

Freshwater ecoacoustics as a tool for continuous ecosystem monitoring

Simon Linke^{1*}, Toby Gifford^{2,3}, Camille Desjonquères^{4,5}, Diego Tonolla⁶, Thierry Aubin⁵, Leah Barclay², Chris Karaconstantis¹, Mark J Kennard¹, Fanny Rybak⁵, and Jérôme Sueur⁴

Passive acoustic monitoring is gaining popularity in ecology as a practical and non-invasive approach to surveying ecosystems. This technique is increasingly being used to monitor terrestrial systems, particularly bird populations, given that it can help to track temporal dynamics of populations and ecosystem health without the need for expensive resampling. We suggest that underwater acoustic monitoring presents a viable, non-invasive, and largely unexplored approach to monitoring freshwater ecosystems, yielding information about three key ecological elements of aquatic environments – (1) fishes, (2) macroinvertebrates, and (3) physicochemical processes – as well as providing data on anthropogenic noise levels. We survey the literature on this approach, which is substantial but scattered across disciplines, and call for more cross-disciplinary work on recording and analysis techniques. We also discuss technical issues and knowledge gaps, including background noise, spatiotemporal variation, and the need for centralized reference collection repositories. These challenges need to be overcome before the full potential of passive acoustics in dynamic detection of biophysical processes can be realized and used to inform conservation practitioners and managers.

Front Ecol Environ 2018; doi: 10.1002/fee.1779

Changes in freshwater ecosystems are not always easily visible, and declines in biodiversity beneath the water surface can go undetected for long periods. We argue that passive acoustic monitoring of freshwater biodiversity and ecosystem health has the potential to overcome three key

problems. First, traditional methods of freshwater ecological monitoring can adversely impact the target biota and affect ecosystem health and habitat integrity; second, the act of sampling introduces bias by attracting some species of fish, while inducing flight responses in other taxa; finally, temporal variation is hardly ever considered because this would require mechanical resampling. Consequently, conventional monitoring is often restricted to limited areas, infrequent time intervals, and manual processing of acoustic data.

Passive acoustic monitoring (PAM), which has been used in marine systems for decades, represents a relatively untapped alternative for studying freshwater ecosystems. Acoustic monitoring involves installing one or more hydrophones (underwater microphones) in the habitat of interest to record sound. PAM systems are largely non-invasive, require limited maintenance (aside from periodic battery replacement and data downloads), and allow for continuous long-term observation with temporal resolution determined by automated recording schedules. Moreover, acoustic detection has no discernible negative impacts on biota.

There are, however, a number of specific challenges to operationalizing PAM in freshwater environments: not all biota are soniferous (ie capable of producing or conducting sound), high frequencies are attenuated rapidly in water, sound propagation in shallow water is complex and not fully understood, and very little is known about the particular sounds produced by individual species in most of these environments. Furthermore, acoustic analysis is complicated by varying levels of background noise produced by water turbulence and, in many locations, human activities. In addition, data management and pro-

In a nutshell:

- Freshwater ecosystems are surprisingly noisy, with underwater sounds produced by aquatic plants and animals, physical processes (eg turbulent water flow), and human activities
- Sound monitoring provides the means for continuous observation in environments in which species and populations are notoriously difficult to track, such as rivers and lakes
- Sound can be used to detect and monitor species of interest, help study ecosystem health or the physical habitat, and identify human-generated, noise-related disturbances in aquatic systems
- Further research is needed to determine natural variations in aquatic sounds, find ways to account for background noise, and examine the complex relationship between sound and ecosystem health
- A key next step is systematic cataloging of freshwater sounds; although there are at present more than 2500 scientific publications relating to freshwater bioacoustics, few recordings are available in international sound repositories

cessing time are often problematic. We present suggestions for future research to address these challenges.

■ Continuous process-based monitoring in freshwater science

In contrast to sample-based surveys, process-based continuous monitoring is a relatively new approach in ecology. The primary goal is to improve our understanding of the rapid changes occurring in many ecosystems. This technique often uses automated analysis processes to detect these changes. In recent years, several large projects have championed this novel approach (eg the National Ecological Observatory Network [NEON; Denes *et al.* 2015] and the Remote Environmental Assessment Laboratory [REAL; Kasten *et al.* 2012] projects). NEON is a long-term program to detect ecological consequences of natural and human-induced environmental changes, and terrestrial sound recorders have been deployed at four NEON sites to conduct acoustic surveys of birds, frogs, and insects. However, continuous monitoring of freshwater environments has yet to be incorporated into any long-term program.

In addition to large-scale projects like NEON and REAL, interest in smaller scale continuous acoustic wildlife monitoring has grown substantially over the past decade (Servick 2014), as researchers in the fields of bioacoustics (animal sounds), and more recently ecoacoustics (the relationship between sound and the environment), have increasingly come to recognize its benefits in both terrestrial and marine settings. Acoustic monitoring in aquatic systems is a non-invasive sampling method, and therefore represents an attractive alternative to conventional sampling techniques. Acoustic signals can provide quantitative information on the biology, ecology, and population status of soniferous aquatic biota through space and time. Such information may include:

- Species presence or absence: for instance, acoustic monitoring has been used in freshwater systems to detect invasive tilapia (Kottege *et al.* 2015);
- Abundance: to our knowledge, acoustic monitoring has not yet been used in freshwater systems to measure the population abundance of a single species or group of species, but it has been used extensively in marine surveys (eg long-term monitoring of the endangered vaquita porpoise [*Phocoena sinus*]; Gerrodette *et al.* 2011);
- Habitat use (eg for feeding or nesting): for example, sediment disturbance by fish during spawning (eg river redhorse, *Moxostoma carinatum*; Straight *et al.* 2014);
- Behaviors (eg courtship): acoustic signals during mating behavior have been extensively described (see Amorim *et al.* [2015] for an overview) and were recently used to estimate fish abundance in a marine fish species, the Gulf corvina (*Cynoscion othonopterus*) (Rowell *et al.* 2017); and
- Movement: acoustic monitoring has been used in marine systems to characterize spatiotemporal variation

in Atlantic cod (*Gadus morhua*) via sounds associated with spawning (Hernandez *et al.* 2013).

We see a role for passive acoustic technology in research on all these aspects of aquatic systems, and especially for processes that require continuous monitoring, such as behavioral traits or movements (eg to retrace precise trajectories).

■ A history of freshwater bioacoustics

Descriptions of sonifery in fish extend back 2000 years (as depicted in Aristotle's *Historia animalium*), and fish behavior and sound production have been active areas of investigation for more than 80 years. The majority of the 2740 articles we recovered via a Google Scholar search using the keywords "+freshwater +bioacoustics" (searched 28 Aug 2017) can be categorized into two broad groups: (1) studies that focused on the mechanisms of biological sound production and behavior and (2) research on the effects of anthropogenic noise on aquatic animals (see next section). The vast literature on fish bioacoustics (see Ladich 2015 for an excellent overview) constitutes a substantial repository of knowledge that could be used in environmental management.

For fish, serious efforts to catalog underwater sounds were first conducted in the 1960s and 1970s, when Fish and Mowbray (1970) systematically cataloged sounds of western North Atlantic fishes, both in situ and in aquaria; however, they focused predominantly on marine fish species. Their final database includes sound recordings of 153 species, all of which are currently available from the Macaulay Library at Cornell University (<http://macaulaylibrary.org>). These archives contain over 120,000 bird recordings, but only 929 fish recordings, most of which were collected prior to 1980. None of the other major online databases (such as the Berlin Animal Sound Archive) contain a substantial number of freshwater species.

Although some studies published over the past decade have highlighted the potential of PAM, these have almost exclusively focused on marine applications, and particularly marine mammals. Rountree *et al.* (2006) predicted that "with the advent of new acoustic technologies, passive acoustics will become one of the most important and exciting areas of fisheries research in the next decade". This paradigm shift has not yet occurred, as acoustic monitoring has so far failed to gain traction as a useful research tool in freshwater environments. Despite a minor resurgence in soundscape studies of freshwater environments over the past decade (Anderson *et al.* 2008; Desjonquères *et al.* 2015), persistent knowledge gaps continue to inhibit its broader adoption. The following sections will synthesize existing knowledge and identify key research priorities that must be addressed before bioacoustic approaches can be fully integrated into aquatic monitoring protocols and programs.

■ Listening to key aquatic groups and processes

We will limit our discussion to biotic sounds produced by fishes, macroinvertebrates, and the physicochemical environment, as well as anthropogenic noises. Other aquatic groups, such as amphibians, may also call underwater, but they are rarely used as indicators in freshwater ecology.

Fishes

Fishes are at the top of the food chain in many freshwater ecosystems, and are a taxonomic group of economic, ecological, and cultural importance. Monitoring fish stocks and communities is therefore a key task in the study of freshwater systems. Fine and Parmentier (2015) discussed two main mechanisms of fish sound production. The first consists of swim-bladder vibrations generated by “drumming” muscles (eg species in the family Terapontidae; Figure 1). The second is the use of stridulatory organs, in which sounds are commonly generated via vibrations of the pectoral girdle or by rubbing the pectoral fins against the pectoral girdle (eg in catfish). Fish calls are understood to be species-specific, and within-species call variation is therefore typically lower than between-species call variation (Rollo and Higgs 2008). Species specificity in terms of the dominant frequency (highest-amplitude frequency in a call’s spectrum) has been demonstrated for two gobies from the same genus (Pedroso *et al.* 2013), whereas a study of cichlids found species-specific differences in call pulse rates (Verzijden 2010). These results are encouraging for species-specific monitoring programs, although more research will be needed to determine whether patterns in within-species call variation can be generalized across taxa.

The estimate of 700–800 species of soniferous fish (both freshwater and marine) is likely conservative (Rountree *et al.* 2006; Luczkovich *et al.* 2008). For instance, Anderson *et al.* (2008), in one of the few comprehensive studies that attempted to identify all sounds captured in a freshwater survey, made 164 hours of recordings at two sites, from which only four fish species could be reliably identified. However, the authors described an additional 58 distinct sounds, many of which were likely produced by fish species that could not be identified due to the paucity of knowledge on species-specific sound production. In addition, analyses of sonifery usually include only actively emitted sounds and not sounds generated by animals interacting with the environment, such as those associated with sediment disturbance during spawning (Straight *et al.* 2014).

Macroinvertebrates

Aquatic macroinvertebrates (aquatic arthropods, mollusks, and worms) are often used as indicators of aquatic ecosystem health in bioassessment and biomonitoring programs (Norris and Thoms 1999), but identification

Figure 1. (a) The spangled grunter (*Leiopotherapon unicolor*) is a sound-producing Australian fish that emits a distinctive grunt by vibrating its swim bladder. (b) A typical grunt has a duration of 100–200 ms and consists of eight parallel frequency bands that move as one, with a varying contour (eg all dipping down and then up simultaneously). This clear acoustic fingerprint can be used for automatic detection (WebAudio File 1).

of samples is time consuming and requires considerable taxonomic expertise. Although ecological community approaches – that is, analyses of sounds emanating from a biological community as a whole – have only rarely been attempted (Desjonquères *et al.* 2015), numerous studies have described four soniferous aquatic insect orders (Trichoptera, Odonata, Coleoptera, and Hemiptera; see the review by Aiken 1985).

The primary mechanism of sound production among aquatic insects is stridulation, although a few species may produce sounds by other means, such as expulsion of air through the spiracles or flight muscle contraction (Aiken 1985). Soniferous aquatic insects produce a wide diversity of sounds, with dominant frequencies ranging from 200–100 kilohertz (kHz) but concentrated mainly within the 5–6.5 kHz range (Figure 2; Aiken 1985). Among the known soniferous taxa, the Trichoptera, some Coleoptera, and the Odonata are generally recognized as indicators of healthy freshwater ecosystems, whereas the Hemiptera (Figure 2) are

Figure 2. (a) A Mediterranean pond in which the activity of a population of *Micronecta* was monitored acoustically with an array of 12 hydrophones submerged in the pond using ropes. *Micronecta* is a genus encompassing several species of pygmy water boatmen that produce distinctive stridulations and that can be used as indicator species in lakes. (b) *Micronecta griseola* generates a broadband high-pitch sound with a dominant frequency of ~17 kHz and a duration of 0.3 seconds. The sound production of this 2-mm species is very conspicuous and detectable at distances of a few meters (WebAudio File 2).

often pollution tolerant (Norris and Thoms 1999). High species specificity in sound production has been described for some Hemiptera (nine species in one genus; King 1999) and Coleoptera (three species in two genera; Wilson *et al.* 2015). There is therefore the potential to monitor water quality using the species-specific sounds of these insect taxa, which would complement the recently developed automated processing technologies now commonly used for video identification of underwater insects (Lytle *et al.* 2010).

Physicochemical processes

In addition to monitoring sounds emitted by biota, the past decade has also seen an increase in acoustic applications for quantifying physicochemical processes, such as sediment transport and water flow turbulence.

Bedload transport and flow turbulence

Underwater soundscapes can be used to differentiate among aquatic habitats such as backwaters, pools, runs, and riffles (Amoser and Ladich 2010; Tonolla *et al.* 2010), and provide a measure of spatial habitat organization (Tonolla *et al.* 2011). These distinctions are primarily determined by physical processes reflecting important hydraulic processes (such as turbulence) and geomorphic processes (such as bedload transport [sediment transport along a river bed]; WebAudio File 3); specifically, low-frequency sound (<1 kHz) is attributed to flow turbulence, whereas movement of streambed sediment dominates acoustic signals above 1 kHz (Tonolla *et al.* 2011; Lorang and Tonolla 2014; Geay *et al.* 2017).

Soundscape analysis could be used for rapid spatial surveying of hydrogeomorphic conditions, and thus to monitor river restoration measures or to characterize the effect of flow release from hydropower plants. Moreover, acoustic signals from streambed particle movements have been used as a non-invasive means of measuring the intensity of bedload transport and distinguishing the size of the material being transported, based on frequency band intensity (Tonolla *et al.* 2011; Geay *et al.* 2017). Finally, underwater sounds produced by flow turbulence and bedload transport most likely provide migratory and directional cues for many freshwater organisms (including fish and aquatic invertebrates), given that most aquatic species probably use acoustic cues in their environment for spatial orientation and positioning within and among suitable habitats (Slabbekoorn and Bouton 2008; Fay 2009).

Gas exchange

Plant respiration and organic matter decomposition emit whistling and ticking sounds when gas bubbles form and are expelled. The sounds produced by oxygen emissions have been used for ecoacoustic monitoring in marine environments (Felisberto *et al.* 2015) and have also been documented in freshwater environments (WebVideo 1). At the water/air interface, sound has been used to estimate re-aeration – an important component in the estimation of whole-stream metabolism – in streams (Morse *et al.* 2007).

Threat monitoring

A growing body of research is concerned with the effect of anthropogenic noise on aquatic ecosystems. Noise can influence aquatic ecosystem health, or be a proxy for other human activities and stressors and can modify behavioral patterns in fish. The groundwork for this was laid in the 1960s, when the response of cutthroat trout (*Oncorhynchus clarkii*) to natural noise levels in Yellowstone National Park was described by Stober (1969); since then, alterations in the levels of underwater noise have been measured in both lakes

and rivers (Stober 1969; Amoser and Ladich 2010; Bolgan *et al.* 2016). At the same time, an increasing number of studies have identified direct impacts of anthropogenic noise on fish behavior (eg Lugli *et al.* 2003), leading to the conclusion that noise can affect fish in multiple ways: by increasing stress levels, changing dispersal behaviors, and interfering with communication. Anthropogenic noise may also alter predator–prey relationships (Slabbekoorn *et al.* 2010).

Monitoring of human-caused sounds may be a useful indicator of potentially damaging human activities, so a secondary benefit from acoustic monitoring is threat estimation by proxy. Underwater monitoring arrays could pick up anthropogenic influences that do not act directly on biota but are an indicator of threats, such as boat, vehicle, or even airplane noise, and proximity to roads or bridges (Kuehne *et al.* 2013).

■ Continuous ecoacoustic monitoring in freshwater environments

Working toward a system that can be used to monitor changes in freshwater ecosystems, we propose combining acoustic monitoring of the four elements discussed above (fishes, macroinvertebrates, physicochemical processes, and threats). Until now, continuous long-term monitoring has only been feasible for physical elements of a river, for example by means of flow gauges or probes to measure water temperature and/or water chemistry. A system that tracks soniferous fishes, macroinvertebrates, and ecosystem processes simultaneously could help to monitor both natural variation and anthropogenic changes in near real time (Figure 3). Continuous recording could also facilitate quantification of natural cyclic phenomena (ie diurnal, lunar, seasonal, and annual variation in environmental and ecological properties), which would allow natural variation to be accounted for when diagnosing anthropogenic changes. Such holistic acoustic monitoring systems have been suggested for terrestrial and marine environments by several authors (eg Kasten *et al.* 2012; Towsey *et al.* 2012).

Research on automated acoustic detection of various species has been expanding in recent years (eg Stowell and Plumbley [2014] classifying bird sounds; Colonna *et al.* [2015] monitoring frogs). However, in addition to a study that monitored sediment disturbance associated with spawning of a large, iconic fish species from the family Catostomidae in the southern US (Straight *et al.*

Figure 3. Whole-ecosystem monitoring: a spectrogram from the Einasleigh River, North Queensland, Australia, featuring sediment gas exchange, fish calls from *Leiopotherapon unicolor*, flow turbulence, and two species of aquatic Hemiptera.

2014), only a single study has attempted to automatically detect calls of a freshwater fish species (that of Kottege *et al.* [2015], who monitored spotted tilapia [*Pelmatolapia mariae*], an invasive fish in Australia, by means of their calls). Automated detection algorithms typically require some “training data” of known calls of the desired type to match against, but this presents a major challenge in many freshwater environments, because little is currently known about the structure and variety of sounds made by target biota in most aquatic systems. We believe that a thorough study of local environmental and species-specific sounds will be a prerequisite for any automated monitoring program.

Another challenge for automated monitoring is data storage. Despite exponential increases in affordable storage capacity over the past several decades, data storage remains problematic, particularly for remote portable recording stations (Aide *et al.* 2013). Data management has been an associated issue with temporally continuous PAM requiring either on-site data storage or limited samples (typically 5 minutes every hour). On-site storage limits the duration of recording without travelling to a site and downloading data, and is prone to water damage or impairment due to other, unanticipated events. The availability of inexpensive and energy-efficient microprocessors and widespread high-speed wireless communication networks offers potential solutions to these problems. By using low-cost microprocessors, audio processing for real-time detection can be run in situ, with high-bandwidth audio stored or transmitted only in cases of detection events (Kasten *et al.* 2012). Moreover, the reduced energy demand and consumption

of these devices increases the feasibility of long-term remote monitoring being powered by local solar arrays.

■ Key research questions to be addressed

Because the science of ecoacoustic monitoring in freshwater systems is still in its infancy, several key research questions must be addressed before a general approach to freshwater monitoring can be developed. Although some of these issues apply to many different kinds of ecosystems (eg the need to characterize spatiotemporal dynamics of sounds and optimize detection performance), freshwater environments often present additional and unique challenges.

Identification and cataloging of species-specific sounds

A comprehensive worldwide catalog of single-species calls and incidental sounds would greatly aid the development and implementation of monitoring schemes by acting as a reference library and clarifying the level of specificity of species' calls. A number of studies exist that describe the sounds emitted by fishes and macroinvertebrates, as well as noises in various freshwater contexts (see above), but this information is fragmented across the spectrum of acoustic, biological, and ecological research. Although few multi-taxon surveys of freshwater systems have been conducted (eg Anderson *et al.* 2008; Desjonquères *et al.* 2015), there is extensive research on the behavioral ecology of fishes (Ladich 2015) and the anatomy of sound production (Fine and Parmentier 2015). Collecting and cataloging the sounds of species associated with these single-taxon studies – as well as some of the multi-taxon surveys – would represent a major step toward practical operationalization.

Recordings of underwater sounds are kept in repositories such as the Macaulay Library sound archive at Cornell University, but the majority of these recordings are decades old, unlike the more recently published literature, in which freshwater acoustics research is actively being conducted across many spatial domains and with many different objectives. For passive acoustics to play a major role in freshwater science, this information needs to be assembled in a single repository, one where cataloged sounds are linked to correlating metadata (Roch *et al.* 2013); Bird-DB is an example of such a database, albeit for terrestrial bioacoustics. If a similar repository were constructed for freshwater organisms, it could then be linked to environmental and biodiversity data available from the Global Biodiversity Information Facility (Flemons *et al.* 2007), the Freshwater Information Platform (www.freshwaterplatform.eu), or similar repositories, to enable more thorough syntheses and analyses. This could potentially speed identification of unknown sounds in aquatic systems, facilitating development of pathways to ecoacoustic monitoring approaches.

Developing appropriate sampling methodologies and statistical techniques

As with other types of biological assessments in water bodies, ecoacoustic approaches will need to account for spatial and temporal variation in acoustic soundscapes, and monitoring regimes will have to be tailored to account for that variation.

Spatial variation in freshwater soundscapes is still largely unexplored apart from two studies. Both Desjonquères *et al.* (2015) in ponds and Tonolla *et al.* (2011) in rivers found that between-site variation in soundscapes was greater than within-site patchiness – an encouraging preliminary result. However, generalizations will only be possible once comprehensive studies assessing sound propagation, as well as patchiness in freshwater systems, have been conducted, thereby laying the foundation for adequate spatial sampling designs in freshwater systems.

All bioacoustic monitoring systems grapple with trade-offs between data volume and recording adequacy: how many hours of recording need to be analyzed to detect trends in ecosystem change. A first, thorough examination of temporal sampling for terrestrial ecoacoustic monitoring concluded that, although there is no magic-bullet solution, diurnal sampling could be optimized so that different habitats are assessed reasonably comprehensively (Pieretti *et al.* 2015). There will likely be the need for calibration depending on the ecosystem, especially as little research has been conducted on temporal patterns in sound-producing activities among freshwater organisms. However, the results of an unpublished pilot study conducted in our lab suggested that 5-second samples taken every 20 minutes over 6 days was enough to capture a fairly comprehensive variety of sound events, although 24-hour sampling was required to capture all sounds.

Temporal acoustic data are often analyzed in the form of acoustic indices – a summary of the raw sound data analogous to richness, diversity, or evenness indices in community ecology. Like their counterparts, these indices require appropriate statistical methods for discriminating statistically significant differences between sites and over time. Methods borrowed from time-series analyses will be particularly pertinent in order to account for serial correlation in acoustic measurements. Indeed, this has been identified as an important issue in ecoacoustics generally (Farina and Gage 2017).

Improving location-specific automatic detection

The performance of an automatic detection system is usually evaluated by computing outcome metrics, such as sensitivity, specificity, and precision (Colonna *et al.* 2015). These metrics depend on the number of false-positive or false-negative detections when comparing the outputs of automatic and manual detections. As with any automatic detection program, these metrics might be affected by non-biological background noise, such as that made by flowing water, rainfall, or boat engines

(Farina and Gage 2017). Moreover, detection of a target sound can also be made difficult by the co-occurrence of other competing biological sounds. Therefore, environments with high background noise levels, due to anthropogenic noise, geophonic sounds (detected in rock, soil, or ice), or other co-occurring species, require algorithmic optimization to ensure reliable detection of the sound of interest (Towsey *et al.* 2012). These technical challenges are not unique to freshwater environments, but the acoustic properties of, for example, shallow streams mean that these challenges require research specific to the medium; the acoustic effects of wind and rainfall on underwater soundscapes differ from those in terrestrial soundscapes. In addition, standard acoustic indices that account for background noise (Pieretti and Farina 2013) will need to be developed for freshwater systems.

Links between sounds and ecosystem health

A recent trend in environmental acoustics is the development of holistic acoustic approaches, in which environmental acoustic recordings are analyzed as a whole, as opposed to trying to isolate individual biotic sounds, as has been typical of bioacoustic research in the past (for an overview of the most commonly used indices, see Sueur *et al.* 2014). Various acoustic indices have been related to non-acoustic environmental indicators. Acoustic diversity, richness, or complexity indices are proven proxies for biodiversity (Sueur *et al.* 2014) and habitat heterogeneity (Tonolla *et al.* 2011).

In freshwater environments, however, the relationship between acoustic richness and ecosystem health is neither straightforward nor universal; richer soundscapes may indicate greater biodiversity and less impacted habitat in some contexts, whereas in others the opposite may be true. For example, soniferous invertebrate abundance underwater can be an indicator of both good and poor ecosystem health. Furthermore, the abovementioned temporal variation and spatial microvariation in underwater acoustics (Desjonquères *et al.* 2015) complicates analysis of any potential relationships between acoustic indices and ecosystem health. For instance, Pieretti and Farina (2013) reported a correlation between fish richness and an index of acoustic complexity, but Staatterman *et al.* (2014) suggested that variation in acoustic complexity could mainly be attributed to individual organisms. Gage and Axel (2014) also highlighted the notion that index choice is neither simple nor clear-cut, and made the case for filtering different frequency bands to increase specificity. This underscores the critical need for further research in this field in order to establish appropriate metrics and robust recording protocols.

Conclusion

A wealth of information about freshwater ecosystems can be obtained through acoustic recordings of multiple trophic levels of biota and the surrounding physicochemical

environment (Figure 3). Acoustic monitoring offers several advantages over existing techniques: it is non-invasive, mitigates observer effects, and affords high spatial and temporal resolution; it also potentially can be implemented for large-scale, long-term projects at reasonable cost.

We believe that whole-ecosystem acoustic monitoring of aquatic ecosystems will be feasible within the next decade, and indeed terrestrial programs are already proliferating. However, several key challenges will have to be overcome to design an operational framework in freshwater environments, as outlined in the above sections.

We view this paper as a call to action for freshwater ecoacousticians, as well as the wider freshwater research community, to share resources and contribute to a collective knowledge base, which could transform freshwater ecoacoustics into an operational discipline for whole-ecosystem monitoring beyond single-species studies over the medium term.
