3 A Systematic Review of the Evidence for Acute Tolerance to Alcohol—the ‘Mellanby Effect’  
4  
5  
6

7 **Abstract**

8 Objective: To review the evidence for ‘the Mellanby effect,’ that is, that the response to a given blood  
9 alcohol concentration (BAC) is more marked when BAC is rising than at the same concentration when  
10 BAC is falling.  
11  
12

13  
14  
15 Methods: We systematically searched the databases EMBASE, Medline, and Scopus up to and including  
16 December 2016 using text words ‘tolerance,’ ‘ascending,’ ‘descending’ or ‘Mellanby’ with Medline term  
17 ‘exp \*alcohol/’ or ‘exp \*drinking behavior/’ or equivalent. Articles were identified for further  
18 examination by title or abstract; full text articles were retained for analysis if they dealt with acute  
19 (within dose) alcohol tolerance in human subjects and provided quantitative data on both the ascending  
20 and descending parts of the BAC–time curve. Reference lists of identified works were scanned for other  
21 potentially relevant material. We extracted and analyzed data on the subjective and objective  
22 assessment of alcohol effects.  
23  
24  
25  
26  
27  
28

29  
30  
31 Results: We identified and screened 386 unique articles, of which 127 full-text articles were assessed;  
32 one provided no qualitative results, 62 involved no human study, 25 did not consider acute tolerance  
33 within dose, and 13 failed to provide data on both ascending and descending BAC. We extracted data  
34 from the 26 remaining articles. The studies were highly heterogeneous. Most were small, examining a  
35 total of 770 subjects, of whom 564 received alcohol and were analyzed in groups of median size 10  
36 (range 5–38). Subjects were often young white men, sometimes subdivided on the basis of drinking or  
37 family history. Doses of alcohol and rates of administration differed. Performance was assessed by at  
38 least 26 different methods, some of which measured many variables. We examined only results of  
39 studies which compared results for a given alcohol concentration (C) measured on the ascending limb  
40 ( $C_{up}$ ) and the descending limb ( $C_{down}$ ) of the BAC, whether in paired or parallel-group studies. When  
41 subjects were given alcohol in more than one session, we considered results from the first session only.  
42 Rating at  $C_{down}$  was better than at  $C_{up}$  for some measures, as expected if the Mellanby effect were  
43 operating. For example, subjects rated themselves less intoxicated on the descending limb than at the  
44 same concentration on the ascending limb in 12/13 trials including 229 subjects that gave statistically  
45 significant results. In 9 trials with a total of 139 subjects, mean difference could be calculated; weighted  
46 for study size, it was 29% [range 24%–74%]. Willingness to drive was significantly greater in 4 of 6  
47  
48

58  
59  
60

1  
2  
3 studies including a total of 105 subjects; weighted mean difference increased by 207% [range 79–300%].  
4  
5 By contrast, measure of driving ability in three groups of a total of 200 trials in 57 subjects showed  
6  
7 worse performance by a weighted mean of 96% [range 3–566%]. In three trials that tested inhibitory  
8  
9 control (cued go or no-go response times), weighted mean performance was 30% [range 14-65%] worse  
10  
11 on the descending limb.

12  
13  
14 Conclusion: The 'Mellanby effect' has been demonstrated for subjective intoxication and willingness to  
15  
16 drive, both of which are more affected at a stated ethanol concentration when BAC is rising than at the  
17  
18 same concentration when BAC is falling. By contrast, objective measures of skills necessary for safe  
19  
20 driving, such as response to inhibitory cues and skills measured on driving simulators, were generally  
21  
22 worse on the descending part of the BAC-time curve for the same BAC.

### 23 24 **Introduction**

25  
26 Ethanol (ethyl alcohol, 'alcohol') impairs cerebral function in a dose-dependent manner, at least at  
27  
28 concentrations above a threshold of 50 mg/dL (0.050 g/dL) (1) (2). However, the relationship between  
29  
30 blood alcohol concentration and cerebral function can be affected by prior alcohol exposure, as  
31  
32 suggested by the apparent tolerance of chronic drinkers to very high concentrations (3).

33  
34 The 'Mellanby effect' (4) or 'Mellanby phenomenon' (5) is the 'The purported phenomenon that the  
35  
36 magnitude of behavioural impairment associated with a given blood alcohol concentration (BAC) is  
37  
38 greater during a rising BAC than during a falling BAC.' The behavioural impairment may be objective  
39  
40 (observed by others) or subjective (experienced by the drinker). In this context, the term 'acute  
41  
42 tolerance' refers specifically to tolerance occurring within one session. (5)

43  
44 Dr. (afterwards Sir) Edward Mellanby himself conducted a series of studies of alcohol absorption and  
45  
46 elimination during the First World War. (6) Mellanby studied four fasted dogs ('Brown, Large Black,  
47  
48 Small Black, White'), and administered various amounts (20–55 mL, equivalent to 1.5–3.3 g/kg) of  
49  
50 alcohol via oro-esophageal tube over several trials. He drew blood for BAC determination at 0.5, 1, 1.5,  
51  
52 2.5 hours, and then at 2-hour intervals after alcohol administration thereafter. He determined BAC by  
53  
54 the potassium dichromate reduction method. He reported that alcohol peaked quite rapidly after  
55  
56 consumption; that the BAC was proportional to the amount consumed; that consumption with milk  
57  
58 inhibited intoxication by delaying GI absorption; and that dogs metabolize alcohol slowly, at a rate  
59  
60 independent of the BAC (zero order kinetics). Mellanby noted the peak BAC ranged from 153- 530  
mm<sup>3</sup>/100 g blood (128 mg/dL to 445 mg/dL), and found a metabolic rate (15.7 mg/dL/hour) very similar

1  
2  
3 to the average rate in humans. He also disproved a belief common at the time that gulping all alcohol at  
4 once would produce less intoxication than would sipping the same amount over a longer period.  
5  
6 Mellanby noted the difficulty assessing intoxication in dogs, because he was only able to use gross  
7  
8 motor abnormalities as evidence of acute intoxication. These consisted of observations of scraping of  
9  
10 the toe-nails on the floor while walking in the early stages of intoxication, hind leg weakness (most  
11  
12 evident while standing still), and a 'rolling gait'; progressing to stumbling, difficulty getting up again after  
13  
14 falling, and peaking with complete inability to walk and collapsing. These observed signs of intoxication  
15  
16 disappeared about 2 hours after administration, and only lethargy and disinterest in the environment  
17  
18 remained, with all other objective signs being normal. Using these observations, he was able to  
19  
20 determine the BAC at which obvious intoxication occurred, and noted the intoxication was only  
21  
22 observable on the ascending limb of the BAC–time curve. On the descending limb, when the same  
23  
24 alcohol concentration was reached, the dogs appeared relatively normal. He postulated that the central  
25  
26 nervous system was most affected initially by the 'sudden attack of the alcohol', or that the 'nervous  
27  
28 system may re-learn to co-ordinate its activities after being under the alcoholic influence.' (6) (7)

29  
30 Mellanby was well aware of the difficulties of determining the degree of intoxication in dogs, and of  
31  
32 extrapolating his results to humans. In 1920 he presented the results of a further experiment, in which  
33  
34 one (unidentified) man was asked to copy a drawing repeatedly after drinking '300 c.c. of [Imperial]  
35  
36 proof spirit diluted to 900 c.c.' that is, approximately 170 mL pure ethanol (equivalent to approximately  
37  
38 10 standard drinks). (8) The changes in his ability to repeat the drawing varied with intoxication, but no  
39  
40 conclusions could be drawn from an experiment with only one subject.

41  
42 Here we consider the evidence that human subjects develop acute tolerance to the effects of alcohol, so  
43  
44 that psychomotor impairment is greater at a given BAC when the concentration is rising ('the ascending  
45  
46 limb of the alcohol curve') than at the same concentration when it is falling (the 'descending limb'). This  
47  
48 postulated phenomenon of acute tolerance has been commonly referred to as the 'Mellanby Effect', but  
49  
50 Sir Edward Mellanby, MD never referred to it as such.

## 51 52 **Methods**

53  
54 We systematically searched the databases EMBASE, Medline, and Scopus from 1946 up to and including  
55  
56 December 2016, using text words 'tolerance,' 'ascending,' 'descending' or 'Mellanby' with Medline term  
57  
58 'exp \*alcohol/' or 'exp \*drinking behavior/' or equivalent. We scanned reference lists of identified  
59  
60 manuscripts meeting the criteria for other potentially relevant material. We identified articles for

1  
2  
3 further examination by the authors according to the title or abstract and retained full-text articles for  
4 further analysis if they dealt with acute (within dose) alcohol tolerance in human subjects, and provided  
5 quantifiable data on both the ascending and descending limbs of the BAC–time curve. In order to  
6 analyze data on the subjective and objective assessment of alcohol effects, we manually reviewed each  
7 eligible paper, extracted the data, and converted all recorded changes into percentage difference  
8 between ascending and descending limb. Due to the heterogeneity, meta-analysis could not be  
9 performed, but the data are presented in summary form as the attached table of the 26 eligible  
10 manuscripts. For the ‘Mellanby Effect’ of acute within-dose tolerance to be operating, the rating or  
11 measurement at  $C_{down}$  would have to be more nearly unimpaired (i.e., more sober) than at  $C_{up}$ .

### 19 Results

20  
21 The database search identified an initial 386 unique articles. These were screened by title and abstract  
22 looking for objective measures in humans, and 127 full-text articles met this inclusion criterion and were  
23 read by the investigators. Of these 127, one provided no quantitative results, 62 involved no human  
24 study, 27 did not consider acute tolerance within dose, and 13 failed to provide data on both ascending  
25 and descending BAC. The remaining 26 articles were analyzed (9) (10) (11) (12) (13) (14) (15) (16) (17)  
26 (18) (19) (20) (21) (22) (23) (24) (25) (26) (27) (28) (29) (30) (31) (32) (33) (34). In addition, there were  
27 three articles containing information on trial subjects from two of these studies (35) (36) (37) .  
28  
29  
30  
31  
32  
33  
34  
35  
36

37 The 26 studies we examined are listed in Table 3. The same subjects on both the ascending limb ( $C_{up}$ )  
38 and the descending limb ( $C_{down}$ ) of the BAC-time curve were examined in 23, and there were 3 parallel-  
39 group studies (16) (19) (25) in which one group was examined on the ascending limb and another on the  
40 descending limb.  
41  
42  
43  
44

45 Researchers assessed the subjective state, cognitive function, and motor abilities by at least 26 different  
46 methods, some of which (e.g. simulated driving performance) measured many variables. These methods  
47 covered the five outcome domains described by Jongen (38). [Table 1]. The studies were highly  
48 heterogeneous, and most studies were small, with a median of only 10 subjects per group [range 5–56],  
49 and a total of 770 subjects. Study subjects were usually young white men, sometimes subdivided on the  
50 basis of drinking habits or family history, or both. Doses of alcohol and rates of administration differed.  
51 All effects seen were dependent on each subject’s prior drinking history and the degree of intoxication.  
52  
53  
54  
55  
56  
57  
58  
59  
60

Analyses sometimes considered changes from baseline, or compared tests with alcohol against placebo. This wide diversity among studies regarding ethanol dose, number of subjects, and experimental tests precluded us from performing a meta-analysis.

In most relevant studies, subjects rated themselves less intoxicated on the descending limb than at the same concentration on the ascending limb of the blood ethanol concentration–time curve, as expected if the Mellanby effect were operating. For example, considering those trials that gave statistically significant results: in 19 trials in 12 studies (9) (12) (13) (14) (17) (21) (22) (23) (24) (30) (33) (34) of a total of 229 subjects, the mean difference, weighted for study size, in the 9 trials providing numerical data, was 29% [range 24%–74%] less intoxicated subjectively. In four studies (9) (21) (30) (33), examining a total of 105 subjects, willingness to drive increased significantly in 4 of 6 trials. Weighted mean improvement in 52 subjects was 207% [range 79–300%]: that is, they were three times as willing to drive on the descending limb. By contrast, measure of driving ability in three groups of a total of 200 trials in 57 subjects (21) (30), showed worse performance by a weighted mean of 96% [range 3–566%]. In three trials (24) (25) (28) testing inhibitory control (cued go/no– go tests), weighted mean performance was 30% [range 14–65%] worse on the descending limb.

In some studies, minor objective measures showed improvement at  $C_{down}$  compared with  $C_{up}$ . The time for a maze task improved by a mean of 11% (13); and for a peg-board task improved by 71% (24). Arithmetic ability improved by 10% to 18% (18) abstraction by 21%, and attempts at abstraction by 182% (19). Results for several domains were inconsistent between studies.

Importantly, measure of driving ability such as lane deviation, line crossing, and speed deviations or excesses showed statistically significant deterioration on the descending limb. Three groups of a total of 200 trials on 57 subjects (21) (30), showed worse performance by a weighted mean of 96% [range 3–566%].

## Discussion

Sir Edward Mellanby's observations on four dogs and one man, perhaps coupled with the subjective experiences of those investigators who had themselves drunk alcohol, have for nearly a century led to the view that the effects of a given BAC are dependent not only on the absolute value but also whether it is increasing or decreasing.

1  
2  
3  
4  
5 We have systematically reviewed the evidence for the Mellanby effect. We may have failed to find  
6 relevant studies, or have excluded them from analysis. However, we have considered both the  
7 references identified by our search and the reference lists of the papers relevant to our review.  
8  
9 Firm conclusions are hampered by the relatively small number of studies, and the experimental  
10 difficulties. The optimal experimental design is uncertain, because repetition on the descending limb of  
11 a test already administered on the ascending limb inevitably introduces a possibility of short-term  
12 training effects. Prior training sessions and placebo studies help to mitigate this. Alternatively, parallel-  
13 group studies are possible. However, these are relatively insensitive, and therefore demand large groups  
14 for statistically robust results. The analysis of placebo-controlled studies is also complex; some authors  
15 have been meticulous in presenting detailed analyses of variance or co-variance, while failing to present  
16 tables of the measurements from which they are derived, so that absolute effect size cannot be  
17 estimated. In several studies, the measures of performance were only presented as graphs.  
18  
19 Martin and Moss noted that the 'Mellanby measure' (of the effect at some concentration C on the  
20 descending limb minus the effect at the same concentration on the ascending limb) is potentially  
21 confounded by differences in the direction of change in BACs on the two limbs of the blood alcohol  
22 curve. (23) Early studies generally looked only at one concentration on the ascending limb and an  
23 approximately similar concentration on the descending limb. Designs using several data points could  
24 allow the slope of the BAC to be incorporated into the analysis. (23) An early study in a single subject  
25 presented results as hysteresis curves. (39) In a few modern studies, notably the study by Cromer et al,  
26 (13) plots showing multiple measures on both limbs demonstrate what are essentially clock-wise  
27 hysteresis curves.

43 The experimental studies may be difficult to generalize to real-world experience. Study subjects are  
44 demographically quite uniform—often young white men, and commonly college students. Some have  
45 personal or family histories of heavy drinking, which may be relevant factors in determining the  
46 responses. For example, results differed between groups considered 'at-risk' and 'non-risk' of alcohol-  
47 related disease (15). In addition, the pattern of drinking and the amount of alcohol consumed during  
48 studies probably differed substantially from real life conditions. In some studies, tests were repeated  
49 after an interval of some days, sometimes more than once, to examine 'sub-acute' tolerance. In those  
50 cases, we examined evidence only for the first study of such a series. Doses of ethanol differed  
51 substantially between studies, from 0.135 mg/kg (18) to 1.16 g/kg (32). Ethanol was administered  
52

2  
3 intravenously in one study (34). In addition, due to obvious safety concerns, most studies used a target  
4 peak BAC near 80 mg/dL, which is the limit above which driving is illegal in the United Kingdom and the  
5 USA. Mellanby observed dogs with BACs mainly in the range of 300–450 mg/dL, much higher than  
6 examined in modern human experiments. It is unknown whether a 'Mellanby Effect' may be more easily  
7 demonstrable in humans when descending from these very high BACs. No experiments have tested this,  
8 and there are safety concerns for study subjects at these high BACs.  
9

10  
11  
12  
13  
14  
15  
16 Some clear results have emerged from our review, in spite of the difficulties in interpreting the  
17 measurements from widely differing tests under many different conditions. The Mellanby effect was  
18 statistically significant and in favour of feeling more sober on the descending limb in 12 of 19 trials of  
19 the subjective feeling of intoxication, with only one result—after intravenous alcohol (34)—being  
20 statistically significant and in favour of subjectively feeling more drunk. The willingness to drive at a  
21 given BAC is twice as great on the descending limb as on the ascending limb, in parallel with the subjects  
22 feeling less drunk. The implication is that subjects almost always feel soberer on the descending limb,  
23 and therefore feel it is safer to drive. By contrast, the ability to drive, as judged by measures made  
24 during simulated driving, does not improve on the descending limb; it deteriorates substantially, with  
25 twice as many faults on the descending limb as on the ascending limb. The inevitable conclusion is that  
26 drivers who have taken alcoholic drinks contributing around 0.65–1 gram ethanol/kg bodyweight (which  
27 is 52–80 g in an 80 kg person, roughly equivalent to 3½–6 US standard drinks of 14 g each) and who are  
28 beginning to sober up are dangerous because their belief that they are less intoxicated is contradicted  
29 by a continued decline in driving skills.

40  
41  
42 The mechanism by which acute tolerance occurs is less clear. Neither breath nor blood alcohol  
43 concentrations reflect the instantaneous concentration at the site of action, presumed to be GABA<sub>A</sub>  
44 receptors in the central nervous system, and perhaps additional neuronal pathways (40). The  
45 disappearance of subjective effects could therefore be due to more rapid clearance of ethanol from the  
46 site of action than from the sampling site. However, this is unlikely to be the explanation, at least in rats  
47 (40). Kaplan et al gave a loading dose of oral ethanol to six male human subjects, followed by re-  
48 administration every 30 minutes to keep breath ethanol concentrations in the range of 80–100 mg/dL  
49 over the next six hours. They showed that even at steady state there is acute tolerance to the effects of  
50 alcohol on word recall; but no tolerance to measures of standing steadiness (body sway) or ability to  
51 maintain a simulated airplane on a centreline (41). Two more recent studies utilized an ethanol clamp in  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 which an IV ethanol load followed by a steady-state infusion produced nearly constant BACs for the  
4 study period, allowing the development of acute tolerance at constant BAC to be studied over time.  
5  
6 Hendershot et al studied 88 young heavy drinkers (average age 19.8 years) who were given an  
7  
8 intravenous load of ethanol sufficient to produce a BAC of 80 mg/dL in 20 minutes, followed by a steady-  
9  
10 state infusion for 80 minutes to maintain the same BAC. They found response inhibition to a 'go/no go'  
11  
12 test worsened as BAC rose, and continued to deteriorate during the steady-state phase (42). Zoethout et  
13  
14 al studied 6 male and 6 female subjects aged 18–39 years. They gave a rapid infusion of ethanol over ten  
15  
16 minutes, followed by a variable-rate infusion to maintain a BAC of 60 mg/dL for 5 hours. They found  
17  
18 some parameters (visual analogue scale alertness, visual tracking, and body sway) fluctuated during the  
19  
20 plateau phase, despite constant BrAC values. However, smooth pursuit eye movements remained  
21  
22 impaired during the steady state (43). Interestingly, these constant BAC experiments failed to show  
23  
24 acute tolerance to subjective feelings of intoxication, suggesting that changes in ethanol concentration,  
25  
26 rather than absolute blood concentrations, determine subjective drunkenness. This makes sense  
27  
28 logically, since as BACs rise, subjects feel increasing intoxication relative to when they started drinking,  
29  
30 and as BACs fall, subjects notice a diminution of subjective intoxication as the time since peak BAC  
31  
32 increases. For psychometric tests of performance, Schweizer and Vogel-Sprott argued that alcohol had a  
33  
34 differential effect on reaction time, which is substantially improved on the descending limb compared  
35  
36 with the ascending limb; and on accuracy, which is impaired to the same extent on both—what they  
37  
38 term 'acute protracted errors.' (44). From this, they argue that alcohol may affect brain hemispheres  
39  
40 differently, a hypothesis that has not yet been verified experimentally.

### 41 **Conclusion**

42 The so-called 'Mellanby effect' is most firmly established for subjective feelings of intoxication. Subjects  
43  
44 feel less drunk and more able to drive during the descending limb of the BAC-time curve than at the  
45  
46 same concentration of alcohol on the ascending limb. Since the effect is not seen when BAC is held  
47  
48 constant, it may well be related to the rate and direction of change in BAC, rather than the development  
49  
50 of acute tolerance to the drug effect.

51  
52 Objective measures of impairment, especially those involving skills necessary for safe driving and those  
53  
54 measured on driving simulators were generally worse during the descending limb for the same BAC.  
55  
56 Slowed reaction times may recover somewhat during the descending limb, but accuracy falls. When  
57  
58 these decrements are combined with a perceived improvement in ability to drive and a loss of inhibitory  
59  
60

1  
2  
3 control, the likelihood of driving while impaired increases, and may explain the binge or problem  
4 drinker's increased risks for motor vehicle crashes.  
5  
6  
7

8  
9 It appears then, that these objective tests are likely to be more robust than a person's own perception.  
10 The studies we have reviewed show that subjects feel less drunk during the descending limb of the BAC-  
11 time curve than at the same concentration of alcohol on the ascending limb. However, objective  
12 measures of impairment, especially those involving skills necessary for safe driving and those measured  
13 on driving simulators, were generally worse during the descending limb for the same BAC. All effects are  
14 dependent on a person's drinking history and the degree of intoxication.

**Table 1: Five major outcome domains**

Derived from Jongen 2016 (38)

Outcome Domains	Tests used for assessment by included studies
A. Alertness/arousal	1. Pauli addition*
B. Attention & processing speed	2. Tracometer**
C. Reaction time/psychomotor function	3. Video game 4. Pursuit rotor test 5. Pegboard test 6. Proprioception 7. Vestibulo-ocular reflex 8. Skin conductance 9. Electromyogram
D. Sensory-perceptual functioning	10. Subjective intoxication 11. Willingness to drive
E. Executive functioning	12. Maze test 13. Cued Go/No-Go Test 14. Shipley IQ test 15. Memory scanning test 16. Random object scan test 17. Vocabulary test 18. Abstraction 19. Short-term memory 20. Information processing 21. Picture recognition 22. Word fragment 23. Free recall 24. Associative learning 25. Driving Simulation

\*Pauli addition: study subjects find a solution to a problem by adding two numbers displayed in two different windows. \*\*Tracometer: Study subjects track moving targets on a screen using a steering wheel

Table 2: Numbers of trials with results for effects on the ascending and descending limb demonstrating significantly 'improved' ('more sober'), non-significant, or significantly 'deteriorated' ('more drunk') results on the descending limb. (Not all studies in which results were statistically significant gave the numerical values for the results).

<b>Test</b>	<b>Significantly improved ('more sober') during C<sub>down</sub></b>	<b>No difference</b>	<b>Significantly worse ('more drunk') during C<sub>down</sub></b>
<b>Subjective tests</b>	16	8	1
Self-rated intoxication	12	6	1
<b>Attention and processing</b>		1	
<b>Reaction time/psychomotor</b>	7	7	
<b>Executive function</b>	9	26	16
<b>Simulated driving</b>		3	12

**Table 3.** Results from 26 trials examining the effect of alcohol both on the ascending and descending limbs of the blood alcohol concentration (BAC)–time curve, known as the ‘Mellanby effect.’

Results are given as the mean percentage difference between measure on the ascending limb, taken as 100%, and the descending limb; statistical significance is quoted from the relevant studies.

A positive difference indicates that subjects felt more sober or that particular performance improved on the downward limb of the BAC–time curve.

	Number of subjects	Group sizes	Test(s)	Dose of ethanol	Mean percentage improvement $\Delta$ (descending limb – ascending limb)	Statistical Significance	Summary: Mellanby Effect
Amlung et al 2014	56 (26 F)	EtOH 28 Placebo 28	a. Perceived danger b. Willingness to drive Subjective intoxication	Calculated to produce a peak BrAC of 100 mg/dL	$\Delta = -50\%$ $\Delta = +300\%$ $\Delta = -30\%$	P<0.001 P<0.001 P<0.01	Positive for subjective effects, but changes in the placebo group
Beirness et al. 1984	18 social drinkers	10 men 8 men	Tracometer	4 x 0.84 mL/kg	Mean $\Delta 1\% \pm 4.93\%$ Six worse, 12 better Graph shows % recovery to be -10% to +10%	NS	Not consistently demonstrated
Bennett et al. 1993	20	10 men 10 men	Video game	0.75 g/kg 1 g/kg	Mean $\Delta 2-3\%$	NS	No
Benton et al. 1982	8	8 men	BrAC when sober Magnitude estimation (ME) of intoxication	2 x 0.65 mL/kg x 2 (2 <sup>nd</sup> drink when BAC from 1 <sup>st</sup> drink had	Day 1 Magnitude estimate after 1 drink (2 <sup>nd</sup> drink given when ME was zero) mean $\Delta 37\%$ (felt better) Day 2 ME (2 <sup>nd</sup> drink given when BrAC was zero)	P<0.03	Yes for subjective intoxication; second drink had less effect in both sessions
Cromer et al 2010	20	9 M, 11 F (all had ethanol then placebo, or the other way round)	Visual analogue scale (VAS) drunkenness; maze test Timed chase Time Total errors Exploratory errors	0 (placebo) 250 mL of vodka 40% and orange juice 60%	VAS  Timed chase test Mean errors mean $\Delta 7\%$ Mean time mean $\Delta 21\%$  “There was no significant difference between limbs of the blood alcohol concentration (BAC) curve for total errors (A), exploratory errors (B), or exploratory errors on the delayed trial (C). Thus, measures of higher order cognition do not show an acute tolerance effect.”	P<0.05 P=0.05  NS NS NS	Yes for subjective intoxication  Yes for visuomotor speed and visuospatial learning  No for higher cognitive function
