ABSTRACT

We have compiled a comprehensive library of all X-ray observations of Magellanic pulsars carried out by *XMM-Newton*, *Chandra*, and *RXTE* in the period 1997–2014. In this work, we use the data from 53 high-mass Be/X-ray binaries in the Small Magellanic Cloud to demonstrate that the distribution of spin-period derivatives vs. spin periods of spinning-down pulsars is not at all different than that of the accreting spinning-up pulsars. The inescapable conclusion is that the up and down samples were drawn from the same continuous parent population, therefore Be/X-ray pulsars that are spinning down over periods spanning 18 years are in fact accreting from retrograde disks. The presence of prograde and retrograde disks in roughly equal numbers supports a new evolutionary scenario for Be/X-ray pulsars in their spin period-period derivative diagram.

Key words: accretion, accretion disks—stars: magnetic fields—stars: neutron—X-rays: binaries

1 INTRODUCTION

We have produced a comprehensive library of all X-ray observations of Magellanic pulsars carried out by the *XMM-Newton*, *Chandra*, and *RXTE* telescopes in the period 1997–2014. The Small Magellanic Cloud (SMC) contains 63 pulsars in high-mass Be/X-ray binaries (HMXBs) (Coe & Kirk 2015; Haberl & Sturm 2016) for which all X-ray data have been released for public use (Yang et al. 2017). In this Letter, we focus specifically on 53 of these pulsars for which we can argue that many are not in spin equilibrium over the entire observational period spanning 18 years. For these pulsars, Yang et al. (2017) carried out a linear regression of their spin periods P_S on timescales much longer than the orbital periods and they measured their long-term period derivatives \dot{P}_S . (For the remaining pulsars in the sample, no pulsations were measured.) Owing to the long observational timescales, these measurements are as robust as currently possible, and they remain unaffected by minor reversals of the \dot{P}_S values in the short term and by periodic variations

caused by orbital doppler motions. The results show that nearly half of these objects are consistently spinning down in the long term which is surprising because we do not know of any physical mechanism as efficient as accretion that would instead slow down these pulsars. This argument was made by Christodoulou et al. (2017) in the context of ultraluminous X-ray pulsars (all three of which are spinning up) and it obviously extends to Be/X-ray pulsars as well.

In order to study spin changes more closely, we separate the Yang et al. (2017) data into two samples, one with pulsars spinning up and another with pulsars spinning down (the “up” and “down” samples); and we compare statistically the two-dimensional (2-D) distributions of their dynamical properties (spin-period derivative vs. spin period) in the two samples (§ 2). We find that the two samples are statistically quite similar. Finally, we present and discuss our conclusions in § 3, where we argue that the results support the presence of retrograde accretion disks in spinning-down pulsars and the presence of moderate magnetic fields in the compact objects of the entire class. Based on these conclusions, we also describe an evolutionary path for the pulsars in the $P_S - \dot{P}_S$ diagram.

Figure 1. The absolute value of period derivative ($\dot{P}_S = dP_S/dt$) is plotted against spin period P_S for the SMC pulsars that are spinning up or down at a significance level of 2σ or better (Yang et al. 2017). There is no difference between the distributions of $|\dot{P}_S|$ vs. P_S in the two samples and this indicates that the long-term changes in spin are caused by accretion in both types of pulsars.

2 DATA ANALYSIS

The data that we use in this analysis were published by Yang et al. (2017), where the pulsars were divided into groups depending on the sign and magnitude of the period derivatives $\dot{P}_S = dP_S/dt$ and their errors. Using the measured errors in \dot{P}_S , a conservative 2σ criterion was initially adopted to separate the objects into those that appear to be close to spin equilibrium and those that are clearly spinning up or down. Yang et al. (2017) then found that $N_{up} = 11$ pulsars are spinning up and $N_{down} = 7$ pulsars are spinning down. These two samples are plotted in Fig. 1 using blue and red open circles connected by dotted line segments. The \dot{P}_S error bars are also plotted; owing to the stringent 2σ criterion, all of them are small.

Yang et al. (2017) finally settled to using a 1.5σ criterion for the data. In our analysis, we filter the same data according to a less stringent 1σ level of significance. In this case, we find that $N_{up} = 16$ pulsars are spinning up and $N_{down} = 14$ pulsars are spinning down. These larger samples are plotted in Fig. 2 using blue and red open circles connected by dotted line segments. The \dot{P}_S error bars are also plotted; the error bars of the additional points relative to those in Fig. 1 are large and extend well outside the open circles used in the figure. Despite the larger errors in Fig. 2, we observe in both figures that the distributions of $|\dot{P}_S|(P_S)$ are quite similar for the up and down samples (blue and red circles, respectively). In fact, there appears to be a trend in all four samples at confidence levels of 90-95%, viz.

$$\log |\dot{P}_S| \approx k \cdot \log P_S - 6, \quad k = 1.1 - 1.4, \quad (1)$$

where \dot{P}_S is expressed in seconds/day and P_S in seconds.

A 2-D statistical analysis confirms the results from visual inspection without a doubt: We adopted the null hypothesis that, in each case, the up and down samples were drawn from the same continuous population $|\dot{P}_S|(P_S)$, and

Figure 2. As in Fig. 1, but for the SMC pulsars that are spinning up or down at the less conservative significance level of 1σ or better.

we applied four independent statistical tests¹ in which the null hypothesis cannot be rejected at any reasonable level of significance. The results are summarized in Table 1. In all cases, the p -values are extremely large indicating that the samples were drawn from the same continuous population. The smallest p -value ($p = 0.4149$) occurs for Hotelling's T^2 test (Mardia et al. 1979) in the 1σ samples that are supposed to be less rigorous than the 2σ samples; but even in this case, the p -value is so large that one cannot reject the null hypothesis at any reasonable level of significance.

The results do not change at all in the less constrained one-dimensional (1-D) comparison of the two $|\dot{P}_S|$ samples irrespective of spin periods: The rigorous 1-D Kolmogorov-Smirnov test (Massey 1951; Marsaglia et al. 2003) confirms the null hypothesis that the up and down $|\dot{P}_S|$ samples were drawn from the same continuous population for any reasonable level of significance. The p -values are very large, 0.9911 for the 2σ data and 0.9821 for the 1σ data.

The remarkable strength of the null hypothesis in the above statistical tests prompted an examination of the raw data in Yang et al. (2017), where a total 53 pulsars are listed as having nonzero period derivatives irrespective of significance. This data set is expected to be contaminated by 23 additional pulsars that are very close to spin equilibrium and their measured $|\dot{P}_S|$ values are too small to be meaningful. We ran the same statistical tests on the raw data ($N_{up} = 27$ and $N_{down} = 26$) and, once again, we could not reject the null hypothesis at any reasonable level of significance. This is because, in this case, the elevated noise is restricted to small $|\dot{P}_S|$ values and occurs in both samples. Thus, our result appears to be statistically robust regardless of the chosen σ -criterion or the level of significance for the null hypothesis.

¹ We used a suite of multidimensional two-sample tests that was written by Lau (2014) and that is distributed freely under the GNU General Public License of the Free Software Foundation.

Table 1. Statistical Tests for Two-Dimensional (2-D) Data Samples

2 σ Samples ($N_{up} = 11, N_{down} = 7$)			
Test	References	Statistic	p -value
Kolmogorov-Smirnov 2-D	1-3	$D=0.2424$	0.9533
Minimum Energy (SR)	4	$E_{nm}=84.1817$	0.9800
Minimum Energy (AZ)	5	$E_{nm} = -0.2472$	0.9300

3 CONCLUSIONS

3.1 Retrograde Accretion Disks

We have studied the statistical properties of two samples of Be-HMXB pulsars in the Small Magellanic Cloud, one with the pulsars spinning up due to accretion over the past 18 years, and another with the pulsars spinning down over the same period. We found absolutely no difference between the two samples: four independent statistical tests (Table 1 and Lau 2014) show that both samples were obtained from the same continuous parent population. We believe that this constitutes evidence that the physical processes are the same in the two groups of pulsars, therefore spinning-down pulsars are also undergoing accretion and their spin periods increase only because the accreted angular momentum is obtained from retrograde disks whose rotation vectors are antiparallel to the spin vectors of the neutron stars.

Retrograde accretion disks have been previously proposed for a few stellar-mass black holes (Zhang et al. 1997; Rao & Vadawale 2012; Reis et al. 2013; Middleton et al. 2014; Morningstar et al. 2014) and for some supermassive black holes in Active Galactic Nuclei (Garofalo et al. 2010; Cowperthwaite & Reynolds 2012; Garofalo 2013), but not for neutron stars in Be/X-ray binaries. A retrograde fossil accretion disk has also been proposed for the anomalous single pulsar CXOU J010043.1-721134 in the SMC (§3.4 in Christodoulou et al. 2016, and references therein). The results of our study indicate that, at this time, there appears to be a larger number ($\approx 50\%$) of retrograde disks around Be/X-ray pulsars than around black holes of all sizes. This result is not really in disagreement with the conclusions from extensive population-synthesis studies that find a smaller percentage ($\sim 5\%$) of retrograde accretion disks in X-ray binaries (e.g., Frangos et al. 2010) because these studies were conducted for Roche-lobe filling supergiant companions that give rise to repeated, short-lived, wind-fed accretion events around compact objects in which the direction of rotation of the accreted gas may be changing from one event to the next (Bildsten et al. 1997; van Kerkwijk et al. 1998, and references therein).

Figure 3. The period derivative ($\dot{P}_S = dP_S/dt$) is plotted on a linear scale against spin period P_S for the 1 σ samples of Fig. 2. The arrows show the direction in which the spin periods evolve over time.

3.2 Magnetic Fields

Another conclusion that can be drawn from the above results concerns the magnitudes of the surface magnetic fields in the Be-HMXB pulsars: it is improbable that the slowdown of the pulsars in the down samples is caused by strong, magnetar-type (Woods & Thompson 2006; Olausen & Kaspi 2014) magnetic fields. If that were the case, then such strong magnetic fields would be able to also counter and slow down the spinup of the accreting pulsars in the up samples, thereby changing the distributions of $|\dot{P}_S|(P_S)$ of the up and down samples. Since no such statistical differences are observed between the two samples, we conclude that there cannot be two different mechanisms changing the spin periods and that the magnetic fields are moderate ($B \sim 0.3 - 10$ TG) in the entire class of Be-HMXB pulsars, as was also found in our two previous studies (Christodoulou et al. 2016, 2017).

3.3 Spin Evolution

The marked similarity between the up and down samples is an invitation to combine the two samples into a larger data set. A linear regression to the combined 2σ data set gives

$$\log |\dot{P}_S| = 1.31(\pm 0.12) \cdot \log P_S - 6.21(\pm 0.23), \quad (2)$$

where \dot{P}_S is expressed in seconds/day and P_S in seconds. The correlation coefficient is $r^2 = 0.884$ and the $p = 0.058$ value is close to the 95% confidence level. The results are similar for the combined 1σ data set:

$$\log |\dot{P}_S| = 1.12(\pm 0.11) \cdot \log P_S - 5.85(\pm 0.21), \quad (3)$$

where $r^2 = 0.802$ and $p = 0.060$. As expected, the correlation is now degraded due to the elevated noise in the 1σ data, but the statistic holds firm near the 95% confidence level. The implication from these results is that spinning up and down pulsars cannot be separated by their P_S values; that is, spinning up/down pulsars do not have predominantly shorter/longer spin periods, as one might have expected; and this observation lends strong support for a surprising evolutionary scenario that cannot be detected in Figs. 1 or 2 where absolute values are plotted. In order to describe this scenario, we plot in Fig. 3 the 1σ samples with \dot{P}_S shown on a linear scale. The 2σ data show the exact same features, albeit with fewer points.

We observe in Fig. 3 that only long-period pulsars show \dot{P}_S values that are substantially different than zero and there is a congested area around $P_S = 140$ -175 s. Long-period pulsars spinning up (blue circles) necessarily evolve in the direction of the blue arrow but their rates are slowed down considerably after they cross the congested area. Below $P_S \approx 100$ s, these pulsars are effectively close to spin equilibrium, although they may continue their spin-up very slowly. In contrast, short-period pulsars spinning down (red circles) necessarily evolve in the direction of the red arrow but they do so very slowly until they cross the congested area, to the right of which they spin down much faster. In both cases, accretion does not appear to be too efficient in changing the spin periods of the short-period pulsars, thus many accretion events are required for these pulsars to make progress in either direction. This entire evolutionary scenario can be understood if the accretion disks can reverse their direction of rotation when the pulsars are near spin equilibrium (e.g., a new accretion phase begins but the inflow has its rotation opposite to that of the preceding phases). Then these pulsars may evolve back and forth near the $\dot{P}_S = 0$ line — but, eventually, sustained accretion in one direction may send some of them in the direction of the red arrow. In fact, hints of such reversals have been seen in the Yang et al. (2017) data which would suggest that reversals can occur over timescales of only $\gtrsim 20$ years.

Another reversal of the rotation of the inflow at very long spin periods closes the loop in Fig. 3 and predicts the fate of long-period pulsars with $P_S \gtrsim 1000$ s that continue to spin down: these objects cannot return from the path that brought them to long periods (red arrow). With their angular-momentum contents reduced so much (~ 1000 times), the next major “retrograde” accretion event (or events) should have no difficulty reversing their spins, facilitating the transition depicted by the black arrow in Fig. 3. This transition appears to proceed fast because no

pulsars are seen at the longest periods with their \dot{P}_S values near zero.

It is interesting to note that in the current four samples (1σ and 2σ , up and down), the pulsars are separated above and below the characteristic spin period of 100 s in equal numbers. This observation also supports the evolutionary scenario discussed above: both groups have to slow down (speed up) their spin evolution at short (long) periods, and both groups have to wait for the same agent (a sequence of consecutive “retrograde” accretion events) that will initiate the process that eventually leads to a spin reversal.
