Manuscript for Marine Environmental Research

April 2007
ABSTRACT

Measurements of nitrate and ammonium in precipitation and associated with aerosols were conducted at Rutgers University Marine Field Station in Tuckerton, New Jersey from March 2004 to March 2005 to characterize atmospheric nitrogen deposition to the Mullica River-Great Bay Estuary. The arithmetic means of nitrate and ammonium concentrations for precipitation samples were 2.3 mg L\(^{-1}\) and 0.42 mg L\(^{-1}\), respectively. Nitrate and ammonium concentrations in aerosol samples averaged 3.7 µg m\(^{-3}\) and 1.6 µg m\(^{-3}\), respectively. Wet deposition rates appeared to vary with season; the highest rate of inorganic nitrogen deposition (nitrate + ammonium) occurred in the spring with an average value of 1.33 kg-N ha\(^{-2}\) month\(^{-1}\). On an annual basis, the total (wet and dry) direct atmospheric deposition fluxes into the Mullica River-Great Bay Estuary were 7.08 kg-N ha\(^{-2}\) yr\(^{-1}\) for nitrate and 4.44 kg-N ha\(^{-2}\) yr\(^{-1}\) for ammonium. The total atmospheric inorganic nitrogen directly deposited to the Mullica River-Great Bay Estuary was estimated to be 4.79 x 10\(^4\) kg-N yr\(^{-1}\), and the total atmospheric inorganic nitrogen deposited to the Mullica River watershed was estimated to be 1.69 x 10\(^6\) kg-N yr\(^{-1}\). Only a fraction of the nitrogen deposited on the watershed will actually reach the estuary; most of the nitrogen will be retained in the watershed due to utilization and denitrification during transport. The amount of N reaching the Mullica River-Great Bay Estuary indirectly is estimated to be 5.07 x 10\(^4\) kg-N year\(^{-1}\), approximately 97% is retained within the watershed. This atmospheric nitrogen deposition may stimulate phytoplankton productivity in the Mullica River-Great Bay ecosystem.

**Keywords:** nitrogen compounds, atmospheric nitrate and ammonium, deposition rate, coastal waters, eutrophication.
1. Introduction

An important portion of nitrogen (N) entering coastal waters is of atmospheric origin. Atmospheric nitrogen can reach coastal waters by direct deposition pathways: wet deposition by precipitation and dry deposition by both aerosol particles and gases, and it can also enter the coastal waters by indirect pathways through deposition first to the land surface and then subsequent runoff. Studies conducted along the east coast of the United States indicate that atmospheric nitrogen deposition represents a significant amount of the total nitrogen input to coastal waters (Fisher and Oppenheimer, 1991; Paerl and Fogel, 1994; Russell et al, 1998; Scudlark et al., 1998; Castro and Driscoll, 2002; Whitall et al., 2003). A large fraction of the atmospheric nitrogen input is in the form of inorganic nitrogen, mainly nitrate (NO$_3^-$) and ammonium (NH$_4^+$). NO$_3^-$ is formed through atmospheric reactions involving NO$_x$, and emission sources for NO$_x$ include fossil fuel combustion from automobiles and industries, biomass burning, and other natural fixation processes. The formation of NH$_4^+$ is mainly by the gas-to-particle conversion reactions of NH$_3$ in the atmosphere, and NH$_3$ is primarily derived from agricultural waste, fertilizers, industrial emissions, and decomposition of organic substances (Seinfeld and Pandis, 1998; Paerl, 2002).

Organic N can also contribute to a sizeable portion of the total wet deposition budget (Cornell et al., 1995; Whitall et al. 2003). Recent measurements for coastal North Carolina indicated that ~30% of the total N in rainwater was organic N (Peierls and Paerl, 1997). Although sources of organic nitrogen in the atmosphere are not well understood, certain contributions to atmospheric organic nitrogen from natural sources such as sea spray droplets and plant pollens have been noted (Prospero et al., 1996).
important component in the total atmospheric deposition could be dry deposition by gas-phase nitrogen which has not been studied widely and is often omitted from calculations of the total N deposition. Recent studies from coastal New Jersey and North Carolina indicate that both oxidized N such as HNO$_3$ and reduced N such as NH$_3$ contribute significantly to the dry deposition of atmospheric nitrogen (CASTNET; Walker et al., 2004). Therefore, careful considerations of the contributions of these gas-phase N species to the dry deposition, as well as organic N, should be incorporated into future atmospheric N measurements.

Nitrogen is a major nutrient that controls primary productivity in many coastal waters, and atmospheric deposition is an important non-point source of both organic and inorganic nitrogen (Ryther and Dunstan, 1971; Vitousek and Howarth, 1991; Nixon, 1995; Paelr, 1995; Paelr and Whitall, 1999; Seitzinger and Sanders, 1999; Rabalais, 2002; Driscoll et al., 2003; Galloway et al., 2003). Excessive fluxes of nitrogen from atmospheric sources result in the eutrophication of many coastal waters in the United States, which is now considered the most widespread water quality problem (Nixon, 1995; Carpenter et al., 1998).

This work focuses on the Mullica River-Great Bay Estuary to characterize the atmospheric inorganic nitrogen (NO$_3^-$ and NH$_4^+$) input from precipitation and associated with aerosols. The Mullica River-Great Bay Estuary is located along the southern New Jersey coastline, approximately 14 kilometers north of Atlantic City. It extends from Lower Bank (freshwater/saltwater interface) in the Mullica River to Little Egg Inlet (polyhaline) and consists primarily of open estuary bordered by salt marshes (Kennish et al., 2004). The waters in this region have traditionally been undisturbed and clean with
little human impact. Most of the Mullica River watershed is sheltered from anthropogenic input because the upstream portions are part of the New Jersey Pinelands National Reserve, while the downstream portions are surrounded by federal and state wildlife refuges (Psuty et al., 1993; Zampella et al., 2001). This estuary, therefore, can serve as an excellent reference location to assess the health of impacted coastal ecosystems in New Jersey. To date, there has been little data collected to evaluate atmospheric nitrogen deposition to this ecosystem.

2. Methods

2.1 Sampling Collection

Atmospheric precipitation and aerosol samples were collected at Rutgers University Marine Field Station (RUMFS) in Tuckerton, New Jersey (39.59° N, 74.34° W) from March 2004 to March 2005. This site is located at the southern tip of a salt marsh peninsula across from the Little Egg Inlet in the Mullica River-Great Bay Estuary (Figure 1). Precipitation samples were collected by a MIC wet-only automatic precipitation sampler controlled by an onsite rain sensor (MIC Company, Richmond, Ontario, Canada). A total of 51 precipitation samples were collected on an event-basis throughout the year, using plastic reservoir sets that were previously cleaned and sealed in plastic bags until use. A precipitation event during this study was arbitrarily defined as the collection of small amounts of precipitation over a raining period that could last for a consecutive three to four days or one day of heavy precipitation. The annual precipitation rate during this study period was 107.5 cm and the average precipitation rate was 8.99 cm/month. After the precipitation sample was collected, the bottle with the
unfiltered sample was labeled. A total of 22 aerosol samples were also collected using a Model 500EL high-volume aerosol sampler with a flow rate of $\sim 1 \text{ m}^3 \text{ min}^{-1}$ (Aquaero Tech, Miami, Florida, USA). Whatman 41 and 48 cellulose filter papers (both with the same filtration efficiency of air particulate matter but different ash maximum) were used to collect the samples, and the sampling duration lasted between 6 and 24 hours. On average, two samples were collected per week from March 2004 to May 2004. After collection, the sample filter was unloaded, placed in a plastic bag and labeled. All samples were stored frozen until analysis.

2.2 Chemical Analysis

To prepare precipitation samples for analysis, the frozen samples were first thawed at room temperature. The pH of each sample was determined with a SevenEasy pH meter (Mettler Toledo, Germany). Each sample was subsequently filtered to remove particulate matter using a polycarbonate filter of 0.45 µm pore size along with a 250 ml Nalgene filtration system. To prepare aerosol samples for analysis, one-fourth of each sample filter was leached in 100 ml deionized water ultrasonically for $\sim 1$ hour. Then the samples were filtered following the same procedure as that used for precipitation sample preparation. The details of the method can be found in Gao et al. (1996). The analysis of nitrate and ammonium in precipitation and aerosols was conducted at Montclair State University (MSU) with a Dionex 2500 Ion Chromatograph (IC) (Dionex Corporation). The 2500 IC system was equipped with an IonPac AG11-HC 4mm guard column and an IonPac AS18 4mm analytical column for anions such as nitrate. An eluent mixture of 50% w/w sodium hydroxide (NaOH) and distilled water was used to elute nitrate and the other anions at a flow rate of $1 \text{ ml min}^{-1}$. Collection of field blanks, analyses of replicates
and an interlaboratory comparison were conducted to assure the data quality. The IC detection limits were 0.05 mg L\(^{-1}\) for nitrate and 0.05 mg L\(^{-1}\) for ammonium. As a data QA/QC procedure, a total of five precipitation samples that were analyzed at MSU were also analyzed at a lab at Rutgers University Pineland Field Station in New Jersey, and the concentrations from the two labs agreed within 15%, although the samples were stored longer at the Pineland Field Station before analysis. Therefore, the different storage times could be a contributing factor to the difference in concentrations as a result of a chemical change in composition over time. There could also be a difference in results due to the age of each of the laboratory’s IC’s column and suppressor as well as different standard operating procedures and quality assurance practices procedures established at different laboratories.

3. Results and Discussion

3.1. Nitrate and Ammonium Concentrations in Precipitation and Aerosols

Figure 2 shows the concentrations of nitrate and ammonium in precipitation. The nitrate concentrations for precipitation were always higher than ammonium concentrations. The arithmetic means of nitrate and ammonium concentrations in precipitation were 2.3 mg L\(^{-1}\) and 0.42 mg L\(^{-1}\), respectively. These results are comparable to other studies conducted along the east coast (Russell et al., 1998; Gao, 2002). Gao (2002) found that the average nitrate concentration for precipitation was 1.8 mg L\(^{-1}\), and the average ammonium concentration was 0.33 mg L\(^{-1}\) for Barnegat Bay, New Jersey. At Edwin B. Forsythe National Wildlife Refuge located in Atlantic County, New Jersey, the annual mean concentration in precipitation was 0.88 mg L\(^{-1}\) for nitrate,
and 0.20 mg L\(^{-1}\) for ammonium in 2005, and in 2004, the nitrate and ammonium concentrations were 1.00 mg L\(^{-1}\) and 0.15 mg L\(^{-1}\), respectively. The eight-year precipitation record (1988-2005) shows the average concentrations of 0.99 mg L\(^{-1}\) for nitrate and 0.16 mg L\(^{-1}\) for ammonium at this location (NADP/NTN). At Washington Crossing in Mercer County in New Jersey, the annual concentrations of nitrate and ammonium in precipitation were 1.53 mg L\(^{-1}\) for nitrate and 0.30 mg L\(^{-1}\) for ammonium in 2004 and 1.04 mg L\(^{-1}\) for nitrate and 0.21 mg L\(^{-1}\) for ammonium in 2005 (NADP/NTN). At the Chesapeake Bay, the volume-weighted average concentrations of nitrate and ammonium from wet deposition were 1.3 and 0.24 mg L\(^{-1}\), respectively (Russell et al., 1998). It is worth noting that there were variations in the average nitrate and ammonium concentrations for the above studies, and there are many factors contributing to the concentration differences, such as the sampling locations, the strength of emission sources, the year of the study, and the precipitation rates.

The values for nitrate and ammonium concentrations in aerosol samples for the spring are shown in Figure 3. The average nitrate and ammonium concentrations were 3.7 µg m\(^{-3}\) and 1.6 µg m\(^{-3}\), respectively. Nitrate concentrations in the aerosol samples were higher than ammonium concentrations in this area. At Barnegat Bay, New Jersey, the nitrate concentrations in aerosol observed during a recent two-year measurement were also higher than ammonium concentrations, with average concentrations of 2.0 ± 0.89 µg m\(^{-3}\) for nitrate and 0.50 ± 0.28 µg m\(^{-3}\) for ammonium (Gao, 2002). However, at Washington Crossing, an inland location in New Jersey, the average concentration of aerosol nitrate in 2004 was 1.2 µg m\(^{-3}\), slightly lower than that for aerosol ammonium (1.5 µg m\(^{-3}\)), and the six-year (2000-2005) average concentrations for aerosol nitrate and
ammonium at this location show the same feature (CASTNET). This feature also exists at other locations in the eastern United States. At Abington, Connecticut, the average aerosol concentrations for the period of 2000-2005 were 0.84 µg m\(^{-3}\) for nitrate and 1.1 µg m\(^{-3}\) for ammonium, and at Blackwater, Maryland for the same period, the average concentrations for aerosol nitrate and ammonium were 1.3 µg m\(^{-3}\) and 1.7 µg m\(^{-3}\), respectively (CASTNET). The higher concentration of aerosol nitrate observed at coastal New Jersey may be attributed to a contribution of sea-salt nitrate in addition to nitrate from non-marine sources. A comparison table of the above studies conducted along the east coast is included in Table 1.

The average value of the pH in all precipitation samples was 4.32, with a range of 3.65 to 5.05, indicating the acidic nature in precipitation at this location. The cause of this acidity is likely anthropogenic emissions from the combustion of fossil fuels which release nitrogen oxides and sulfur dioxide into the atmosphere. These gas pollutants are the primary sources for acid deposition because they are later transformed into nitric and sulfuric acids which increase the acidity of precipitation (Seinfeld and Pandis, 1998). Figure 4 demonstrates a negative correlation between pH and nitrate and ammonium concentrations in precipitation: high nitrate and ammonium concentrations were related to low pH values. Acidic rainfall combined with high inorganic nitrogen concentrations could increase primary productivity when compared to more neutral rain (Paerl, 1985).

3.2. Atmospheric Flux Calculations

Based on the in situ measurements of nitrate and ammonium, the atmospheric flux via wet and dry deposition can be calculated using wet and dry deposition models for the Mullica River-Great Bay Estuary. Wet deposition involves the removal of atmospheric
substances within clouds and below the cloud base mainly by precipitation (Pryor and Barthelmie, 2000). The wet deposition flux ($F_w$) (mg m$^{-2}$ month$^{-1}$) can be calculated by the following equation:

$$F_w = 10 C_r \times P$$  \hspace{1cm} (1)

where $C_r$ is the concentration of nitrate or ammonium in precipitation (mg L$^{-1}$), $P$ is the precipitation rate (cm month$^{-1}$), and 10 is a unit conversion factor. Dry deposition can be defined as the removal of gaseous and particulate species from the atmosphere without precipitation. Gas diffusion, impaction, and gravitational settling play a role in the dry deposition of particles. The particle dry deposition process depends primarily on the particle size. The atmospheric flux via dry deposition ($F_d$) (mg m$^{-2}$ month$^{-1}$) can be calculated by the following equation:

$$F_d = (2.592 \times 10^4) \times C_{air} \times V_d$$  \hspace{1cm} (2)

where $C_{air}$ is the concentration of nitrate or ammonium in the air (mg m$^{-3}$), $V_d$ is the dry deposition velocity (cm s$^{-1}$), and $2.592 \times 10^4$ is a unit conversion factor. The average dry deposition velocities are assumed to be 0.34 cm s$^{-1}$ for aerosol nitrate and 0.19 cm s$^{-1}$ for aerosol ammonium. These values were derived based on in situ measurements of three sets of aerosol particle-size distributions with a cascade impactor sampler at the same location conducted in an earlier study (Gao, 2002); therefore, these $V_d$ values are consistent for the same geographical area, and this could limit uncertainty. On the other hand, due to a number of environmental factors (wind speed and direction, solar radiation, air temperature, relative humidity, etc.), which constantly change from time to time even within the same area, the use of the above $V_d$ values could involve substantial uncertainties. For this reason, we adopted the ±50% uncertainty associated with the
average values assumed by Gao (2002). We acknowledge that higher uncertainty levels with a range of 0.001 – 2 cm s\(^{-1}\) are possible as suggested by other researchers (Slinn and Slinn, 1980; Williams, 1982; Clark and Kremer, 2005). These deposition velocities were previously used within the same study region. There are uncertainties associated with the values of dry deposition velocity and these values can only serve as first approximations.

3.3. Seasonal Patterns of Atmospheric Nitrogen Deposition

Total wet deposition (nitrate + ammonium) appeared to be highest in the spring for the Mullica River-Great Bay Estuary, with the average rate being 1.33 kg-N ha\(^{-2}\) month\(^{-1}\), which accounts for approximately 41% of the total wet deposition (Figure 5a). Total dry deposition appeared to increase from March to May 2004: 0.089 kg-N ha\(^{-2}\) month\(^{-1}\) for March, 0.118 kg-N ha\(^{-2}\) month\(^{-1}\) for April, and 0.177 kg-N ha\(^{-2}\) month\(^{-1}\) for May, approximately a 20-30% increase per month (Figure 5b). However, this study could not determine the seasonal variation in dry deposition at this location due to limited aerosol sampling. The preliminary results suggest that the formation of nitrate and ammonium in the atmosphere could be promoted by increased air temperature and solar radiation intensity. Many studies have found that atmospherically deposited nitrogen varies seasonally, with the highest concentrations and deposition fluxes occurring during the warmer seasons (Russell, et al., 1998; Gao, 2002; Luo et al., 2002; Sheeder et al., 2002; Whitall et al., 2003). These seasonal patterns may be the result of a seasonal variation in the precipitation rates and the emission of nitrogen species into the atmosphere (Gao, 2002; Sheeder et al., 2002). The direction from which an air mass originates can also affect the deposition of nitrogen species. Meteorological parameters during the measurement period of this study indicate that a high atmospheric nitrogen
deposition event is usually associated with the air masses having an inland origin, and vice versa, consistent with many previous observations (Prospero et al., 1996; Whitall et al., 2003; Butler et al., 2005; Clark and Kremer, 2005).

3.4. Annual Atmospheric Nitrogen Deposition

Based on the average monthly deposition rates, the annual wet deposition fluxes for nitrate and ammonium were estimated to be 6.21 kg-N ha\(^{-2}\) year\(^{-1}\) and 3.77 kg-N ha\(^{-2}\) year\(^{-1}\), respectively, for the Mullica River-Great Bay Estuary. The dry deposition flux for this same region was estimated to be 0.219 kg-N ha\(^{-2}\) month\(^{-1}\) for nitrate and 0.169 kg-N ha\(^{-2}\) month\(^{-1}\) for ammonium. However, the dry deposition flux values only reflect the dry deposition of nitrogen for the spring due to the limited aerosol sampling. Assuming that there is no seasonal change for the remainder of the year, the annual dry deposition was roughly estimated to be 0.874 kg-N ha\(^{-2}\) year\(^{-1}\) for nitrate and 0.670 kg-N ha\(^{-2}\) year\(^{-1}\) for ammonium. These estimates may involve certain degrees of uncertainties since the dry deposition was not directly measured for the entire year and it is likely to change with season.

The above results are comparable to other studies (Table 2). At Washington Crossing in Mercer County, New Jersey, annual wet deposition of nitrate and ammonium was estimated to be 4.0 kg-N ha\(^{-2}\) year\(^{-1}\) and 3.23 kg-N ha\(^{-2}\) year\(^{-1}\), respectively, in 2004. Annual dry deposition was estimated to be 0.1 kg N ha\(^{-2}\) year\(^{-1}\) for nitrate and 0.5 kg N ha\(^{-2}\) year\(^{-1}\) for ammonium during the same year (CASTNET/NADP-NTN). In 2005 at Edwin B. Forsythe National Wildlife Refuge located in Atlantic County, New Jersey, annual wet deposition of nitrate and ammonium was estimated to be 9.83 kg N ha\(^{-2}\)
year\(^{-1}\) and 2.22 kg N ha\(^{-2}\) year\(^{-1}\), respectively (NADP/NTN). Annual dry deposition values were not available for this site.

Based on the above calculations, the total annual atmospheric deposition flux for nitrate was then calculated to be 7.08 kg ha\(^{-2}\) year\(^{-1}\) and 4.44 kg ha\(^{-2}\) year\(^{-1}\) for ammonium to the Mullica River-Great Bay Estuary. Nitrate deposition accounts for ~61% of the total inorganic nitrogen deposition to this estuary (Table 3). The surface area of the Mullica River-Great Bay Estuary is 4,160 ha (41.6 km\(^2\)) (Kennish et al., 2004). Consequently, the total atmospheric nitrate and ammonium directly deposited to this estuary is estimated to be 4.79 x 10\(^4\) kg N year\(^{-1}\). An estimate of the total atmospheric nitrate and ammonium deposited to the Mullica River’s watershed is determined to be 1.69 x 10\(^6\) kg N year\(^{-1}\), based on the area of the watershed (147,500 ha) (Zampella et al., 2001).

It is worth noting that the annual deposition estimates of atmospheric nitrate and ammonium from this study represents the atmospheric deposition for a specific year only (March 2004-March 2005). Due to the changes in precipitation rates, air pollution emission rates, etc. from year to year, interannual variability in deposition likely exists in this area. A recent two-year measurement of atmospheric nitrate and ammonium within the same region (Gao, 2002) shows that the annual wet deposition decreased ~2% for nitrate and almost 16% for ammonium from year one to year two. Therefore, it is necessary to establish a long-term record of atmospheric N deposition to a sensitive coastal ecosystem through multi-year atmospheric measurements.

Dissolved organic nitrogen (DON) in precipitation may contribute to the total atmospheric N deposition. Atmospheric DON has recently drawn increasing attention as
a significant additional source of “new” N input to both coastal and oceanic regions (Cornell et al., 1995; Seitzinger and Sanders, 1999). Measurements from coastal North Carolina indicate that 30% of rainwater N concentrations and deposition occurred in organic form, and ~20-30% of atmospheric organic N was available for the uptake by primary producers on short time scales (Peierls and Paerl, 1997). Studies conducted in Narragansett Bay, Rhode Island, show that ~19% N in precipitation is organic N (Nixon et al., 1995). At Lewes, Delaware, organic N in precipitation accounts for ~23% of the total N (Scudlark et al., 1998). Preliminary results obtained from the analysis of limited precipitation samples collected at Barnegat Bay show that DON accounts for ~20% of the total dissolved N in precipitation in this area (Gao, unpublished data). Earlier studies conducted in the same region show that DON accounts for an important portion of the total atmospheric N deposition, ~20% at New Brunswick and 7-12% at Barnegat Bay in New Jersey (Seitzinger and Sanders, 1999). Clearly, DON in precipitation is an important component of the total atmospheric N over the coastal ocean. Due to the limited scope of this study, DON was not measured, and therefore the current estimate of total atmospheric wet deposition in this region, in particular bioavailable N, may be undervalued. Assuming that the portion of DON in wet deposition is the same as those mentioned above, the total atmospheric N fluxes by wet deposition from this study could be underestimated by ~10-20%.

3.5. Contribution of Atmospheric Deposition to the Annual Nitrogen Input to the Mullica River-Great Bay Estuary

All atmospheric nitrogen deposited directly to the Mullica River-Great Bay Estuary is available for use by primary producers. However, only a fraction of the
Nitrogen deposited on the watershed will actually reach the estuary. Most of the nitrogen will be retained in the watershed and/or utilized and denitrified during transport through the watershed. After utilizing a simple retention model outlined in Whitall et al. (2003) based on the land cover at the site, the amount of N actually reaching the Mullica River-Great Bay Estuary indirectly is estimated to be $5.07 \times 10^4$ kg N year$^{-1}$, approximately 97% is retained within the watershed. This value is considered a rough estimate because an average retention value for generalized land use types was applied to the entire watershed. Parameters, such as soil N content, soil type, land slope, elevation and vegetative type, which are land parcel-specific, determine true nutrient detention values (Valigura et al, 1996, Whitall et al., 2003). At the Neuse River Estuary in North Carolina, approximately 94% of atmospheric N was retained in the watershed. The land cover that dominates in the watershed is forest, similar to the Mullica River-Great Bay Estuary (Whitall et al., 2003). In Waquoit Bay, Massachusetts, 89% of atmospheric N is lost within the watershed; approximately 10% reaches the estuary. In this area, urban land such as residential areas cover approximately 39% of the land, with natural vegetation only covering 21% (Valiela, et al., 1997).

The total amount of atmospheric inorganic nitrogen entering the Mullica River-Great Bay Estuary is $9.86 \times 10^4$ kg N year$^{-1}$, approximately 49% is the result from direct deposition and 51% from indirect deposition. Considering the limited surface area of this estuary compared with that of the watershed (a ratio of 1:35), the direct deposition of atmospheric nitrogen certainly accounts for a large portion of the total input of this nutrient to the estuary. This atmospheric nitrogen deposition data will be extremely valuable in the development of an annual nitrogen budget for the estuary.
4. Conclusions

Nitrogen is a major nutrient that controls primary productivity in many coastal waters, and atmospheric deposition is an important non-point source of both organic and inorganic nitrogen. This project was the first to quantify the atmospheric inorganic nitrogen (nitrate and ammonium) input to the Mullica River-Great Bay Estuary. The average concentrations of nitrate and ammonium in the precipitation samples were 2.3 mg L\(^{-1}\) and 0.42 mg L\(^{-1}\), respectively. The average aerosol concentrations were 3.7 µg m\(^{-3}\) for nitrate and 1.6 µg m\(^{-3}\) for ammonium in the spring. Atmospheric wet deposition of nitrogen appeared to vary with season; the highest flux occurred during the spring, with an average value of 1.33 kg-N ha\(^{-2}\) month\(^{-1}\) accounting for approximately 41% of the total annual wet deposition. This seasonal deposition could be influenced by the variation in emission source strength, precipitation rate, and the origin of the air masses.

The total (wet + dry) annual atmospheric deposition fluxes were 7.08 kg N ha\(^{-2}\) year\(^{-1}\) for nitrate and 4.44 kg N ha\(^{-2}\) year\(^{-1}\) for ammonium. The total atmospheric inorganic nitrogen directly deposited to this estuary was estimated to be 4.79 x 10\(^4\) kg N year\(^{-1}\). The estimated deposition of N to the Mullica River watershed was 1.69 x 10\(^6\) kg N year\(^{-1}\). Only ~3% of the inorganic N deposited to the watershed ultimately reaches the estuary. The total amount of atmospheric inorganic nitrogen entering the Mullica River-Great Bay Estuary is 9.86 x 10\(^4\) kg N year\(^{-1}\); approximately 49% is the result from direct deposition and 51% from indirect deposition. High atmospheric nitrogen deposition may stimulate phytoplankton productivity in this coastal ecosystem. It is worth noting that these percentages are based on the calculations with nitrate and ammonium only. If gaseous N species and organic N were included, the values would likely change to some
extent. Therefore, future fieldwork should include simultaneous measurements of gas-phase N and organic N in addition to N in aerosol and precipitation phases, to improve the atmospheric N flux estimates.

**ACKNOWLEDGEMENTS:**

Special thanks to the staff at Rutgers University Marine Field Station for help with this research, especially Gregg Sakowicz for his help with precipitation sample collection and Roger Holden for equipment installation. Thanks to Michael Kennish for valuable comments and Dennis Gray for assistance with cation analysis. This research was supported by a graduate research fellowship from the Estuarine Reserves Division of National Oceanic and Atmospheric Administration Grant number NA04NOS4200135.
