7	71	F	< 24 h	IV	B	+++	Pneumonia
AD 1	89	F	4:30 h	VI	C	-	pneumonia
AD 2	69	M	5 h	VI	C	-	pneumonia
AD 3	67	F	6 h	VI	C	-	pneumonia, dehydration
AD 4	81	F	6 h	VI	C	-	pneumonia
AD 5	91	F	5:45 h	VI	C	-	ruptured aneurysm
control 1	80	M	7 h	0	0	-	cachexia, dehydration
control 2	93	F	6 h	II	0	-	cachexia
control 3	84	M	7 h	I	0	-	Exacerbation of COPD
control 4	77	F	n.d.	I	A	-	cachexia

capCAA: capillary cerebral amyloid angiopathy; AD: Alzheimer's disease; PMD: post-mortem delay; M: male; F: female; COPD: chronic obstructive pulmonary disease

Immunohistochemistry

5 µm paraffin sections were mounted on coated glass slides (Menzel Gläser super frost PLUS, Brainschweig, Germany) and dried O/N at 37 °C. Sections were deparaffinized and rehydrated by xylene and a sloping concentration of ethanol (100%, 96% and 70%). Endogenous peroxidase was blocked by incubating the sections in methanol + 0.3% H₂O₂ for 30 minutes. Antigen retrieval was established by boiling the sections in 1 mM EDTA buffer for 10 minutes. Sections were O/N incubated with anti-P-gp or anti-BCRP antibodies (Table 2) diluted in PBS supplemented with 1% BSA. Next, sections were incubated for 1 h with relative secondary antibodies HRP-labelled. For P-gp HRP EnVision undiluted solution was used. For BCRP sections were incubated with goat anti-mouse IgG2a HRP-labelled. Peroxidase labelling was visualized by EVDAB 1:50. Sections were then stained for Aβ with anti-Aβ (mouse, DAKO) for 1h, after a further 15 minutes treatment with formic acid. After 60 minutes incubation with alkaline phosphatase conjugated goat anti-mouse IgG1, tissue sections were washed in 0.2 M Tris-HCl buffer, pH 8.5. Alkaline phosphatase was visualized by Liquid Permanent Red (LPR; Dako, Glostrup, Denmark). Finally, tissue sections were counterstained with haematoxylin. Slides were covered with aqueous mounting medium (Aquatex, Merck, Darmstadt, Germany). Between all incubation steps, sections were extensively washed with PBS (pH 7.4).

Immunofluorescence

For colocalization studies, cryosections were incubated in thioflavin S solution (100 mg/ml) for 5 minutes to stain A β fibrils and washed subsequently 3 times in ethanol (70% in water). Sections were incubated with normal goat serum 1:10 in PBS containing 1% bovine serum albumin for 10 minutes. For P-gp and BCRP staining sections were incubated O/N with a mix of primary antibodies: mouse-anti P-gp/BCRP and rabbit-anti factor VIII diluted in PBS containing 1% bovine serum albumin. Sections were then incubated with secondary antibodies: Cy5 labelled goat-anti-rabbit 1:100, diluted in EnVision goat-anti-mouse HRP (Dako, Glostrup, Denmark) for 30 minutes. For the immunohistochemical analysis of clusterin, sections were incubated O/N with a mix of primary antibodies: mouse-anti clusterin (IgG1) and mouse-anti A β 4G8 (IgG2b). Subsequently, sections were incubated with isotype-specific secondary antibodies: goat-anti-mouse IgG2b horseradish peroxidase (HRP) and biotinylated goat-anti-mouse IgG1. An incubation step of 1 h with Streptavidine-Alexa633 followed. For all stainings peroxidase labelling was visualized by reaction with rhodamine-tyramide (1:3000) in presence of 0.01% of H₂O₂ for 5 minutes. After washing, slides were covered with Vectashield (Vector laboratories, Burlington, CA, USA). Between all incubation steps, sections were extensively washed with PBS (pH 7.4). Fluorescent analysis was performed with a Leica TCS SP2 AOBS confocal laser-scanning microscope (Leica Microsystem, Heidelberg, Germany). Quantification of vessel expressing ABC transporters was performed by manually counting the percentage of positive vessels in four 100 times magnified fields per slide. Total amount of vessels in the field was counted based on factor VIII staining.

Cell culture

The human cerebral microvascular endothelial cell line (hCMECs) that expresses key BBB proteins were maintained in EBM-2 medium (Clonetics, Cambrex BioScience, Wokingham, UK) which was supplemented with VEGF, IGF-1, EGF, basic FGF, hydrocortisone, ascorbate, gentamycin and 2.5% fetal bovine serum (FBS) 40. T75 Flasks, 96 wells plates and 24 wells plates were coated with type 1 collagen (Gibco HBSS, Invitrogen, USA). hCMECs were detached at 37 °C with 2 ml trypsin/EDTA in PBS. Cultures were grown to confluence at 37 °C in 5% CO₂ until the formation of monolayers (Carrano, et al., 2011b; Weksler, et al., 2005).

A β preparations

Synthetic A β 42 (Bachem, Bubendorf, Switzerland) and A β 40 (Anaspec, USA) were dissolved in 0.1% ammonium hydroxide and stored in 50 μ l, 1 mM aliquots at -80 °C. A β 40 and A β 42 preparations enriched in oligomers (O40, O42) and fibrils (F40, F42) were prepared essentially as described before (Chafekar, et al., 2008; Dahlgren, et al., 2002).

Fibrils were prepared as follows: 100 μ M A β was prepared in 10% HCl sterile solution, diluting stock drop by drop on vortex, followed by 10 minutes sonication. A β was incubated for 24h at 37 °C in order to form aggregates. The preparation was further diluted in culture medium to obtain appropriate concentrations prior to cell treatments. Oligomers were prepared as follows: 100 μ M A β was prepared in FBS-free cell medium, diluting stock drop by drop on vortex, followed by 10 minutes sonication. A β was incubated for 24 h at 4 °C in order to form oligomers. The preparation was further diluted in culture medium to 100 nM prior to cell treatments and incubated at RT for 1 h alone or in combination with 10 nM clusterin (isolated from human plasma by affinity chromatography as previously described (Krijnen, et al., 2005; Mulder, et al., 2012; Murphy, et al., 1988).

Electron microscopy

A β aggregates were applied to formvar carbon-coated copper grids (Stork Veco BV, Eerbeek, The Netherlands) and dried for 10 min. Grids were negatively stained with uranyl acetate for 5 min and examined with a Zeiss EM109 electron microscope to characterize the A β preparations.

Viability assay

The cytotoxicity of synthetic A β preparations was assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT; Sigma Aldrich, Germany) assay. hCMECs were cultured in 96 well plates until they reached confluence. Cells were incubated for 24 hours with 100 nM of A β 40 and A β 42 fibrils or oligomers enriched preparations with or without 10 nM clusterin. Cells were incubated with MTT (1 mg/ml) for 3 hours at 37°C. The formazan-salt generated by mitochondria of viable cells as a result of conversion of MTT was dissolved in glycin/DMSO (ratio 1:6) and the absorbance was measured at 540 nm.

mRNA isolation and real-time quantitative PCR

To investigate mRNA expression of ABC transporters, hCMECs were grown on a 24 wells plate until they reached confluence. Cells were incubated for 24 hours with 100 nM of A β 40

and A β 42 fibrils or oligomers enriched preparations with or without 10 nM clusterin. mRNA was isolated by using the mRNA capture kit (Roche Applied Science, Almere, the Netherlands) following the manufacturer's protocol. mRNA was reverse transcribed using the reverse transcription system kit (Promega, Madison, USA) according to the manufacturer's instructions using GeneAmp PCR system 9700 (Applied Biosystems, Foster City, USA). cDNA was diluted 3 times and quantified for mRNA levels of P-gp and BCRP relative to the housekeeping gene GAPDH. The accumulation of PCR product is measured using Sybergreen II (Applied Biosystems, Foster City, USA). Primers were developed using the program Primer Express 2.0 (Applied Biosystems, Foster City, USA). The sequences of primers are as follows: human P-gp: sense 5'-GTCCCAGGAGCCCATCCT-3', antisense 5'-CCCGGCT-GTTGTCTCCATA-3'; human BCRP: sense 5'-AGATGGGTTTCCAAGCGTTCAT-3', antisense 5'-CCAGTCCCAGTACGACTGTGACA-3'. The PCR amplification was performed in triplicate in a 7900 HT Fast Real-Time PCRSystem (Applied Biosystems, Foster City, USA). Relative expression levels of the ABC transporters in relation to the reference GAPDH were calculated using the mathematical model: $\Delta\Delta CT$. The formula is $2^{-\Delta\Delta CT}$ where $\Delta CT = CT_{\text{target}} - CT_{\text{reference}}$ and $\Delta\Delta CT = \Delta CT_{\text{sample}} - \Delta CT_{\text{calibrator}}$.

Statistical analysis

Data were analyzed statistically by Student's t-test or analysis of variance (ANOVA) followed by post hoc analysis with Bonferroni's method (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$).

Results

P-gp and BCRP protein expression in capCAA and AD

To visualize the expression pattern of the ABC transporters P-gp and BCRP in AD and capCAA samples and correlate it to A β deposition, tissue sections from occipital cortex of AD with and without capCAA and non-demented controls were co-stained for A β and either P-gp or BCRP (Fig. 1). No A β deposits were observed in control cases. AD without capCAA showed A β accumulation in classical and diffuse plaques and occasionally in large vessels and leptomeningeal vessels. In capCAA cases, A β was mainly found to be deposited in capillaries and larger vessels, with few or no amyloid plaques (Fig. 1).

In our cohort of severe capCAA cases, $39.6 \pm 21.5\%$ of microvessels was A β -positive.

In occipital cortex specimens of non-neurological control patients, homogeneous P-gp expression was observed in the cerebrovasculature and particularly in the microvasculature (Fig. 1a).

Interestingly, in capCAA most of the A β laden vessels showed profound loss of P-gp expression compared to controls (Fig. 1b). P-gp expression remained detectable in vessels not affect-

Figure 1. P-gp and BCRP expression in capCAA, AD and controls. Immunohistochemical detection of ABC transporter P-gp (a-c) and BCRP (d-f) in occipital cortex section from the brain of normal (a,d), AD (c, f) and capCAA case (b, e). ABC transporters (brown) are normally expressed in endothelial cells of capillaries as observed in control cases and in AD. A β (pink) is found deposited in parenchymal or vascular plaques, respectively in AD and capCAA cases. A severe loss of P-gp and BCRP is observable in A β -laden capillaries in capCAA cases compared to AD and controls.

ed by A β deposition. Expression of P-gp was occasionally detected in glial cells surrounding amyloid positive vessels, not in controls cases. In AD cases without capCAA the expression of P-gp in the capillary bed appeared unaltered (Fig. 1c), although we could observe some P-gp positive microglia in classical plaques.

BCRP showed a similar distribution pattern as P-gp in control cases, with strong immuno-reactivity in capillaries (Fig. 1d). We also observed a reduced expression of BCRP in capCAA cases, specifically in A β -laden vessels (Fig. 1e). No obvious changes were found in AD cases

Figure 2. Loss of P-gp expression in capCAA: co-localization study and quantification. a) Triple immunofluorescence analysis confirmed loss of P-gp (red) in endothelial cells affected by A β deposition. A β was detected by Thioflavin S (green). Endothelial cells were detected by endothelial markers factor VIII-von Willebrand (blue). b) Quantification of P-gp expressing capillaries in capCAA, AD and control microvasculature is shown in the graph. Bars indicate the percentage of P-gp positive microvessels. *** $p < 0.001$, by Student t test.

when compared to controls (Fig. 1f). No immunoreactivity for BCRP on glial cells could be detected.

To quantify the number of vessels positive for P-gp and BCRP, we performed a triple-staining for A β , P-gp/BCRP and the endothelial marker factor VIII (Fig. 2a and Fig. 3a). The total number of vessels per field was calculated based on the reactivity for factor VIII and did not significantly differ in the 3 groups.

The percentage of microvessels lacking P-gp expression was calculated showing that in the capCAA group 45.3 \pm 13.4% of the vessels lacked P-gp immunoreactivity (Fig. 2b). 75.3 \pm 17.7% of A β -positive microvessel lacked P-gp expression. P-gp negative microvessels all co-local-

Figure 3. Loss of BCRP expression in capCAA and AD: co-localization study and quantification. a) Triple immunofluorescence analysis confirmed loss of BCRP (red) in endothelial cells affected by or in proximity of A β deposition. A β was detected by Thioflavin S (green). Endothelial cells were detected by endothelial markers factor VIII-von Willebrand (blue). b) Quantification of BCRP expressing microvessels in capCAA, AD and controls microvasculature is shown in the graph. Bars indicate the percentage of P-gp positive microvessels. *p<0.05, ***p<0.001, by Student t test.

ized with A β . In AD cases without capCAA P-gp staining of microvessels appeared to be of lower intensity, however no significant reduction was observed in the number of P-gp positive vessels in the AD group without capCAA compared to controls.

The number of BCRP-positive vessels was strongly reduced in capCAA cases, up to $50.8 \pm 12.9\%$ of the total blood vessels, but no differences in staining intensity were observed. $77.4 \pm 15.5\%$ of A β -positive microvessel lacked P-gp expression in capCAA cases. Upon quantification we could measure a reduction also in AD cases without capCAA, counting up to $18.1 \pm 6.1\%$ BCRP negative vessels Fig. 3b).

A β effects on P-gp and BCRP gene expression

The observed reduction of P-gp and BCRP in the capillary endothelium of capCAA brain coincided with A β deposition, which suggests that A β may influence the expression of these transporters. To assess this, we analysed by means of quantitative real-time PCR, the expression of P-gp and BCRP by cultured human cerebral endothelial cells (hCMEC/D3) *in vitro* upon treatment (24 h) with either fibrils enriched or oligomers enriched A β 40, or either fibril enriched or oligomer enriched A β 42 preparations (100 nM). Of the 4 preparations tested, the oligomeric form of A β 42 induced a significant downregulation ($37.3 \pm 9.6\%$) in P-gp transcription levels (Fig. 4a) in line with the reduced expression observed by immunostaining in the human capCAA brains (Fig. 2b). No changes in the transcription levels of BCRP mRNA could be observed in the brain endothelial cell culture after exposure to A β (Fig. 4b).

Clusterin alters A β effects on ABC transporters

The expression of clusterin is upregulated in AD brains and clusterin is also known as an amyloid associated protein localizing with A β plaques and CAA (McGeer, et al., 1994; Zhan, et al., 1994). We therefore studied the distribution of clusterin in the human AD brains with and without capCAA by immunostaining. Our immunohistological examination confirmed the high levels of clusterin in the AD and capCAA cases and the colocalization of clusterin with A β deposits, in parenchymal plaques as well as in areas with (capillary) CAA (Fig. 5).

Due to the strong interaction of clusterin and A β , we hypothesized that the first can modify the effects of the latter, especially when aggregated around the capillary endothelium. To test this, we exposed a monolayer of human brain endothelial cells to a mixture of A β and clusterin and measured the expression of P-gp and BCRP (Fig.6).

Figure 4. A β effects on P-gp and BCRP gene expression. P-gp (a) and BCRP (b) mRNA expression was assessed by q-PCR on hCMEC upon 24 h A β treatment. Cells were treated with fibrillar or oligomeric preparation of A β 40 and A β 42 at 100 nM. (F40: Fibrillar A β 40; O40: oligomeric A β 40; F42: fibrillar A β 42; O42: oligomeric A β 42). P-gp expression is reduced by A β 42 oligomers. No effect on BCRP expression was observed. P-gp and BCRP expression was normalized to the expression of house-keeping gene GAPDH. Data were represented as the mean \pm SEM; n=at least three experiments with triplicate samples. * p <0.05, by Student t test.

Upon co-incubation with clusterin, A β fibrils and oligomers yielded similar results with respect to P-gp expression. Clusterin was found to predominantly affect the fibrillar A β preparations (of both A β 40 and A β 42) inducing a reduction in P-gp mRNA levels ($36.8\pm 0.12\%$ and $46.8\pm 0.14\%$ respectively) when compared to A β treatment alone. On the other hand, the oligomeric A β -clusterin preparations did not significantly differ from oligomeric A β alone in their ability to affect P-gp expression.

In these conditions, a significant reduction in P-gp expression was observed when cells were treated with 100 nM fibrillar A β 42 ($41\pm 0.5\%$) or oligomeric A β 42 ($37\pm 0.7\%$) in the presence of 10 nM clusterin. Clusterin alone did not induce significant changes in P-gp mRNA levels (Fig. 6a). Importantly, using the same set-up, no changes were observed in BCRP mRNA expression levels (Fig. 6b). Used treatments did not affect the cell viability as determined by MTT assay (data not shown).

Figure 5. Clusterin expression in capCAA, AD and control brain tissue. Expression of clusterin was detected by triple immunofluorescence analysis. A β was detected by Thioflavin S (green) and anti- A β antibody 4G8 (red). No A β or clusterin was detected in control tissue. Clusterin (blue) is strongly expressed in and around A β -laden capillaries and A β plaques. Merge shows colocalization of A β and clusterin in capCAA and AD cases.

EM characterization of A β preparations

The characterization of the A β preparations by electron microscopy (EM) confirmed the difference in aggregation state between fibrils and oligomers (Fig. 7). A β fibrils clearly exhibited thread-like fibrillar structures whereas the oligomeric preparations showed smaller and amorphous aggregates of various sizes. There was no difference in appearance between A β 40 and A β 42, although A β 40 fibrils seemed longer and less complex than A β 42 fibrils.

Clusterin and clusterin-A β preparations were also analysed by EM. Clusterin appeared as electron dense globular aggregates associated in amorphous larger complexes. When co-incubated with clusterin, the appearance of A β preparations changed drastically, as the oligomeric and fibrillar preparation appeared identical to each other as judged by EM. There was no remnant of the fibrillar structure of neither the fibrils, nor the aggregates visible in the oligomeric preparations. Clusterin/A β complexes were large and homogeneously strongly electron dense, characterized by a somehow random organization of small compact globular units (Fig. 7).

Figure 6. Clusterin alters A β effects on ABC transporters. P-gp (a) and Bcrp (b) mRNA expression was assessed by q-PCR on hCMEC upon 24 h 100 μ M A β treatment in the presence of clusterin. Fibrillar and oligomeric preparations of A β 40 and A β 42 were incubated for 1h with 10 μ M clusterin at room temperature prior to cell treatment. (F40: Fibrillar A β 40; O40: oligomeric A β 40; F42: fibrillar A β 42; O42: oligomeric A β 42). Transporter expression was normalized to the expression of house-keeping gene GAPDH. Clusterin altered the effects of the fibrillar, but not the oligomeric preparations, on P-gp expression. No effects on BCRP expression were detected. Data were represented as the mean \pm SEM, n=at least three. *p<0.05, **p<0.005 compared with vehicle treated endothelial cells; #p<0.05 compared A β preparations with and without clusterin, by twoway ANOVA followed by post hoc Bonferroni test.

Figure 7. Electron microscopy characterization of A β preparations. Figure shows electron micrographs of fibrillar and oligomeric A β preparations individually or in combination with clusterin. Preparations were incubated 24 h followed by a further incubation of 1h with or without clusterin prior to being added to the cell cultures. (F40: Fibrillar A β 40; O40: oligomeric A β 40; F42: fibrillar A β 42; O42: oligomeric A β 42).

Discussion

In this study we have shown that the expression of ABC transporters P-gp and BCRP is severely decreased in capCAA cases compared to AD cases lacking microvascular amyloid deposits. *In vitro* treatment with the oligomeric form of A β 42 specifically induces a reduction in P-gp expression, not BCRP expression, in cultured human brain endothelial cells. Furthermore, the presence of clusterin, which is highly expressed in capCAA affected vessels, strongly affects A β -mediated effects on P-gp, modifying the aggregation state of A β and inducing an oligomeric-like reduction in P-gp expression.

In our study we observed a selective loss of P-gp expression of in the microvasculature of cases with established capCAA compared to AD cases without amyloid-laden microvessels. P-gp, a transmembrane protein of 170 kDa, is thought to have a pivotal role in the clearance of A β from the brain and it has been shown to mediate the transport of A β in *in vitro* cell cultures (Kuhnke, et al., 2007; Lam, et al., 2001) and *in vivo* in AD mouse models (Cirrito, et al., 2005; Hartz, et al., 2010). We here are the first to report reduced expression of the ABC transporters P-gp and BCRP in cases with established capCAA using immunohistochemistry on *post-mortem* tissue. Several groups have analysed the expression of P-gp in models of AD. In hAPP mice, P-gp expression and function was profoundly reduced and re-instating its function restored the levels of amyloid in the brain of treated animals (Hartz, et al., 2010). Moreover, in a human cohort of non-demented elderly a reduced expression of P-gp was correlated with the extent of amyloid plaques (Vogelgesang, et al., 2002) and with vascular amyloid (Vogelgesang, et al., 2004). Diminished expression of P-gp has also been demonstrated in confirmed AD cases and correlated to vascular amyloid deposits (Jeynes and Provias, 2011; Wijesuriya, et al., 2010). In a recent *in vivo* study decreased P-gp function was measured in AD patients by positron emission tomography (PET) (van Assema, et al., 2012). Together, these data indicate that P-gp may have a role in the pathogenesis of AD. Our current findings confirm and extend this hypothesis that low capillary P-gp expression is specifically related to capCAA and not parenchymal A β deposition as we did not observe significant changes in P-gp expression in AD without microvascular amyloid deposits.

We show here a severe reduction in BCRP expression in A β -laden capillaries and we are the first to report a decrease in BCRP expression not only in capCAA, but also to a lesser extent

in AD without microvascular A β deposits. To date, there are conflicting reports in literature on the role of BCRP as an A β transporter and its involvement in AD pathogenesis is unclear. BCRP has been shown to transport A β 40 in murine and human endothelial cell systems (Tai, et al., 2009; Xiong, et al., 2009) while others reported no effect on A β transport (Hartz, et al., 2010; Krohn, et al., 2011). It has been shown that the expression of BCRP is unaltered in AD cases (Wijesuriya 2010) or even upregulated (Xiong 2010). Such differences are probably due to different techniques. In the study of Xiong and coworkers BCRP expression was measured by microarray analysis using RNA extracted from brain tissue. This provides an assessment of BCRP levels in the brain, and in all the different brain cell populations, and not specifically in the microvasculature. Wijesuriya et al. analyzed BCRP expression in hippocampal blood vessels of AD by immunohistochemistry and did not observe any significant changes compared to controls. In our study we found a slight decrease in vascular BCRP expression in the occipital cortex of AD cases, and a more striking loss in capCAA. Therefore regional differences might exist in the brain expression of BCRP and the occipital area, which is also the preferential site for capCAA, could represent a hot spot in the brain particularly susceptible to vascular changes.

In our approach we have considered capCAA and AD without microvascular pathology as separate entities. Despite the overlap of the pathological conditions, half of AD cases do not show A β deposition at the capillaries (Thal, et al., 2008a) and it appears that the downstream effects on the function of the BBB differs. It is conceivable that the altered expression of the ABC transporters P-gp and BCRP that we have observed specifically in capCAA is secondary to amyloid deposition in affected capillaries. We here provide evidence that A β induces a downregulation of brain endothelial P-gp *in vitro*, although it is not excludible that an initial reduction in P-gp and/or BCRP is responsible for an initial impaired clearance of A β from the brain, which ultimately causes amyloid accumulation in microvasculature. In turn, impaired P-gp and BCRP expression may become more profound in later stages due to the amyloid deposition itself. This last hypothesis is supported by the fact that we observed a significantly lower expression of P-gp in capCAA cases, even in non-A β -affected vessels, compared to controls and AD. Whether reduced P-gp and BCRP expression in capCAA is a primary or secondary effect can, however, not be concluded from *post-mortem* immunohistochemical studies, as high cerebral concentrations of diffusible amyloid in the severe capCAA cases

might affect the status of the endothelium, even in the absence of local insoluble deposits.

Changes in P-gp and BCRP expression in capCAA can be attributed to the inflammatory processes around A β -laden vasculature. P-gp and BCRP are regulated by pro-inflammatory cytokines (IL-6, TNF-alpha, IL-1 beta) (Miller, 2010) or under inflammatory conditions (Kooij, et al., 2011). Activated glial cells, surrounding microvessels (Bruinsma, et al., 2012; Carrano, et al., 2011a; Carrano, et al., 2011c; Richard, et al., 2010), secrete high levels of pro-inflammatory cytokines when challenged with A β , especially in combination with clusterin (Mulder, et al., 2012; Nielsen, et al., 2011) and could have a detrimental effect on P-gp and BCRP expression.

Although we could mimic reduced expression of P-gp *in vitro* upon A β treatment in human cerebral microvascular endothelial cells (hcMEC), we did not observe changes in BCRP expression. This is probably due to the fact that A β does not trigger a massive release of cytokines in hcMEC at the conditions we tested (Poller, et al., 2010), which might be necessary to downregulate BCRP.

The observed P-gp decreased expression in our *in vitro* system might be associated with the induction of the NADPH oxidase complex by amyloid treatment (Carrano, et al., 2011b) as it has recently been shown that NADPH oxidase activation in endotoxin-activated microglia lower the function of P-gp (Matsumoto, et al., 2012). We previously demonstrated that pre-aggregated fibrillar A β induces NADPH oxidase-driven release of reactive oxygen species in hcMEC via binding to RAGE (Carrano, et al., 2011b) and we hypothesise that RAGE might be involved also in the downregulation of P-gp, but further investigation is needed in order to clarify this point.

We showed here that clusterin is present at high concentrations in capCAA brains and strictly colocalized with vascular amyloid deposits. Recent genome-wide association studies repeatedly identified clusterin as a genetic risk factor for sporadic AD (Harold, et al., 2009; Lambert, et al., 2009). Clusterin also binds to and facilitates the transport of A β across the BBB through binding to low-density lipoprotein receptor-related protein 2 (LRP2) (Calero, et al., 2000) (Bell, et al., 2007) (Zlokovic, 2008). When the ratio A β :clusterin is in favour of A β , as in the conditions we tested, clusterin is incorporated in the A β aggregates. *In vitro* we found that clusterin interaction with A β aggregates not only is able to change the aggregation state of the

amyloid species, but by doing so it also alters the effects of fibrillar A β 42 on P-gp expression. In our system the binding of clusterin to A β fibrils changed the latter to complexes with *in vitro* effects similar to the oligomeric A β alone or oligomeric A β complexed with clusterin. On the other hand, no functional change was observed when we co-incubated A β oligomers with clusterin. Possibly this is due to the fact that clusterin disassembles A β fibrils into smaller particles with properties similar to the oligomers (Oda, et al., 1995). The effects evoked by clusterin might be either 1) conformational dependent: the binding to clusterin exposes one or multiple epitopes interacting with the endothelial cell surface; or 2) size dependent: the new generated small aggregates can be transported through the BBB. Both, either together or independently, might trigger a cascade of events leading to a change in P-gp expression.

In the light of our findings the reduced expression of the ABC transporters in AD and specifically in capCAA cases, might have relevant clinical implications. Several patient studies have suggested that humans with P-gp polymorphisms, or those receiving P-gp inhibitors, exhibit different pharmacological responses or even neurotoxicity in response to the administration of several drugs, such as loperamide, chemotherapeutics, antidepressants and antiepileptics when compared with control subjects (Greenberg, et al., 2005; Loscher, 2007; Sadeque, et al., 2000; Uhr, et al., 2008).

Vice versa, the selective loss of the function of P-gp may also have a beneficial effect by promoting the entry of therapeutics into brain. Some antiepileptics, most of which induce multi-drug resistance, might be part of such a category, as very recently it has been found that the antiepileptic drug levetiracetam ameliorates memory performance in mild cognitive impairment cases and AD mouse model (Bakker, et al., 2012; Sanchez, et al., 2012).

Therefore assessing *in vivo* P-gp function by PET in AD and capCAA patients could be useful in the clinical practice as therapeutic intervention outcomes can differ in cases with altered BBB profile. Furthermore and most importantly, as we have shown that a significant difference exists in P-gp expression between capCAA and AD, P-gp function assessed by PET could therefore be used as a diagnostic biomarker to clinically discriminate capCAA from AD.

Similar implications may hold true for BCRP, although, to date no specific PET tracers are available to reliably determine BCRP function *in vivo* (Dorner, et al., 2011). Nonetheless,

BCRP remains an interesting target and the mechanisms involved in BCRP regulation and its role in the development of AD and capCAA need to be further elucidated.

Our data suggest that P-gp expression is the key ABC transporter affected in capCAA. We therefore hypothesize that alterations of P-gp at the cerebral capillaries are key to and specific for capCAA mediated disease progression and that loss of P-gp activity may serve as a selective marker for capCAA. The identification of underlying mechanisms of observed alterations of P-gp at the cerebral microvasculature in capCAA may hold the key for novel intervention strategies to limit A β accumulation within the brain thus preventing cognitive decline and concomitant neurodegeneration.

Acknowledgements

We thank Jan Fritz (Department of Pathology, VU medical center, Amsterdam, the Netherlands) for the electron microscopy analysis and George Scheffer and Rik Scheper (Department of Pathology, VU medical center, Amsterdam, the Netherlands) for the production and characterization of P-gp and BCRP antibodies. We thank the Netherlands Brain Bank (Amsterdam, the Netherlands), especially Michiel Kooreman, for providing excellent post-mortem human brain tissue, and are grateful to all patients and controls that donated their brains.

Summary and discussion

capCAA and AD

Amyloid β protein deposition in the walls of capillaries is a subtype of cerebral amyloid angiopathy (CAA) referred to as capillary CAA (capCAA). CapCAA is a neuropathological feature present in 51% of AD cases (Thal, et al., 2008). Patients with capCAA can also present with rapidly progressive dementia disease or can have a diagnosis of vascular disease. We have selected cases with prominent capCAA pathology, in which vascular $A\beta$ is the main form of amyloid deposition. The presence of extensive capCAA distinguishes a subgroup of AD cases showing few or no parenchymal plaques, the characteristics of which are studied and described in this thesis.

Identification of differentially expressed proteins in clinical cases that present capCAA pathology could reveal specific insight in the underlying molecular mechanism resulting in the disturbed clearance of $A\beta$ across the BBB as well as specific biomarkers for capCAA.

For the aim of this thesis the following main goals were formulated:

- Describe the neuropathological characteristics of capCAA, common features and differences with classic AD.
- Assess BBB changes in capCAA and underlying pathological pathways.

Spatial localization of $A\beta$ isoforms: $A\beta_{40}$ and $A\beta_{42}$

In chapter 2 we described the main histopathological features of capCAA comparing it with CAA in larger blood vessels (from now on referred to as CAA) and with the common hallmarks of AD (Richard, et al., 2010). Hereto, we histopathologically analyzed a unique cohort of severe capCAA cases. Interestingly, we observed major differences between capCAA and CAA. Firstly, capCAA is more often accompanied by dyschoric changes, i.e. extrusion of $A\beta$ fibrils that radiate from the vessel wall into the brain parenchyma, compared to CAA. Such changes may occur in two distinct forms: bulb-like dense deposits sitting on the capillary walls and flame-like $A\beta$ aggregates spreading from the capillaries into the neuropil. Upon studying the composition of the amyloid deposits in capCAA we could demonstrate that both

the main A β isoforms, A β 40 and A β 42, are present in capCAA. Specifically, we showed that A β 42 is the main component of the dense bulb-like deposits adjacent to the capillary wall, while A β 40 accumulation was predominantly found in the flame-like deposits. These features are significantly different from what has been observed in CAA-affected vessels in AD. In CAA the main isoform present is A β 40, which is mostly localized within the vessel walls of arteries and leptomeningeal vessels. In CAA A β intercalates between smooth muscle cells and the tunica media and adventitia of small and mid-sized arteries. Capillaries lack such a structural organization (i.e. several concentric layers) in which A β can accumulate, therefore when the amyloid starts aggregating around the capillaries it cannot be trapped within the vessel walls and naturally spreads into the surrounding neuropil. The bulb-like deposits of A β 42 that we described are likely to be the seeding focal points where A β aggregation starts, as it is known that A β 42 is highly fibrillogenic and a seed of A β 42 exponentially increases and speeds up fibril formation *in vitro* and *in vivo* (Lehner, et al., 2011). The peculiar deposition pattern seen in capCAA is also different from what is seen in the classical plaques of AD patients. The bulb-like and flame-like deposits remarkably resemble classical plaques, especially when they are combined and occur in the same location, with the dense bulb resembling the globular amyloid core of the plaque and the flames the halo of the plaque. In the absence of an isotype specific staining, capCAA with such characteristics can be easily mistaken for a plaque residing next to a capillary. Despite these morphological similarities, the core of classical plaques is mainly composed of A β 40, versus the capCAA bulbs being A β 42, and the diffuse halo is predominantly composed of A β 42, versus the capCAA flames being A β 40. This clearly shows that plaques and capCAA are two distinct phenomena, which are likely the result of different pathological pathways involved in A β aggregation and clearance. Importantly, the occurrence of plaques and capCAA are inversely correlated, meaning that areas of the brain densely affected by capCAA deposits show less plaque burden. This might implicate that the local microenvironment influences A β depositing either as plaque or capCAA, suggesting that capCAA occurs in those areas where A β flows toward the circulation in the attempt of being cleared from the brain. Amyloid driven pathogenesis/hypothesis of AD was first described by our own group with Masters and Beyreuther in 1989 (Rozeumuller, et al., 1989), but what is the mechanism directing the aggregation of A β either toward the parenchymal compartment or the vascular one? It has been shown that in mouse models the ratio of A β 40:A β 42 is a critical factor that influences the formation of CAA or plaques. In the

presence of a high A β 40:A β 42 ratio, the formation of CAA is favored. Increasing the concentrations of both A β 40 and A β 42, maintaining the ratio in favor of A β 40, induces the formation of both plaques and CAA. On the other hand, when A β 42 is the main amyloid isoform, only plaques are formed (Oppenheim, 1909). It has also been demonstrated that the ApoE genotype can modify the ratio A β 40:A β 42 in transgenic AD mice. ApoE4, the most important risk factor for capCAA and AD, increases the ratio A β 40:A β 42 and, by doing so, switches the deposition of A β from the parenchyma to the vasculature compartment (Divry, 1927). ApoE is able to influence A β aggregation and alters both transport and clearance of soluble A β in the brain. ApoE isoforms do not differentially influence A β production *in vivo*; however, ApoE isoforms differentially affect A β clearance before A β deposition, with ApoE4 resulting in clearance that is slower than ApoE3 and ApoE2 (Glennner and Wong, 1984b).

In human capCAA cases the brain ratio A β 40:A β 42 is higher than in AD and the frequency of ApoE4 alleles is higher as well. It would be tempting to speculate that ApoE4 is the culprit, but it is not that simple. Although ApoE4 has a strong association with developing capCAA and also correlates with capCAA severity, having one or two ApoE4 alleles is neither sufficient nor necessary for developing capCAA. Other factors are likely being involved and contribute to the modulation of A β clearance and aggregation.

Figure 1. Schematic representation of A β deposition in capCAA and CAA. Dyschoric A β accumulates as dense bulb-like deposits (blue) and flame deposits (red) in capCAA microvessels. Flames and bulbs are often lacking in large vessels CAA, where A β (black) predominantly accumulates between smooth muscle cells layers and tunica media and adventitia.

Amyloid associated proteins

Next to A β and ApoE, virtually all vascular and parenchymal A β depositions contain several inflammation-related proteins (Akiyama, et al., 2000; Eikelenboom and Stam, 1982; Eikelenboom and Veerhuis, 1996). These so-called A β -associated proteins (AAP) include clusterin, complement proteins, serum amyloid P component (SAP), α 1-antichymotrypsin (ACT), ICAM-1, α 2-macroglobulin, small heat shock proteins (sHSP) and heparan sulphate proteoglycans. These proteins play a role in the transport, fibrillogenesis, deposition and toxicity of A β and they are also important for the sequestration of neurotoxic A β species in plaques or CAA. Normally most AAPs are produced at low levels in the brain, however their synthesis rate increases in AD, following A β deposition (Eikelenboom and Stam, 1982; Greenberg, et al., 2008). Due to the involvement of AAPs in determining A β aggregation and transport, we have investigated their expression in capCAA cases. We have specifically shown that clusterin, laminin, complement proteins and SAP expression are strongly increased in capCAA. This increased expression was more striking in capCAA-affected vessels compared to what we observed around senile plaques, and clusterin, laminin, complement proteins and SAP strictly colocalized with fibrillar capillary amyloid deposits (chapter 3).

Besides ApoE, recent genome-wide association studies repeatedly identified clusterin as a genetic risk factor for sporadic late-onset AD (Harold, et al., 2009; Lambert, et al., 2009). Clusterin is associated with amyloid plaques, but we showed in chapter 3 and chapter 5 that its expression is significantly higher in capCAA. Similar to ApoE, clusterin is a glycoprotein involved in the clearance of A β peptides and fibrils by binding to low-density lipoprotein receptor-related protein 2 (LRP2) (Bell, et al., 2007; Calero, et al., 2000; Zlokovic, 2008) and enhancing endocytosis of fibrils by glial cells. The binding of clusterin to A β should promote A β clearance and thus overexpression of clusterin could be a cellular defense mechanism aimed at reducing A β levels in the capCAA brain. On the other hand, it has been demonstrated that the presence of clusterin can alter the aggregation of the amyloid leading to the formation of slowly sedimenting, non fibrillar A β complexes that are toxic to neurons (Bibl, et al., 2008; Goos, et al., 2009) and endothelial cells (chapter 5). Furthermore, an AD mouse model crossed with clusterin knockouts deposits fewer A β fibrils and have healthier neurites than those with clusterin, suggesting the protein exacerbates pathology (DeMattos, et al., 2002). The effect of clusterin may depend on the relative ratio of the protein to A β ; small

amounts of clusterin may stabilize oligomers, but not completely encase them, allowing the molecules to exert toxic effects.

Clusterin can also inhibit the activation of the complement system. This is an important property since several studies have demonstrated that protein aggregates, such as A β , can activate the complement system and provoke inflammatory responses in AD (Vinters, et al., 1996). Although clusterin is highly expressed in and around capCAA-affected vessels, it is apparently not able to regulate complement activation. Histochemical studies have revealed that in capCAA and CAA the complement system is activated and amyloid deposits contain several complement factors, e.g. C1q protein, and the membrane attack complex C5b-9 (chapter 3) (Eikelenboom and Stam, 1982; Eikelenboom and Veerhuis, 1996).

So it seems that the putative protective effects of clusterin fail in capCAA, where not only we observe a tremendous deposition of fibrillar A β , but also a severe inflammatory response, including activation of the complement system.

Inflammatory response in capCAA

Neuroinflammation seems to be a common response associated with capCAA and plaques as clusters of activated glial cells are observed in close proximity to capCAA-affected vessels and classic senile plaques. The inflammatory reaction associated with A β deposits is thought to play a role in the pathogenesis of AD and contributes to the symptoms of cognitive decline (Arends, et al., 2000; Rozemuller, et al., 2005). Interestingly, it appears that microglia and astrocytes are highly activated around amyloid-laden capillaries, while in large CAA-affected vessels, in the absence of dyschoric changes, we only observed reactive astrocytes, no activated microglia. Activation of glial cells is mainly related to the presence of dyschoric A β deposits in capCAA. These deposits induce recruitment and activation of microglia cells around the affected blood vessels, in contrast with the mild glial response observed around vessels with dense and compact globular A β deposits (chapter 2).

A similar pattern was observed when we analyzed the distribution of hyperphosphorylated tau and ubiquitin, which accumulate in dystrophic neurites. In all cases the parenchyma surrounding capCAA contains numerous dystrophic neurites showing similarities with the disturbances occurring around classical plaques in AD. Remarkably, dystrophic neurites are rarely seen in close proximity to large A β -laden vessels without dyschoric changes.

	capCAA	AD
<i>Aβ</i> deposition	vascular	parenchymal
Aβ40:Aβ42	Aβ40>Aβ42	Aβ40<Aβ42
tau	+	++
glia activation	+	+
CD45+ microglia	-	+
	(proinflammatory phenotype)	
<i>ApoE4</i>	++ (frequency 0.54)	+ (frequency 0.36)
<i>Clusterin</i>	++	+
<i>SAP</i>	++	+
<i>Complement</i>	++	+
<i>Lamininβ2</i>	++	-
<i>tight junctions</i>	-	+
<i>RAGE</i>	++	+
<i>P-gp</i>	-	+
<i>BCRP</i>	-	+

Figure 2. Summary of the characteristics of capCAA and AD studied in this thesis.

Both glia activation and neuritic changes strictly correlate with the severity of Aβ load in the tissue and vasculature. Microglia clustered around capCAA capillaries not only appear morphologically activated but show a marked expression of the reactive oxygen species (ROS) generating enzyme NADPH oxidase-2 (NOX-2), suggesting increased production of ROS and consequent oxidative stress around capCAA (chapter 4).

It is reasonable to hypothesize that the parenchymal reaction associated with capCAA (or more generally with dyschoric changes) is related to the amyloid conformational structure rather than the Aβ species. Similar inflammatory reactions can be found in other forms of amyloidosis. Interestingly, also prion amyloid fibrils lead to severe tauopathy and microglia

accumulation (Gonzalez-Mariscal, et al., 2011; Overgaard, et al., 2011).

Another peculiar observation we came across analyzing glia activation, and particularly the microglia, is the absence or low expression of CD45 by microglia in patients with capCAA. CD45 is an immunomodulator which reduces the proinflammatory phenotype of microglia cells, switching them to a more phagocytic mode, as demonstrated in an AD mouse model (Biffi, et al., 2010). The lack of CD45 might not only be involved in an impaired removal of A β by microglia, but also fuel the development of a severe inflammatory response around capCAA, inducing the microglia to secrete proinflammatory cytokines. Although these are preliminary observations, studying the phenotype of glial cells recruited around A β deposits can potentially be very interesting and deserves further investigation.

The abnormal production of pro-inflammatory cytokines, chemokines and the complement system, as well as ROS, by microglia, can disrupt nerve terminals causing dysfunction and loss of synapses, which correlates with memory decline (Hensley, 2010). These inflammatory mediators are produced by activated microglia and reactive astrocytes, but also neurons and vascular endothelial cells can further contribute to the production of pro-inflammatory cytokines, acute phase proteins and complement.

Vascular-derived products of a permanently dysfunctional endothelium could result in neuronal injury in neurodegenerative disease states. In the A β loaded brain, an injured/altered brain endothelial cell can also release factors that are injurious or toxic to neurons (Biffi and Greenberg, 2011; Glenner and Wong, 1984a).

To summarize, in capCAA both activated glial cells and endothelium can release proinflammatory cytokines and ROS, which compromise not only neuronal function but also BBB function and integrity (chapter 2 and 4).

BBB alterations in capCAA

An important function of the BBB that may go awry in AD and capCAA is the regulation of the brain pool of A β . Brain A β levels, which are in equilibrium with plasma and CSF A β concentrations, are modulated by influx and efflux of soluble A β across the BBB via interaction with specific receptors and transporters located on brain endothelium.

In capCAA accumulation of A β occurs exactly at the interface of the CNS and the systemic circulation, affecting those locations responsible for transport and clearance of A β into the venous or CSF compartments. The role of capCAA in altering and modulating BBB function and integrity, which directly affects A β clearance, is of particular relevance in understanding AD pathophysiology.

Brain endothelial cells regulate the neuronal milieu both by their synthetic functions as well as by their BBB function. Therefore, disturbance in cerebrovascular metabolic or transport functions could result in a noxious neuronal environment in the capCAA brain.

Disturbed clearance of A β

A β is mainly produced in neurons and astrocytes and then released into the brain interstitial fluid (Revesz, et al., 2002). Under normal conditions A β is cleared or removed, keeping A β concentrations low and thereby avoiding aggregation. Several pathways involved in A β clearance have been described: (1) A β endocytosis by astrocytes and microglial cells; (2) A β enzymatic degradation (e.g., by neprilysin or the insulin-degrading enzyme (IDE)); (3) A β transport across the BBB and/or (4) A β drainage along perivascular spaces (Thal, et al., 2008). If any of these mechanisms fail the result is an increased retention of A β within the brain and consequently A β aggregation and deposition as either plaques or (cap)CAA.

In capCAA the deposition of A β occurs at the level of the BBB; it is therefore feasible that the mechanism principally altered in capCAA patients is A β transport across the BBB. Accumulating evidence from patients and animal models of AD suggests that vulnerable brains may suffer from an increase in A β influx receptors and/or a decrease in A β efflux receptors (Bell and Zlokovic, 2009; Deane, et al., 2004).

The involvement of RAGE (receptor for advanced glycation endproducts) appears to be very

important in the development of the AD and capCAA pathology, since RAGE mediates the influx of A β into the brain parenchyma and consequently in an unbalanced situation enhances A β accumulation. RAGE is also known to be critical regarding the effects exerted by A β through its binding to the transporter. A β /RAGE interaction has been reported to activate NOX and a cascade of effects such as NF- κ B-mediated endothelial activation resulting in secretion of proinflammatory cytokines, the expression of adhesion molecules and suppression of cerebral blood flow (Zlokovic, 2008), fueling not only A β accumulation but also oxidative stress and inflammatory responses associated with capCAA.

While RAGE is expressed at relatively low levels in the microvasculature under physiological conditions, its expression is upregulated with increasing ligand concentration, including A β (Donahue and Johanson, 2008). In AD brains, RAGE is upregulated and found in neurons, astrocytes, and microglia particularly in proximity to A β plaques and neurofibrillary tangles (Deane and Zlokovic, 2007; Donahue, et al., 2006). We confirmed that A β induces a local up-regulation of RAGE in capCAA cases as well. In chapter 4 we have shown a striking increase in RAGE expression in capCAA-affected capillaries and demonstrated that A β cytotoxic effects on endothelial cells are exerted at least partially by its binding to RAGE.

Low density lipoprotein receptor/related protein 1 (LRP-1) is also expressed in the cerebral microvasculature and is a major A β efflux transporter (Shibata, et al., 2000). ApoE4, but not ApoE3 or ApoE2, blocks LRP1-mediated A β clearance from the brain and, hence, promotes its retention (Di Paolo and Kim, 2011). Reduced LRP1 levels in brain microvessels, perhaps in addition to altered levels of other efflux transporters like P-glycoprotein (P-gp), are associated with A β cerebrovascular and brain accumulation during ageing in rodents, non-human primates, and humans. In addition, LRP1 levels are increased in transgenic AD mice models as well as patients with Alzheimer's disease (Abbott, et al., 2010).

In fact, we have shown that the expression of two other efflux transporters for A β at the BBB, P-gp and breast cancer resistance protein (BCRP), is severely affected when we compare capCAA with controls and AD lacking microvascular amyloid pathology (chapter 5). These transporters are thought to facilitate the release of A β into the blood stream, subsequent to A β uptake mediated by LRP-1 in the endothelial cells of the capillaries. If one of these proteins is downregulated, cerebral A β levels are bound to rise. It has been demonstrated that mice lack-

ing P-gp at the BBB have reduced clearance of A β from the CNS and lower levels of LRP1 in brain capillaries (Cirrito, et al., 2005).

We also showed that P-gp loss in capCAA can be related to clusterin. The effects of clusterin on A β aggregation have significant repercussions on P-gp expression, as A β /clusterin complexes might have a peculiar interaction with cell membranes or other molecules inducing a stronger downregulation of P-gp than A β aggregates alone. This may represent an additional detrimental role for clusterin in the pathogenesis of capCAA.

Figure 3. The role of blood–brain barrier transport in brain homeostasis of A β . A β is produced from the A β precursor protein (APP), both in the brain and in peripheral tissues. Clearance of A β from the brain normally maintains its low levels in the brain. This peptide is cleared across the blood–brain barrier (BBB) by the low-density lipoprotein receptor-related protein 1 (LRP1). LRP1 mediates rapid efflux of a free, unbound form of A β and of A β bound to apolipoprotein E2 (ApoE2), ApoE3 from the brain’s interstitial fluid into the blood, and ApoE4 inhibits such transport. LRP2 eliminates A β that is bound to clusterin (CLU) by transport across the BBB. ATP-binding cassette P-gp and BCRP mediates A β efflux from the brain endothelium to blood across the luminal side of the BBB. Cerebral endothelial cells, pericytes, vascular smooth muscle cells, astrocytes, microglia and neurons express different A β -degrading enzymes, including neprilysin (NEP), insulin-degrading enzyme (IDE), tissue plasminogen activator (tPA) and matrix metalloproteinases (MMPs), which contribute to A β clearance. In the circulation, A β is bound mainly to soluble LRP1 (sLRP1), which normally prevents its entry into the brain. Systemic clearance of A β is mediated by its removal by the liver and kidneys. The receptor for advanced glycation end products (RAGE) provides the key mechanism for influx of peripheral A β into the brain across the BBB. Faulty vascular clearance of A β from the brain and/or an increased re-entry of peripheral A β across the blood vessels into the brain can elevate A β levels in the brain parenchyma and around cerebral blood vessels. At pathophysiological concentrations, A β forms neurotoxic oligomers and also self-aggregates, which leads to the development of A β plaques and cerebral amyloid angiopathy (modified from Zlokovic, *Nature Reviews Neuroscience* 12, 723-738).

The accumulation of clusterin and clusterin/A β complexes on the abluminal side of the BBB is possibly due to a reduction in the expression of the receptor that transports them across the BBB, LRP2.

The transport of A β across the BBB is a delicate and intricate mechanism mediated by proteins (transporters) the expression of which is modulated by several factors, first of all A β itself. It is quite remarkable that A β induces upregulation of the influx transporter RAGE and downregulation of the A β efflux transporters, meaning that initial subtle increases in A β concentration would degenerate in a more profound A β brain retention due to impaired clearance. We postulate that AAPs involved in the clearance of A β (like apoE and clusterin) are responsible to initiate this cascade slowing the rate of A β removal. In this scenario, the local environment surrounding the capillaries is subjected to increased levels of A β , which eventually aggregate in the microvasculature.

Multiple pathogenic cascades, possibly more than the ones described in this thesis, in the neurovascular unit may contribute to faulty clearance of amyloid across the BBB and amplify neuronal dysfunction and injury in capCAA.

Breaking the barrier

BBB disruption is a common feature of virtually all neurodegenerative disorders and so, along with neuroinflammation, can be viewed as a key component in the process of neurodegeneration. Changes in the cerebral microvasculature have been reported in brains of AD subjects (Abbott, et al., 2010; Blasig, et al., 2011; Claudio, 1996; Farkas and Luiten, 2001; Perlmutter and Chui, 1990). However, the mechanisms that underlie massive deposition of A β aggregates in cerebral blood vessels and brain parenchyma are poorly understood. Likewise, processes involved in A β -driven neuroinflammation and associated BBB malfunction are largely unknown.

In vitro studies support the idea that A β deposition affects BBB integrity since different A β peptides are able to increase endothelial permeability (Blanc, et al., 1997; Tai, et al., 2009) and induce altered expression and translocation of tight junctions (TJs) proteins in human and animal endothelial cells (Gonzalez-Velasquez, et al., 2008; Marco and Skaper, 2006).

When analyzing TJs we observed a marked loss of key TJ proteins, such as occludin, claudin-5 and ZO-1 in A β -laden microvessels (Carrano, et al., 2011), which was confirmed later by

Hartz and colleagues (Hartz, et al., 2012).

To unravel pathways involved in BBB damage and A β -induced oxidative stress in brain endothelial cells, an *in vitro* approach was taken using a validated human brain endothelial cell line. We showed a significant dose-dependent downregulation of TJ proteins occludin and ZO-1 mRNA levels upon A β treatment. Such downregulation is due to the release of reactive oxygen species mediated by the binding of A β to RAGE, which in turn activates NOX. The role of RAGE in contributing to BBB disruption is not only limited to the modulation of TJs expression but also affecting TJs integrity through induction of matrix metalloproteases (Coisne and Engelhardt, 2011).

Together, our data suggest that A β contributes to the loss of barrier integrity in capCAA by decreasing TJ protein expression. Likely consequences are barrier leakage and radiological cortical cerebral microhaemorrhages (accumulation of iron loaded macrophages)(Gonzalez-Velasquez, et al., 2008; Zipfel, et al., 2009), which are commonly associated with CAA (Menon and Kidwell, 2009; Raposo, et al., 2011).

Damaged BBB has been confirmed by immunohistochemical examination of capCAA brains revealing leakage of fibrinogen into the brain parenchyma. Fibrinogen was found as a diffuse staining throughout the parenchyma surrounding affected vessels and we frequently detected colocalization of fibrinogen with fibrillar capillary A β deposits. In the most severe cases fibrinogen immunoreactivity was present in tissue surrounding all A β -laden vessels, suggesting an ongoing disruption of BBB integrity. The histopathological changes, including reduced TJ expression, glia cell activation and fibrinogen leakage, all correlated with severity of capCAA pathology. Blood proteins, such as fibrinogen, have essential functions in the maintenance of integral vasculature homeostatic processes involved in blood clotting. However, under pathological conditions a weakened BBB could allow extravasation of plasma proteins into parenchymal regions of the brain. A likely consequence of increased infiltration of proteins is the exacerbation of inflammatory responses mediated by the resident immune responding cells, microglia.

Microglia may not only initiate an inflammatory response to A β but also amplify and sustain inflammation in response to fibrinogen extravasation (Ryu and McLarnon, 2009). In this case a chronic inflammatory environment could be maintained by reciprocal signaling between

activated microglia and perturbed vasculature. Concomitant to cognitive decline, the inflammatory reaction associated with capCAA could impair the function and integrity of the BBB and decrease A β removal, which contributes to disease progression. The inflammatory reaction associated with the vasculature exacerbates A β effects on the BBB, and specifically the impairment of the BBB integrity. Such damage of the BBB may play a significant, if not critical role in the pathogenesis of AD and capCAA, especially in terms of any distortions of the homeostatic balance of the brain, and in particular of cerebral A β levels.

Therapeutic strategies and search for biomarkers

Considerable effort has been made in recent years toward gaining a better understanding of the pathogenesis of AD, and in developing novel therapeutic approaches. However to date, there is no effective treatment that can prevent, delay or cure the disease and most of the latest clinical trials focusing on decreasing A β load in the brain have been unsuccessful. Interestingly, anti-A β immunization therapies resulted in reduced numbers of plaques in the brain parenchyma. However, in some patients this led to an increase in vascular amyloid and subsequent vasogenic edema (Alzheimer, 1907; Dierksen, et al., 2010). It is interesting that the risk of developing vascular side effects are strongly correlated to the ApoE4 allele, implying that an impaired A β clearance results in an ineffective treatment. Differential response to therapy, in such cases, might be due to the presence of ongoing (cap)CAA pathology. In AD cases with a certain degree of capCAA, or with an increased risk of developing capCAA (apoE4 carriers), plaque burden might be reduced, inducing the movement of A β from the parenchyma toward the vasculature district, in the attempt to be cleared via the blood stream. We have shown that in capCAA cases, clearance through the BBB is impaired because of altered expression of transporters and amyloid associated proteins, leading to build up of A β in and around the vasculature and consequent vascular complications.

Clinical diagnosis of “probable AD” is based on neuroimaging and biochemical analysis of the cerebrospinal fluid (CSF), together with neuropsychological examination. Reduced CSF A β 42 levels are consistently observed in AD patients (Mulder, et al., 2010), while, in contrast, levels of the more soluble CSF A β 40 are normal (Bibl, et al., 2008). Furthermore, the increased CSF total tau and phosphorylated tau concentrations in AD (de Jong, et al., 2007) are likely related to the pathological accumulation of these proteins in neurofibrillary tangles. AD pa-

tients with many microbleeds have even lower CSF A β 42 levels than AD patients without microbleeds, potentially due to additional amyloid deposition in cerebral vessel walls (Goos, et al., 2009) and CAA patients, presenting with lobar hemorrhage, exhibit lowered CSF levels of both A β 42 and A β 40 compared with controls and even to AD (Verbeek, et al., 2009). CapCAA cases would likely show lower levels of CSF A β 42 and A β 40 together with slightly increased CSF tau, reflective of the pathological features observed in the brain and how they compare to classical AD pathology. This remains an assumption as a comparative CSF analysis of AD, capCAA and CAA cases has yet to be performed, possibly due to the difficulties in differentially diagnosing these diseases during life.

Although guidelines to diagnose CAA during life exist (Boston criteria) (Knudsen, et al., 2001), these are not specific for capCAA. Hence currently, it is not possible to clinically define whether an AD case has capCAA pathology. Clinical evaluation of capCAA is very difficult, and although severe capCAA is associated with rapidly progressive dementia (Eurelings, et al., 2010), ApoE4 genotype (Richard, et al., 2010; Thal, et al., 2008) and occurrence of microbleeds (Dierksen, et al., 2010; Goos, et al., 2012), these findings are also observed in AD, or to be precise, in the heterogeneous population that we clinically define as AD.

Identifying biomarkers capable of discriminating subgroups in the AD population during life, in first instance cases affected by microvascular amyloidosis, is critical for the diagnosis of capCAA and the design of clinical trials, in terms of inclusion or exclusion of specific sub-populations for determined treatments. It also appears obvious that two sub-populations of AD, as diverse as we have described in this thesis, could benefit from different therapeutic approaches.

With our proteomics analysis of *post-mortem* tissue (chapter 3) we aimed to identify markers that could discriminate capCAA from AD. We have shown that proteins involved in A β aggregation and clearance at the BBB are severely modulated in capCAA, while these processes are marginally affected in AD. The ideal biomarker should be specific for capCAA and easily measurable *in vivo*, either in CSF (or even better, in plasma) or by brain imaging. Although we are still far from being able to pinpoint “the biomarker” for capCAA or AD, we have shown that cases with predominant microvascular (capCAA) or parenchymal (AD) A β are different enough to show significant differences in a small cohort using a proteomics approach.

In this thesis we have described common and different neuropathological features between AD and capCAA and pioneered the proteome analysis of capCAA and compared it with classical AD in *post mortem* tissue (chapter 3) describing pathways subjected to differential modulations, in first instance BBB related alterations. It is now important to continue in the direction of assessing the validity and feasibility of such proteins for use as biomarkers, for instance analyzing their modulation *in vivo* during disease progression in animal models and in human cases, e.g. by CSF analysis and brain imaging.

Conclusion

CapCAA is a distinct entity that defines sub-groups of both CAA and AD and whose pathogenesis is specifically associated with decreased transendothelial clearance of A β . CapCAA has a considerable influence on the BBB, affecting its integrity and function, and thereby affecting the homeostasis of the ageing brain.

We have demonstrated here that although capCAA and AD share some pathological hallmarks, several proteins involved in A β clearance are differentially deregulated. Proteins specifically up or down regulated in capCAA (and not in AD) might underscore altered pathogenic pathways explaining why A β accumulates around the brain vasculature instead of depositing as plaques in the brain parenchyma, as observed in AD. Furthermore, the identification of proteins that are clearly different between AD and capCAA cases could be used as biomarkers for the diagnosis of capCAA during life.

Appendices

Nederlandse samenvatting

De ziekte van Alzheimer

De ziekte van Alzheimer (AD) is een irreversibele, progressieve hersenaandoening die langzaam het geheugen en denkvermogen en uiteindelijk het zelfs het vermogen om eenvoudige taken uit te voeren, aantast. AD is de meest voorkomende oorzaak van dementie onder oudere personen. Dementie is het verlies van cognitief handelen – denken, herinneren en redeneren. Het leidt onder meer tot gedragsveranderingen, en heeft sterke invloed op het dagelijks leven en dagelijkse activiteiten.

Hoewel de oorzaak of oorzaken van AD nog niet volledig duidelijk zijn, is het gevolg van AD in de hersenen overduidelijk. AD beschadigt en vernietigt hersencellen (neuronen). Een door AD aangetast brein telt veel minder cellen en veel minder verbindingen tussen de overgebleven hersencellen dan een gezond brein. Door het voortschrijdende verlies van neuronen, zorgt AD voor significante krimp van de hersenen.

Wanneer doktoren hersenmateriaal van een AD patiënt onder een microscoop bekijken, zien ze drie soorten afwijkingen, die de typische kenmerken van AD worden genoemd:

Kluwen (*tangles*). Hersencellen zijn afhankelijk van een intern ondersteuning- en transportsysteem, dat essentiële bouwstenen en voedingsstoffen door de uitgestrekte axonen van de neuronen kan transporteren. Dit systeem staat of valt bij het goed functioneren van het eiwit tau. In de neuronen van een door AD aangetast brein binden lange slierten van dit eiwit samen tot een kluwen, waardoor het transportsysteem in de cel tot stilstand komt. Dit falen van het transportsysteem wordt sterk in verband gebracht met de afname van het aantal hersencellen bij AD.

Eiwit ophopingen (*amyloïde plaques*). De samenklontering van het eiwit beta-amyloid kan hersencellen op meerdere manieren beschadigen en vernietigen, ondermeer door het verstoren van de communicatie tussen de cellen. Hoewel de uiteindelijke oorzaak van het afsterven van hersencellen bij AD niet bekend is, is de ophoping van beta-amyloid één van de meest voornaamste verdachten.

Eiwit ophoping in de vaatwand (*vascular amyloid deposits*). Staat ook wel bekend als cerebrale amyloïde angiopathie (CAA) en is de ophoping van beta-amyloid op de wanden van

de bloedvaten in de hersenen. Er kunnen twee vormen van CAA worden beschreven: CAA type 1 wordt gekarakteriseerd door de eiwit ophoping in capillairen en wordt daarom vaak capillaire CAA (capCAA) genoemd. CapCAA komt voor in 51% van alle AD gevallen en correleert met de ernst van de dementie; CAA type 2 wordt gekarakteriseerd door beta-amyloid ophopingen in de grotere bloedvaten.

De amyloïde ophopingen vergroten de kans dat de aangetaste vaten slecht functioneren en verhogen daarmee de kans op hersenbloedingen en tasten de functionaliteit van de bloed-hersen barrière (BBB) aan.

Amyloïde ophoping

Een verminderde klaring van beta-amyloid uit de hersenen via de bloedvaten en/of een verhoogde terugstroom van beta-amyloid vanuit de perifere vaten leidt tot een verhoogd niveau van beta-amyloid in het hersenweefsel – het parenchym – als plaques en rondom de hersenvaten, als CAA. Bij pathofysiologische concentraties vormt beta-amyloid neurotoxische oligomeren en aggregeert op zichzelf verder wat uiteindelijk leidt tot CAA en parenchymale plaques. Omdat de klaring een cruciale rol speelt in de handhaving van beta-amyloid concentraties in de hersenen, en daarmee in de formatie van plaques en CAA, kan het feitelijke transport van het eiwit over de bloed-hersen barrière een hoofdrol spelen in de pathologische cascade welke leidt tot AD.

De bloed-hersen barrière

De bloed-hersen barrière (BBB) is de scheiding tussen het circulerende bloed en de hersenen die ervoor zorgt dat de hersenen een sterk gereguleerd (micro-)milieu kan onderhouden, hetgeen noodzakelijk is voor efficiënte neurotransmissie. De BBB is semi-permeabel; wat wil zeggen dat het sommige stoffen doorlaat, terwijl het andere stoffen selectief de toegang weigert. In de meeste weefsels in het lichaam zijn de kleinste bloedvaten, de capillairen, omgeven door endotheel cellen met kleine openingen – fenestrae – tussen de cellen. Door deze openingen kunnen (voedings-) stoffen eenvoudig de bloedvaten in en uit. Echter, in de hersenen zijn deze fenestrae afwezig en sluiten de endotheelcellen strak op elkaar aan. Ze vormen een zogenaamd *tight junction*, waardoor stoffen niet zomaar de bloedvaten uit kunnen gaan. Ontwrichting van de BBB is een gemeenschappelijk kenmerk van vrijwel alle neurodegeneratieve stoornissen en kan zo, samen met neuronale inflammatie, gezien worden als één van de be-

langrijkste componenten in het proces van neurodegeneratie. Omdat in capCAA beta-amyloid aggregeert op de vaatwanden, op het grensvlak van de hersenen en de bloedsomloop, daar waar beta-amyloid juist uit de hersenen verwijderd dient te worden, is de rol van capCAA op de werking en integriteit van de BBB en daarmee samenhangend de klaring van beta-amyloid, van bijzonder belang in het begrijpen van de pathofysiologie van AD.

Doelstellingen

De aanwezigheid van uitgebreide capCAA onderscheidt een subgroep van AD gevallen met weinig tot geen parenchymale plaques, waarvan de eigenschappen en kenmerken in dit proefschrift zijn onderzocht en beschreven. Identificatie van differentieel tot expressie gebrachte eiwitten in klinische gevallen met capCAA pathologie, zou specifiek inzicht kunnen geven in de achterliggende moleculaire mechanismes welke leiden tot de verstoorde klaring van beta-amyloid over de BBB. Tevens kunnen hierdoor specifieke bio-markers geïdentificeerd worden voor capCAA.

Gezien de centrale rol van de vasculaire en BBB compartimenten in de regulatie van beta-amyloid klaring is het doel van de studies, zoals beschreven in dit proefschrift, het onderzoeken en beschrijven van de rol van beta-amyloid transport eiwitten, evenals de expressie van specifieke BBB/endotheel eiwitten in de ADCAA hersenen en het uitzoeken van de vermeende rol van CAA in de ontwikkeling van de AD pathologie. Hiertoe is mijn proefschrift gericht op de vasculaire veranderingen welke plaats vinden in de capillaire vorm van CAA. Op zowel de gemeenschappelijke als de onderscheidende eigenschappen met “klassiek” AD, op de eiwitten welke een rol spelen in het transport van beta-amyloid over de BBB, waaronder amyloid-beta transporters en amyloid geassocieerde eiwitten, en een aantal eiwitten welke een significante rol kunnen spelen bij de algemene homeostase en onderhoud van de vasculaire endotheel en BBB compartimenten.

Voor het uiteindelijke doel van dit proefschrift zijn de volgende algemene doelstellingen geformuleerd:

- Beschrijf de neuropathologische eigenschappen van capCAA, en de gemeenschappelijke en onderscheidende eigenschappen met klassiek AD.
- Onderzoek de veranderingen aan de BBB in capCAA en diens achterliggende pathologische trajecten.

Hoofdstuk 2 beschrijft de pathologische eigenschappen van capCAA, de relatie tussen amyloïde afzettingen in capCAA, CAA en parenchymale plaques en de verspreidingspatronen van neurofibrillaire veranderingen, inflammatoire markers en ApoE rondom amyloïde laesies.

Om de differentiële eiwit expressie tussen AD en capCAA in de hersenen te bestuderen, wordt in **Hoofdstuk 3** een proteomics studie beschreven. We hebben verschillende eiwitten geïdentificeerd welke specifiek meer tot expressie komen in capCAA, hetgeen vervolgens verder onderzocht is middels immunohistochemische technieken. We hebben de expressie onderzocht van de eiwitten laminin, clusterin en SAP en van de activatie van het complement systeem in capCAA en AD hersenen. Zowel laminin, clusterin, SAP en de complement eiwitten colocaliseren met beta-amyloid aggregaten in CAA en capCAA hersenweefsel. Opvallend is dat we een sterkere colocalisatie aantreffen met de vasculaire beta-amyloid afzetting in vergelijking met de parenchymale ophopingen in AD hersenen.

Hoofdstuk 4. We onderzochten BBB veranderingen in capCAA met de nadruk op de veranderingen in de *tight junction (TJ)* alsmede tekenen van neuronale inflammatie. We hebben aangetoond dat beta-amyloid schadelijk is voor de endotheel cellen in de hersenen via de binding aan RAGE en de daaropvolgende oxidatieve stress, wat uiteindelijk leidt tot verstoring van de TJs en verlies van BBB integriteit, wat zichtbaar is door de aanwezigheid van fibrinogeen in capCAA weefsel.

De expressie en functie van ABC transporters is mogelijk cruciaal in de ontwikkeling van AD en capCAA. We laten in **Hoofdstuk 5** zien dat P-gp en BCRP minder sterk tot expressie komen in capCAA, maar niet minder in AD, en dat beta-amyloid en clusterin invloed hebben op de mate van expressie van P-gp. Dit speelt mogelijk een cruciale rol in de ontwikkeling van verschillende amyloïde afzettingen.

Samenvatting

CapCAA is een afzonderlijke entiteit die subgroepen van zowel CAA en AD identificeert en de bijbehorende pathogenese is specifiek geassocieerd met een verminderde klaring van beta-amyloid bij de BBB. CapCAA heeft een significante invloed op de BBB, tast zijn integriteit en functie aan en draagt daarmee bij aan een verstoorde homeostase van het verouderende brein. We hebben hier aangetoond dat hoewel capCAA en AD een aantal gemeenschappelijke

pathologische kenmerken delen, verscheidende eiwitten wel degelijk verschillend zijn ontregeld. Eiwitten die specifiek meer of juist minder tot expressie komen in capCAA (en niet in AD) tonen mogelijke veranderde pathogene cascades aan. Dit zou kunnen verklaren waarom beta-amyloid aggregeert rond de hersenvaten in plaats van in het brein parenchym, zoals bij AD. Verder zouden de eiwitten, waarvan aangetoond is dat ze duidelijk anders tot expressie komen in capCAA ten opzichte van AD, gebruikt kunnen worden voor de ontwikkeling van biomarkers voor de differentiele diagnose van capCAA bij nog in leven zijnde patiënten.

List of abbreviations

A β	amyloid β
AD	Alzheimer's Disease
APOE	apolipoprotein E
APOJ	apolipoprotein J
APP	amyloid precursor protein
ARS	antigen retrieval step
BACE	β -site AAP-cleaving enzyme
BBB	blood brain barrier
BCRP	breast cancer resistance protein
C1q	Complement factor 1q
C3d	Complement factor 3d
C5-9	Complement factor 5-9
CAA	cerebral amyloid angiopathy
capCAA	capillary cerebral amyloid angiopathy
CERAD	consortium to establish a registry for Alzheimer's disease
CJD	Creutzfeldt-Jakob disease
CNS	central nervous system
DAB	diaminobenzidine
DPI	diphenylene iodonium
ECs	endothelial cells
EOAD	early onset Alzheimer's disease
ELISA	Enzyme linked immuno-sorbent assay
EM	Electron microscopy
EV	EnVision Method

FBS	fetal bovine serum
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GFAP	glial fibrillary acidic protein
HCMEC	human cerebral microvascular endothelial cell
HRP	horseradish peroxidase
LA	lipoic acid
LRP	Low-density lipoprotein receptor related protein
MRP	multidrug resistance-associated protein
MTT	3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
NFκB	nuclear factor kappa-light-chain-enhancer of activated B cells
NFT	neurofibrillary tangles
NOX	NADPH oxidase
O/N	over night
PET	Positron emission tomography
P-gp	P-glycoprotein
PIB	Pittsburgh compound-B
PMD	post mortem delay
PS	presenilin
RAGE	receptor for advanced glycation end products
ROS	reactive oxygen species
SAP	serum amyloid P component
SMC	smooth muscle cells
TJ	tight junction
ZO	zona occludens

Curriculum vitae

Anna Carrano was born on September 12th, 1983, in northern Italy. She studied Medical Biotechnology and Molecular Medicine at the University of Milan with a curriculum focused on Neuroscience. Anna always dreamt to pursue a career abroad and during her MSc studies she was awarded with an Erasmus Scholarship in The Netherlands, which allowed her to obtain research experience in a foreign country. After successfully completed her studies in Italy, she returned to the Netherlands and started her PhD project within the Neuropathology group at the department of Pathology at the VU medical center, Amsterdam in March 2008, under the supervision of A.J. Rozemuller, H.E. de Vries, J.M. Hoozemans and J. van Horssen. During her PhD training her scientific interest focused on neuropathological changes occurring in Alzheimer's disease cases with severe amyloid deposition in the brain vasculature, also known as cerebral amyloid angiopathy. Since March of this year she works as a postdoctoral researcher at the Department of Neuroscience of the Mayo Clinic in Jacksonville, Florida in the United States of America.

Acknowledgements

This book is finally finished and this is the very last chapter that needs to be written. I dreaded this moment and procrastinated it indefinitely, not so much because I don't want to say thank you to all the amazing people that helped me get here, but because this is like saying goodbye, and I never liked it much. It is so difficult to write my acknowledgements from the other side of the ocean, away from everyone, from every single person I am going to name, without feeling emotional. But I am thankful, nonetheless, with my teary eyes, to all the people that made this project a success and the writing of this thesis possible.

My immense gratitude goes to all my supervisors, promotors and co-promotors, to Anne-mieke, Elga, Jeroen and Jack. It goes without saying that none of this would have been possible without you. You have thought, inspired, supported, and guided me all the way through. You are not only excellent scientists, you are amazing people and I am honored I have got to learn from you all and be part of your lives. Thank you also to Saskia, Rob and Piet, for your precious inputs and suggestions, and for sharing your wise knowledge with me.

Thank you to all the lab people, at the dept. of Pathology and Molecular cell biology and immunology, that helped with the bench work, when my two hands were not enough and my weeks too short. To everybody that contributed to make my experiments successful, and we all know it is not always the case.

Thanks to all my friends, to the PhD fellows, to the undergrad students, to the technicians, for making the lab (and The Netherlands in general) a better place to be, for sharing a laugh, a chat over a coffee and scientific frustrations (especially!) more often than we would like to admit. A special word for my Italian mates, the Netherlands feels a much sunnier place with you guys around!

Thanks to my family, the Italian and the Dutch one, moms and dads, sisters and husband, near and far, for staying close to me no matter what, no matter where. It made all the difference.

Thank you to Tineke and my furry babies for keeping me sane while going through the odys-

sey of writing this thesis. For giving me love and attention when I needed it the most.

And last thank you to my husband Maarten, who has been there all the way since my first day in the Netherlands. There is not enough space here to thank you and not enough words.

I miss you all and I long for the day I will see you again.
