We point out that the mutual annihilation of an electron-hole pair at a tunnel barrier leads to teleportation of the state of the annihilated electron to a second, distant electron—if the latter was previously entangled with the annihilated hole. We propose an experiment, involving low-frequency noise measurements on a two-dimensional electron gas in a high magnetic field, to detect teleportation of electrons and holes in the two lowest Landau levels.

Teleportation is the disembodied transport of a quantum mechanical state between two locations that are only coupled by classical (incoherent) communication [1]. What is required is that the two locations share a previously entangled state. Teleportation has the remarkable feature that the teleported state need not be known. It could even be undefined as a single-particle state, which happens if the teleported particle is entangled with another particle that stays behind. Teleportation then leads to “entanglement swapping” [2,3]: Preexisting entanglement is exchanged for entanglement between two parties that have never met.

Experiments with photons [4] have demonstrated that teleportation can be realized in practice. Only linear optical elements are needed [5,6], if one is satisfied with a success probability <1. Such nondeterministic teleportation plays an essential role in proposals for a quantum computer based entirely on linear optics [7]. A central requirement for nontrivial logical operations is that the linear elements (beam splitters, phase shifters) are supplemented by single-photon sources and single-photon detectors, which effectively introduce nonlinearities.

Teleportation of electrons has not yet been realized. The analogue of teleportation by linear optics would be teleportation of free electrons, that is to say, teleportation using only single-particle Hamiltonians. Is that possible? A direct translation of existing linear optics protocols would require single-electron sources and single-electron detectors [8]. Such devices exist, but not for free electrons—they are all based on the Coulomb interaction in quantum dots. In this Letter, we would like to propose an alternative.

The key observation is that the annihilation of a particle-hole pair in the Fermi sea teleports these quasiparticles to a distant location, if entanglement was established beforehand. This two-way teleportation scheme is explained in Fig. 1. The two entanglers are taken from Ref. [9]. There it was shown that the “no-go” theorem for entanglement production by linear optics does not carry over to electrons. In linear optics, no entanglement can be generated from sources in thermal equilibrium [10,11]. For electrons, on the contrary, this is possible. A tunnel barrier in a two-channel conductor creates entangled electron-hole pairs in the Fermi sea, using only single-particle elastic scattering. No single-electron sources are needed. Our proposal for teleportation uses the inverse process, the annihilation of a particle-hole excitation by elastic scattering.

The simplest case.—The analysis is simplest for the entangled state $|1\rangle_L |1\rangle_h + |1\rangle_h |1\rangle_L / \sqrt{2}$. The subscripts $e$ and $h$ refer, respectively, to the electron and the hole at two distant locations. The particle to be teleported is

![FIG. 1. Schematic description of teleportation by particle-hole annihilation. A voltage $V$ applied over a tunnel barrier produces pairs of entangled electron-hole pairs in the Fermi sea. One such pair $(e_L, h_L)$ is shown at the left. For a simplified description, we assume spin entanglement in the state $(|1\rangle + |1\rangle) / \sqrt{2}$, where the first arrow refers to the electron spin and the second arrow to the hole spin. (The more general situation is analyzed in the text.) A second electron $e_R$ in an unknown state $\alpha |1\rangle + \beta |1\rangle$. The electron $e_R$ can annihilate with the hole $h_L$ by tunneling through the barrier at the center. If it happens, and is detected, then the state of $e_L$ collapses to the state of $e_R$. (Notice that $|1\rangle$ annihilates with $|1\rangle$ and $|1\rangle$ annihilates with $|1\rangle$, so $e_L$ inherits the coefficients $\alpha$ and $\beta$ of $e_R$ after its annihilation.) The diagram shows a second entangler at the right, to perform two-way teleportation (from $e_R$ to $e_L$ and from $h_L$ to $h_R$). This leads to entanglement swapping: $e_L$ and $h_R$ become entangled after the annihilation of $h_L$ and $e_R$.](image-url)
between the two ends is indeed a demonstration of teleportation.

The usual limitations [1] of teleportation apply. Since tunneling is an unpredictable stochastic event, it has to be detected and communicated (by classical means) to the distant location. There is therefore no instantaneous transfer of information since the electron has to be annihilated in order to be teleported, its state cannot be copied. Teleportation by particle-hole annihilation presents a rather dramatic demonstration of the no-cloning theorem of quantum mechanics [12].

A major obstacle to teleportation in the solid state is the requirement of fast time-resolved detection. To circumvent this difficulty, we identify a low-frequency noise correlator that demonstrates the entanglement swapping resulting from two-way teleportation. Two-way teleportation means that upon annihilation the electron and the hole are teleported to opposite ends of the system.

The noise correlator measures the degree of entanglement at the two ends. This demonstrates teleportation if the two ends are not connected by any phase coherent path.

The general case — We now proceed to the general formulation of teleportation by particle-hole annihilation. We follow Ref [9] by focusing on a particular implementation using edge channels in the quantum Hall effect regime (see Fig 2). The entangled degree of freedom is the Landau level index \( n = 1, 2 \), which labels the two occupied edge channels near the Fermi energy \( E_F \). Electrons are incident in a narrow range \( \pm \Delta \) above \( E_F \) from two voltage sources. We write the incoming state,

\[
|\Psi_{in}\rangle = a_{L,0}^\dagger a_{L,1}^\dagger a_{R,0}^\dagger a_{R,1}^\dagger |0\rangle,
\]

in second quantized form, in terms of operators \( a_{L,n}^\dagger \) (that excite the \( n \)th edge channel at the left (right) voltage source) (The excitation energy \( 0 < \epsilon < \Delta \) is omitted for simplicity). The vacuum state \( |0\rangle \) represents the Fermi sea at zero temperature (all states below \( E_F \) occupied, all states above \( E_F \) empty).

Scattering matrices \( S_L \), \( S_R \) (for the left and right barriers acting as entanglers), and \( S_0 \) (for the central barrier acting as annihilator) transform the incoming state \( |\Psi_{in}\rangle \) to the outgoing state \( |\Psi_{out}\rangle \). The full expression for \( |\Psi_{out}\rangle \) is lengthy, but we need only the terms that correspond to the annihilation of the electron and the hole at the central barrier. If the election and the hole have annihilated, this implies that there are two filled edge channels in contact.

![FIG 2 Proposed realization of the teleportation scheme of Fig 1, using edge channels in the quantum Hall effect](image-url)
A and two empty edge channels in contact B. These terms can be extracted by the projection operator

\[ P = n_{A,1}n_{A,2}(1 - n_{B,1})(1 - n_{B,2}). \]

We have introduced the number operator \( n_{X,n} = b_{X,n}^\dagger b_{X,n} \), with \( b_{X,n}^\dagger \), the creation operator for the \( n \)th edge channel approaching contact \( X = A, B \) in Fig. 2.

The projected outgoing state,

\[ \mathcal{P}[\Psi_{\text{out}}] = \left( ab_R^1 b_{R,2}^1 + \beta b_L^1 b_{L,2}^1 \right) + \sum_{n,m=1,2} \gamma_{nm} b_{L,n}^1 b_{R,m}^1 (b_{L,n}^1 b_{A,2}^1) \cdot \]

contains three types of contributions: (i) a term \( \propto \alpha \) describing two filled edge channels to the right of the right barrier (creation operator \( b_{R,n}^1 \)); (ii) a term \( \propto \beta \) describing two filled edge channels to the left of the left barrier (creation operator \( b_{L,n}^1 \)); (iii) a sum of four terms \( \propto \gamma_{nm} \) describing one filled edge channel at the left and one at the right. The coefficients \( \alpha, \beta, \gamma_{nm} \) are given in terms of the reflection and transmission matrices of the three barriers:

\[ \alpha = (r_l \sigma_x^{L})_{12} (r_{R}^{L} \sigma_y^{R} r_{R}^{T})_{12}, \]

\[ \beta = (l_l \sigma_y^{L})_{12} (l_{R}^{L} \sigma_x^{R} r_{R}^{T})_{12}, \]

\[ \gamma = l_l \sigma_y^{L} r_{R}^{T} \sigma_y^{L} l_{R}^{L} l_{R}^{T} r_{R}^{T}. \]

The superscript \( T \) indicates the transpose of a matrix and \( \sigma_x \) is a Pauli matrix. If we denote by \( \tau \ll 1 \) the order of magnitude of the tunneling amplitudes, then \( \alpha = O(\tau^2) \), \( \beta = O(\tau^3) \), and \( \gamma = O(\tau^4) \), so it is justified to neglect \( \beta \) relative to \( \gamma \).

To identify the entangled electron-hole excitations, we transform from particle to hole operators at contact \( A \) and to the right of the right barrier: \( b_{R,n}^1 \rightarrow c_{R,n} \), \( b_{L,n}^1 \rightarrow c_{L,n} \). The new vacuum state is \( |0\rangle = b_R^1 b_L^1 b_{L,1}^1 b_{A,2}^1 \). The projected outgoing state becomes

\[ \langle \langle \delta I_{L,n}(\omega_1) \delta I_{R,m}(\omega_2) \delta I_{A}(\omega_3) \delta I_{B}(\omega_4) \rangle \rangle = 2\pi \delta \left( \sum_{i=1}^4 \omega_i \right) C_{nm}. \]

It does not matter if \( \delta I_A \delta I_B \) is replaced by \( \delta I_A^2 \) or \( \delta I_B^2 \); that only changes the correlator by a minus sign. Following Ref. [14], we have calculated \( C_{nm} \) in terms of the transmission matrices, with the result

\[ C_{nm} = 2(e^\delta V/h) |M_{nm}|^2, \quad M = (l_l r_{R}^{T} (l_{R}^{L} \sigma_x^{R} r_{R}^{T})). \]

As in earlier work [15], we use low-frequency current correlators in the tunneling regime to detect entanglement through the violation of a Bell inequality. We need the following rational function of correlators:

\[ E = \frac{C_{11} + C_{22} - C_{12} - C_{21}}{C_{11} + C_{22} + C_{12} + C_{21}}. \]

By mixing the channels locally at the left and right ends of the system, the transmission and reflection matrices are transformed as \( t_l \rightarrow U_l t_l, r_{R} \rightarrow U_{R} r_{R} \), with unitary \( 2 \times 2 \) matrices \( U_L, U_R \). The Bell parameter [16],

\[ E = E(U_L, U_R) + E(U_L^T, U_R) + E(U_L, U_R^T) - E(U_L^T, U_R^T), \]

is maximized by a certain choice of \( U_L, U_L^T, U_R, U_R^T \) at the value [17]

\[ E_{\text{max}} = 2[1 + 4M_1 M_2 (M_1 + M_2)^{-2}]^{1/2}. \]
determined by the two eigenvalues $M_1, M_2$ of the matrix product $MM^\dagger$

To close the circle, we need to show that $MM^\dagger$ and $\gamma \gamma^\dagger$ have the same eigenvalues, so that Eqs. (9) and (14) imply the one-to-one relation $E_{\text{prod}} = 2(1 + C^2)^{1/2}$ between the concurrence and the maximal value of the Bell parameter [18]. In general, the two sets of eigenvalues $M_1, M_2$ and $\Gamma_1, \Gamma_2$ are different, but they become the same in the tunneling regime. Here is the proof.

In the tunneling regime, the reflection matrices $r_L, r_R, r_0$ are close to being unitary. For any $2 \times 2$ unitary matrix $U$, it holds that

$$\sigma_\gamma U^T = e^{i\phi} U^\dagger \sigma_\gamma,$$

with $e^{i\phi}$ the determinant of $U$. With the help of this identity, we may rewrite Eq. (6) as

$$\gamma = e^{i\phi} t_{LR}^T t_{LR}^* t_{L0}^* t_{R0} \sigma_\gamma = e^{i\phi} M \sigma_\gamma.$$

Hence, $\gamma \gamma^\dagger = MM^\dagger$, as we set out to prove.

A final remark: The Bell inequality states that $|r| \leq 2$ for a local hidden-variable theory [16]. We have not proven this statement for our fourth-order correlator (although we do not doubt that it holds). What we have proven is that a measurement of the fourth-order correlator can be used to determine the degree of entanglement, which is all we need for our purpose.

**Discussion.**—The invention of Bennett, Brassard, Crépeau, Jozsa, Peres, and Wootters [1] teleports isolated and, hence, distinguishable particles, so it applies equally well to bosons (such as photons) as it does to fermions (such as electrons). However, the difficulty of isolating electrons in the solid state has thus far prevented the realization of their ingenious idea. What we have shown here is that the existence of the Fermi sea makes it possible to implement teleportation of noninteracting fermions using sources in local thermal equilibrium—something which is fundamentally forbidden for noninteracting bosons [10,11]. Our fermions are not isolated electrons but particle-hole excitations created by tunneling events. The act of teleportation is the inverse process, the annihilation of the particle when it tunnels into the hole.

An advantage of working with particle-hole excitations in the Fermi sea is that no local control of single electrons is required. Indeed, the experiment proposed in Fig. 2 does not need nanofabrication to isolate and manipulate electrons. A disadvantage is that the success rate of teleportation is small, because tunneling is a rare event. Since the particle-hole excitation survives if the tunneling attempt has failed, it should be possible to increase the teleportation rate by introducing more tunnel barriers in series.

To perform the experiment outlined in Fig. 2 is a major challenge. We point out some recent progress in different but related experiments. To detect the entanglement swapping, one needs to measure a fourth-order cumulant of fluctuations of tunneling currents. Typically, only the second-order cumulant is measured in noise experiments. A recent successful measurement [19] of the third cumulant in a tunnel junction promises more progress in this direction. To perform teleportation, coherence of the edge channels should be maintained over the relatively long distance between the left and the right contacts. An interferometric experiment on edge channels in a geometry of a similar scale has been recently reported [20]. Finally, we mention an alternative proposal [21] to use quantum dots in zero magnetic field as entanglers, instead of tunnel barriers in a strong magnetic field.
