The use of statistical complexity metrics has yielded a number of successful methodologies to differentiate and identify signals from complex systems where the underlying dynamics cannot be calculated. The Mori-Zwanzig framework from statistical mechanics forms the basis for the generalized non-Markov parameter (NMP). The NMP has been used to successfully analyze signals in a diverse set of complex systems. In this paper we show that the Mori-Zwanzig framework masks an essentially simple closed form of the first NMP, which, for $C^1$ smooth autocorrelation functions, is solely a function of the second moment (spread) and amplitude envelope of the measured power spectrum. We then show that the higher-order NMPs can be constructed in closed form in a modular fashion from the lower-order NMPs. These results provide an alternative, signal processing-based perspective to analyze the NMP, which does not require an understanding of the Mori-Zwanzig generating equations. We analyze the parametric sensitivity of the zero-frequency value of the first NMP, which has been used as a metric to discriminate between states in complex systems. Specifically, we develop closed-form expressions for three instructive systems: band-limited white noise, the output of white noise input to an idealized all-pole filter, $f$, and a simple harmonic oscillator driven by white noise. Analysis of these systems shows a primary sensitivity to the decay rate of the tail of the power spectrum.

I. INTRODUCTION

Time series analysis is often employed to characterize systems where the generating physics is either too complex or involves too many degrees of freedom to be predicted. These systems frequently arise in financial [1,2] and biological [3–6] systems. One of the earliest metrics used to characterize a system is the Shannon information entropy, which ascribes a numerical score to the system based on the randomness of the underlying statistics driving the process [7]. This methodology, originally used in communications theory, was adapted to nonlinear deterministic dynamical systems with the use of Kolmogorov-Sinai entropy [8]. While successful for the analysis of chaotic systems this approach can fail to detect the statistical simplicity of random behavior [9]. This has motivated the development of “statistical complexity metrics,” which measure the correlation structure of an interacting system and its subsets [10], allowing for the analysis of multi degree of freedom probabilistic systems.

This methodology has generated a plethora of statistical complexity metrics, often with ambiguous relationships to each other, which often do not provide a clear interpretation of what the metric is actually measuring [10]. The application of these complexity metrics to time series analysis has thus seen the emergence of an interesting phenomenon where signals from complex systems can be successfully differentiated, but there is little insight into the nature of these differences.

An excellent example of this problem has been the application of the generalized non-Markov parameter (NMP), which is effectively a complexity metric developed from the Mori-Zwanzig theory of nonequilibrium statistical physics [11]. The NMP has been used in a diverse range of fields such as geology [12], astrophysics [13], cardiology [5], and neurophysiology [6]. In these complex systems the NMP

*john.varghese@uqconnect.edu.au
We then suggest, but do not prove, that these operations remove correlation structure from the spectrum and thus there is limited information about the system in the higher-order NMP. This analysis is consistent with Ref. [17], which argues the memory kernels can “veil” the properties of the physical system. The ZF-NMP\(_1\) is then analytically calculated for three instructive systems: simple harmonic oscillator (SHO) driven by white noise, band-limited white noise, and white noise passed through an ideal all pole filter. We show that the dominant feature of ZF-NMP\(_1\) is the slope of the tail of the measured power spectrum. We lastly show with numerical simulation that these expressions are also valid for noisy sampled systems where the power spectrum is not known a priori.

The work performed in this paper may be considered an extension to that in Ref. [18]. The work in Ref. [18] is concerned with developing the zero-frequency NMP for dynamical systems defined from time propagation operators with causal correlation functions. This greatly simplifies the spectral analysis (principally because the Fourier transforms with causal correlation functions. This greatly simplifies the dynamical systems defined from time propagation operators is concerned with developing the zero-frequency NMP for arbitrarily high number but for simplification we will consider evolution of a subset of all the objects in the system. For system of interest. Often we are only concerned with the measured power spectrum. We lastly show with numerical simulation that these expressions are also valid for noisy sampled systems where the power spectrum is not known a priori.

The contribution of the neglected variables is accounted for in the memory (convolution) function and stochastic forcing terms. The convolution term is a consequence of the state vector, which describes the observables of interest. This resides in a subspace of the Hilbert space of the full dynamic system at time zero, rotating as time increases outside of this subspace into the full Hilbert space. The evolution of this state vector outside this subspace is modeled as stochastic forces randomly rotating the state vector [20].

The difficulty with the GLE Eq. (1) is that the presence of the noise term makes the system a stochastic integrodifferential equation, which is mathematically difficult to analyze. The equation can be reduced to a standard integrodifferential by projecting the observable at time zero \( \hat{G}(0) \) onto the evolution equation and performing an ensemble average \( \langle \cdots \rangle \). The noise terms are constructed such that for all time they stay orthogonal to the observable at time zero [21], and thus the noise term is removed. Thus,

\[
\langle S(t) \hat{G}(0) \rangle = 0 \tag{2}
\]

\[
\langle \hat{G}(t) \hat{G}(0) \rangle = m_0(t), \tag{3}
\]

where \( m_0(t) \) is the autocorrelation function of the observable \( \hat{G}(t) \). Applying these operations to Eq. (1) yields an integrodifferential equation for the evolution of the autocorrelation function, \( m_0(t) \), of our single observable of interest [20]:

\[
\frac{dm_0(t)}{dt} = \lambda_0 m_0(t) - \Lambda_0 \int_0^t m_1(t - t')m_0(t')dt' \quad t \geq 0. \tag{4}
\]

There is a subtlety regarding the evolution of the autocorrelation function that must be highlighted. The autocorrelation function by definition is a symmetric function defined for both negative and positive time; however, the GLE Eq. (1) is only defined for positive time and thus the evolution of the autocorrelation function in Eq. (4) is only defined for positive time. This point will be important when considering the FT of the memory kernel in this section.

The first memory kernel can be shown by the second fluctuation dissipation theorem to be the autocorrelation (and thus symmetric) function of the stochastic forcing function.
 Arbitrarily higher-order equations can be constructed by interchanging the positions of the autocorrelation function \( m_{n-1}(t) \) with the memory kernel \( m_n(t) \) and introducing a new memory kernel \( m_{n+1}(t) \) to replace \( m_n(t) \) into the convolution term. This is known as the Mori-Zwanzig chain, with the memory kernel autocorrelation functions acting as the links of the chain:

\[
\frac{dm_{n}(t)}{dt} = \lambda_n m_n(t) - \Lambda_n \int_0^t m_{n+1}(t-t')m_n(t')dt' \quad t \geq 0.
\]

By convention, all of the considered autocorrelation functions are normalized such that \( m_n(0) = 1 \). For the first autocorrelation function [\( m_0(t) \)] this can be achieved by dividing every term in Eq. (4) by an appropriate normalizing factor. For the remaining memory autocorrelation functions the normalization is ensured by the form of the \( \Lambda_n \) relaxation factors.

In this paper we use the following FT convention:

\[
F(\omega) = \mathcal{F}[f(t)](\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt \quad (7)
\]

\[
f(t) = \mathcal{F^{-1}}[F(\omega)](t) = \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\infty} F(\omega)e^{i\omega t} d\omega. \quad (8)
\]

Notice that an equivalent normalization of unity requirement on the FT of the \( n \)th memory autocorrelation function, which we refer to as the \( n \)th order memory power spectrum, \( M_n(\omega) \), can be constructed using the Wiener-Khinchin theorem [22]:

\[
\int_{-\infty}^{\infty} M_n(\omega)d\omega = 2\pi. \quad (9)
\]

The form of the \( \lambda_n \) relaxation parameters can be determined from manipulation of Eq. (4) as

\[
\lambda_n = \lim_{t \to 0^+} \frac{dm_n(t)}{dt} = 0 \quad \forall \ m_n(t) \in C^1. \quad (10)
\]

Notice that because the time correlation function in Eq. (4) is only defined for positive time, the limit is taken from above. Due to the symmetry of autocorrelation functions, and as long as there is no breakdown in smoothness of the derivative (that is it belongs to the \( C^1 \) or higher set of functions) at the origin, this parameter must be zero in continuous time. An equivalent requirement can be constructed in the frequency domain:

\[
\lambda_n = \lim_{h \to 0^+} \frac{1}{2\pi} \int_{-\infty}^{\infty} M_n(\omega)(e^{i\omega h} - 1)d\omega. \quad (11)
\]

By the dominated convergence theorem, if \( P(\omega) \) decays \( O(\omega^{-2}) \) or faster, the limit can be brought inside the integral and the integrand evaluated to yield the indeterminate function \( 0/0 \). Applying L'Hôpital's rule, if \( P(\omega) \) decays \( O(\omega^{-3}) \) or faster, then the limit can again be brought inside the integral and shown to be zero. Since the power spectrum must be symmetric, this \( O(\omega^{-3}) \) decay is not possible. Thus, if \( P(\omega) \) decays \( O(\omega^{-4}) \) or faster, \( \lambda \) is zero. As a counter example, an autocorrelation function with a \( c(t) = e^{-\omega |t|} \) and \( P(\omega) \equiv O(\omega^{-2}) \) structure, which has a nonzero \( \lambda \) value, was considered in Ref. [16].

The \( \Lambda_n \) relaxation parameter cannot be defined from Eq. (4) without the previously stated constraint that \( M_{n+1}(0) = 1 \). Taking the derivative of Eq. (4), applying the Leibniz rule for differentiating the convolution term, and taking the limit as time goes to zero yields

\[
\Lambda_n M_{n+1}(0) = \lambda_n \lim_{t \to 0^+} \frac{m_n(t)}{dt} - \lim_{t \to 0^+} \frac{d^2 m_n(t)}{dt^2}. \quad (12)
\]

As discussed previously, if \( M_n(\omega) \) decays \( O(\omega^{-4}) \) or faster, \( \lambda_n \) will be zero. Enforcing the condition that the memory kernel \( M_{n+1}(t) \) must be unity at time zero gives the following expression:

\[
\Lambda_n = -\lim_{t \to 0^+} \frac{d^2 m_n(t)}{dt^2}, \quad \forall \ m_n(t) \in C^1
\]

\[
= \frac{1}{2\pi} \int_{-\infty}^{\infty} \omega^2 M_n(\omega)d\omega. \quad (13)
\]

The second expression has been generated by application of the Weiner-Khinchin theorem and is in agreement with that obtained in Refs. [23] (which considered a similar Mori-Zwanzig kinetic equation with \( \lambda \) set to zero) and [18]. Notice that this expression shows that \( \Lambda_n \) is a measure of the spread (second central moment) of the \( M_n(\omega) \) power memory spectrum.

### III. NON-MARKOV PARAMETERS

The non-Markov parameters \( \epsilon_n(\omega) \) are defined as the square root of the ratio of FT of the preceding memory kernel \( [M_{n-1}(\omega)] \) and the memory kernel \( M_n(\omega) \) \([5,11,13]\):

\[
\epsilon_n(\omega) = \sqrt{\frac{M_{n-1}(\omega)}{M_n(\omega)}} \quad n \geq 1. \quad (14)
\]

By the Wiener-Khinchin theorem, the \( M_0(\omega) \) term in the first NMP is immediately recognized as the measured power spectrum of the signal. The higher-order memory power spectrum can be evaluated by taking the FT of both sides of Eq. (4), with a Heaviside distribution included in the Fourier kernel. The resultant equation in Fourier space can be algebraically rearranged to yield an expression for the FT of the memory kernel. The inclusion of the Heaviside distribution is necessary as the evolution of the autocorrelation function in Eq. (4) is only valid for positive time, whereas the FT is defined for all positive and negative time. This function was evaluated previously in Ref. [16]:

\[
M_n(\omega) = \frac{\lambda_{n-1}}{2\Lambda_{n-1}} + \frac{4}{\Lambda_{n-1}} \left( \frac{M_{n-1}(\omega)}{M_{n-1}(\omega)^2 + \mathcal{H}(M(\omega)_{n-1}(\omega))^2} \right). \quad (15)
\]

Where \( \mathcal{H}[\cdots] = \) is the Hilbert transform integral, which is defined in terms of the Cauchy principal value (p.v.):

\[
\mathcal{H}[F(\omega)](\omega) = \frac{1}{\pi} \text{p.v.} \int_{-\infty}^{0} \frac{F(\omega')}{\omega - \omega'} d\omega'. \quad (16)
\]
Note that care must be taken with sampling continuous time systems in order for the discrete time form of the memory kernel to be equivalent to Eq. (15) [17].

The *n*th memory power spectrum \( M_n(\omega) \) can be determined from the previous memory power spectrum. The *n*th memory power spectrum can then be constructed in a modular fashion from the measured power spectrum \( M_0(\omega) \) using Eqs. (10), (13), and (15). For signals with memory kernel spectra with decay rates \( O(\omega^{-4}) \) or greater, or equivalently with memory autocorrelation functions belonging to the \( C^1 \) or greater set this has a particularly simple form:

\[
M_n(\omega) = \frac{4^n M_0(\omega)}{\prod_{k=0}^{n-1} \Lambda_k (M_k(\omega)^2 + \mathcal{H}[M_k(\omega)]^2)^2}. \tag{17}
\]

Thus, the FT of the memory kernels are defined in terms of a product series of nonlinear integral transforms of the measured power spectrum. The generalized NMP is given in closed form using Eqs. (14) and (15):

\[
\epsilon_n(\omega) = \sqrt{\frac{\Lambda_{n-1}}{2}} |V_{n-1}(\omega)|^2 + \mathcal{H}[M_{n-1}(\omega)]^2
\]

\[
= \sqrt{\frac{\Lambda_{n-1}}{2}} |V_{n-1}(\omega)|^2, \tag{18}
\]

where \( |V_n(\omega)| \) is the amplitude envelope [7] of the memory kernel spectrum. Thus, when the conditions of Eq. (10) are satisfied, the first NMP is solely a function of the spread and amplitude envelope of the power spectrum. The description of the memory power spectrum in Eq. (15) as a ratio of the previous memory power spectrum and its amplitude envelope suggests two interesting properties of these parameters. First, the successive memory power spectra will decay at slower rates than the previous memory power spectra. Second, since the action of the amplitude envelope is to smooth out the underlying function, the higher memory power spectra will become flatter and flatter over the support of the original power spectrum. We will show this behavior of the higher-order memory power spectra in the systems we analyze in Secs. IV and V.

This raises questions about the validity of using the higher-order NMP to analyze a measured system. First, in the noise-free case the successive amplitude envelopes will “smear” out the measured spectrum, thereby losing the correlation structure. Thus, the higher-order NMP may not be measuring anything “interesting” about the system. This interpretation may explain why two of the physical systems considered in Ref. [18] (ideal gas and an ideal gas with linear interaction perturbations) had distinct ZF-NMP1 but identical higher-order zero-frequency NMP values. Second, in any signal acquisition process, noise will certainly be present. It can be seen from Eq. (4), with \( \lambda = 0 \), that extracting the memory kernel is a deconvolution of a Volterra integral equation of the first kind. These convolution equations are often ill posed [24]. Thus, it is possible that in any measured system, interesting structure seen in the higher-order NMP are actually the manifestation of numerical errors and or noise.

Notice that by the symmetry property of the power spectrum \( M_n(\omega') = M_n(-\omega') \) the Hilbert transform of the power spectrum is zero at zero frequency:

\[
\mathcal{H}[M_n(\omega)](0) = \frac{-1}{\pi} \text{p.v.} \int_{-\infty}^{+\infty} \frac{M_n(\omega')}{\omega'} \, d\omega' = 0. \tag{19}
\]

Using Eqs. (14), (17), and (19), closed form expressions for the zero-frequency values of the generalized NMP that solely depend on the spread and the DC offset of the *n*th memory power spectrum can be obtained. These expressions are in agreement with the calculations in Ref. [18]:

\[
\epsilon_n(0) = \frac{\sqrt{\Lambda_n}}{2} M_n(0). \tag{20}
\]

We pay particular attention to the zero-frequency values of the first NMP (ZF-NMP1):

\[
\epsilon_1 = \frac{M_0(0)}{2\sqrt{2\pi}} \int_{-\infty}^{+\infty} \omega^2 M_0(\omega) d\omega. \tag{21}
\]

The complicated structure of the Mori-Zwanzig chain Eq. (4) obfuscates the fact that the ZF-NMP1 (and indeed the generalized NMP) is solely a function of the measured power spectrum. Indeed the Mori-Zwanzig equations and associated memory kernels do not even need to explicitly be considered. These results suggest that signal metrics to differentiate complex systems can be developed by analyzing different properties of the measured power spectrum. The previous success of the NMP [5,6,12,13,16] helps elucidate specifically what properties (spectral spread and DC offset) should be explored, but does not necessarily require Mori-Zwanzig theory to interpret the results.

The dependence of the ZF-NMP1 on the DC offset value of the spectrum raises an important digital signal processing issue regarding the use of this parameter for “real-world” measured systems. Spectrum values determined from nonparametric estimation methods (e.g., Welch’s method) will be random variables (typically Chi-squared distributed [25]). Thus, if the ZF-NMP1 is to be used as a signal metric, it would be advisable to use a large number of signal samples and appropriate statistical tests or parametric spectrum estimation techniques (e.g., Burg’s method) to reduce the variance associated with this metric [25].

It is interesting to note that the rich class of behavior generated by Markovian dynamics will all have a common ZF-NMP1 value of infinity [11]. Thus, in this framework different purely Markov systems cannot be differentiated, representing a degeneracy. Methodologies have been developed to explore and analyze the behavior of these Markov processes given only measurements of the system. An example of this is modeling the unknown Markov system as a set of coupled, Langevin equations (representing the restricted case of Eq. (1) with the memory kernel term set to zero) and performing an Eigenanalysis on the diffusion matrix of the corresponding Fokker-Planck equation [26]. This approach was used to successfully model the power response curves of wind farm turbines [27].
IV. EXPLICIT CALCULATION OF ZF-NMP$_1$ FOR PHYSICAL SYSTEMS

In this section we derive the ZF-NMP$_1$ for three instructive stochastic processes: simple harmonic oscillation driven by white noise, band-limited white noise, and the output of white noise passed through an idealized all-pole filter. We perform this analysis to understand how sensitive this parameter is to specific variation in the measured power spectra. This provides insight into what changes, in terms of spectral properties, the ZF-NMP$_1$ was detecting in the measured complex systems analyzed in [5,12,14,15].

A. Simple harmonic oscillation driven by white noise

The SHO driven by white noise provides an excellent bridge between understanding the (ZF-NMP$_1$) in the original framework of the Markovity of the system and the signal processing framework of the structure of the spectrum. This system also provides one of the few systems where the higher-order memory power spectra can be analytically calculated. The difficulty in the general case is due to the evaluation of the Hilbert transforms. The dynamics of the SHO driven by white noise are given by

$$\frac{d^2x(t)}{dt^2} + 2\zeta \omega_0 \frac{dx(t)}{dt} + \omega_0^2 x(t) = W(t),$$

where $\omega_0$ is the angular natural frequency, $\zeta$ is the damping ratio, and $W(t)$ is the white noise stochastic process with constant amplitude power spectrum.

The normalized power spectrum of this process is given by

$$M_0(\omega) = \frac{4\zeta \omega_0^3}{(\omega_0^2 - \omega^2)^2 + 4\zeta^2 \omega_0^4 \omega^2},$$

Notice that $M_0(\omega)$ decays $O(\omega^{-4})$ and thus $\lambda_0 = 0$. The contour integrals required to determine the $\Lambda_0$ from the spectral form of Eq. (13) are relatively difficult for arbitrary $\zeta$, $\omega_0$ parameters. Instead, the $\Lambda_0$ relaxation parameter will be determined from the autocorrelation function form for the different damping regimes: over, under, and critically damped.

The normalized autocorrelation structure of the underdamped (UD) SHO is given by

$$m_0(t)_{UD} = e^{-\zeta \omega_0 |t|} \left[ \cos(\omega_0 t) + \frac{\zeta}{\sqrt{1 - \zeta^2}} \sin(\omega_0 |t|) \right],$$

where $\omega^2 = \omega_0^2(1 - \zeta^2)$ is the damped natural frequency. The critically damped case is determined in the limit of $\omega_1 \rightarrow 0$. The overdamped case is determined by setting $\omega_1 \rightarrow i\omega_1$, which transforms the trigonometric functions in Eq. (24) to hyperbolic trigonometric functions.

The $\Lambda_0$ relaxation parameter is given for all three damping regimes by

$$\Lambda_0 = \omega_0^2,$$

The ZF-NMP$_1$ of the SHO driven by white noise can now be written using Eqs. (20), (23), and (25) as

$$\epsilon_1(0) = 2\zeta.$$
difficult for arbitrary damping ratios) can be analytically calculated:

\[ |V_0(\omega)|^2 = \frac{4(\omega^2 + 4\omega_0^2)}{(\omega^2 + \omega_0^2)^2} \]

\[ M_1(\omega) = \frac{4\omega_0}{\omega_0^2 + 4\omega_0^2} \]  

\[ m_1(t) = e^{-2\omega_0 t}. \]  (29)

Notice that \( M_1(\omega) \) decays \( O(\omega^{-2}) \) and thus \( \lambda \) will be nonzero. Using Eqs. (10), (12), and (29),

\[ |V_1(\omega)|^2 = \frac{4}{\omega_0^2 + 4\omega_0^2} \]

\[ \frac{M_1(\omega)}{|V_1(\omega)|^2} = \omega_0 \]  (30)

\[ \lambda_1 = -2\omega_0 \]  (31)

\[ \Lambda_1 = 0. \]  (32)

Thus, the \( M_2(\omega) \) memory power spectrum will be infinite due to the scaling by the inverse of \( \Lambda_1 \). This shows that the second-order zero frequency NMP will be zero. Analysis of Eq. (15) shows the higher-order memory kernels and generalized NMP will give pathological divide by zero solutions. This result can be explained as follows: The exponential first-order memory function satisfies the differential equation:

\[ \frac{dm_1(t)}{dt} = \lambda_1 m_1(t). \]  (33)

This is exactly the Zwanzig-Mori Eq. (6) for the first memory kernel \( m_1(t) \) with the convolution term (and thus \( \Lambda_1 \)) equal to zero. It is interesting to identify the unscaled second memory power spectrum \( M_2(\omega) \) given by Eqs. (30) and (31) [that is not obeying the constraint in Eq. (9)] is white noise. This indicates the second-order memory kernel \( m_2(t) \) will be a Dirac \( \delta \) distribution centered at time zero. This distribution cannot be scaled such that it satisfies the requirements of Eq. (9), which also helps explain why \( \Lambda_1 \) is zero.

Figure 2 shows the first three numerically determined memory kernels for the underdamped harmonic oscillator (\( \zeta = 0.25, \omega_0 = 200 \)) using Eqs. (13) and (15) and assuming Eq. (10) is satisfied. Notice that the \( M_2(\omega) \) term is constructed assuming \( \lambda_2 = 0 \) [thus, \( \Lambda_2 \) is defined from Eq. (13) rather than Eq. (12)], so that the flat white noise structure can be identified. Notice that this flattening of the higher-memory kernels is exactly as was postulated in Sec. II.

**B. Band-limited white noise**

The normalized power spectrum for the white noise process banded between \((-\omega_0, +\omega_0)\) is given by

\[ M_0(\omega) = \frac{\pi}{\omega_0^2} \theta(\omega + \omega_0) - \theta(\omega - \omega_0), \]  (34)

where \( \theta(\cdots) \) is the Heaviside distribution. The \( \Lambda_0 \) relaxation parameter is given by the spectral form of Eqs. (13) and (34):

\[ \Lambda_0 = \frac{1}{2\omega_0} \int_{-\omega_0}^{+\omega_0} \omega^2 d\omega = \frac{\omega_0^2}{3}. \]  (35)

The first memory power spectrum is given by

\[ M_1(\omega) = \frac{12\pi}{\omega_0} \theta(\omega + \omega_0) - \theta(\omega - \omega_0) \left\{ \frac{\pi^2}{\omega_0^2} + \ln \left( \frac{\omega_0^2 + \omega^2}{\omega_0^2 - \omega^2} \right) \right\}. \]  (36)

The ZF-NMP is given by Eqs. (20), (34), and (35):

\[ \epsilon_1(0) = \frac{\pi}{2\sqrt{3}}. \]  (37)

This is interesting because it shows that the ZF-NMP is independent of the bandwidth of the band-limited white noise. Mathematically this can be understood to be due to the normalization requirement, as the noise process occupies more bandwidth and the spread increases, the amplitude of this noise decreases and so does the DC offset. These two parameters must change such that the ZF-NMP remains constant. We cannot extend our analysis to the infinite bandwidth white noise process because the correlation structure is a Dirac \( \delta \) distribution for which it is not possible to normalize to unity, nor define its derivatives in the limit of zero time as is required for the relaxation parameters.

Figure 3 plots the first five numerically determined memory power spectra of the band-limited white noise (\( \omega_0 = 50 \)) system using Eqs. (13), (17), and (34). Notice that all the memory power spectra [except for the measured power spectrum \( M_0(\omega) \)] converge to a common spectral structure, indicating limited utility of the higher-order NMP. The higher-order \( \Lambda_n \) relaxation parameters will not equal zero because the compact support of the band-limited white noise prevents the memory power spectra from becoming white noise.
solutions, or equivalently the autocorrelation function from ever becoming a Dirac δ distribution.

C. Ideal all-pole filter

The ideal all-pole filter refers to a piecewise continuous spectrum that consists in log-log (base e) space of a straight line of height $h$, which goes from 0 to the corner frequency $\omega_c$, and then another straight line that has a negative slope proportional to the order of $m$, which goes from the corner frequency $\omega_i$ to infinity. The Bode plot of this spectrum is shown in Fig. 4. The actual value of the height $h$ is determined by the normalization requirement of Eq. (9). This is an idealized filter because the cusp (breakdown of the first derivative) at the corner frequency creates an unphysical “infinite-power” requirement on the filter [7]. Intuitively we expect the NMP to depend on both the order and corner frequency of the filter, but we show that it depends solely on the slope of the tail (i.e., $m$) of the power spectrum.

We can mathematically represent the power spectrum of our idealized all-pole filter in log-log (base e) frequency space as

$$\ln[M_0(\omega)] = \begin{cases} 
  h & 0 \geq |\omega| \geq |\omega_c| \\
  -2m(\ln[|\omega_0|] + h) & |\omega_c| \geq |\omega| \geq \infty.
\end{cases}$$

(38)

We can map this to frequency space by taking the antilog (in base e) of both sides of Eq. (38). There are two things to notice: First, the power spectrum is symmetric about the origin, whereas the log-log (in base e) power spectrum is one sided. Thus, we make the solution obtained in frequency space symmetric about the zero-frequency origin. The log-log (in base e) power spectrum when mapped to the power spectrum will start at $\omega = 1$ (because $e^0 = 1$ in the bounds for the constant straight line). We simply extend the bounds of the power spectrum to $\omega = 0$ in frequency space.

The constant $\alpha = e^h$ will be determined such that the power spectrum has the appropriate normalization required by Eq. (9):

$$\alpha = \frac{\pi (2m - 1)}{2m\omega_c}. \quad (39)$$

The power spectrum is given by

$$M_0(\omega) = \begin{cases} 
  \frac{\pi(2m-1)}{2m\omega_c} & 0 \geq |\omega| \geq |\omega_c| \\
  \frac{\pi(2m-1)}{2m\omega_c} \left(\frac{\omega}{\omega_c}\right)^{-2m} & |\omega_c| \geq |\omega| \geq \infty.
\end{cases}$$

(40)

In order to simplify analysis, we will only consider ideal all-pole filters of order $m$ of 2 or higher.

The $A_0$ relaxation parameter can be determined from the spectral form of Eqs. (13) and (40):

$$A_0 = \frac{(2m - 1)\omega_c^2}{3(2m - 3)}. \quad (41)$$

Using Eqs. (20), (40), and (41), the ZF-NMP$_1$ is given by

$$\epsilon_1(0) = \frac{\pi}{m} \sqrt{\frac{(2m - 1)^3}{48(2m - 3)}}. \quad (42)$$

The most interesting result from Eq. (42) is that, similar to the band-limited white noise case, the ZF-NMP$_1$ for the ideal all-pass filter is independent of the corner frequency. The ZF-NMP$_1$ is sensitive to the order of the filter. Figure 5 shows an inverse relationship between the decay rate of the tail of the power spectrum and the ZF-NMP$_1$ value. Similar to the SHO, the more spread out the power spectrum, the larger the ZF-NMP$_1$. An obvious difference between these two systems is that the ZF-NMP$_1$ for the SHO is unbounded, whereas (at least for $m \geq 2$) the ZF-NMP$_1$ of the ideal all-pole filter is approximately bounded between 1.17 ($m = 2$) and 0.9 ($m \rightarrow \infty$). Notice that while the ZF-NMP$_1$ does depend on the tail of this spectrum, it is not particularly sensitive to it.

It can be seen that the ZF-NMP$_1$ value for the ideal all-pole filter converges to the band-limited white noise case for sufficiently large slope order ($m \approx 10$ or higher). This result is to be expected, because as the slope of the ideal all-pole filter

Ideal All Pole Filter of Order m vs. ZF−NMP1

FIG. 5. (Color online) Plot of ZF-NMP1 of the output of white noise fed into the ideal all pole filter vs. slope order (m). Notice that for sufficiently large slope order the NMP converges to the band-limited white noise solution.

increases, the spectrum will converge to the band-limited white noise spectrum. It is trivial to formally show that the NMP of this idealized all-pole filter converges to the band-limited white noise process in the limit of infinite filter order:

$$\lim_{m \to \infty} \epsilon_1(0) = \lim_{m \to \infty} \frac{\pi}{2\sqrt{3}} \sqrt{\frac{(2m)^3}{48m^2(2m)}} = \frac{\pi}{2\sqrt{3}}. \quad (43)$$

Figure 6 plots the first five numerically determined memory power spectra of the ideal all-pole filter (m = 4,ω0 = 50) using Eqs. (13), (17), and (40). Notice that (similar to the critically damped simple harmonic oscillator shown in Fig. 2) the higher-order memory power spectra are flatter and lose the correlation structure present in the measured M0(ω) spectrum. This further validates the flattening of the higher memory kernels as postulated previously in Sec. II. Again, this raises questions about the utility of the higher-order NMP as system metrics.

V. NUMERICAL DETERMINATION OF NMP FROM SAMPLED TIME SERIES

We finish by determining the memory power spectra and ZF-NMP1, using the closed form Eqs. (17)–(20), from what can be considered as a model of the sampled time series of the displacement of the SHO driven by white noise. We model the system as a second-order auto regressive [AR(2)] process:

$$x[n] = \phi_1 x[n-1] + \phi_2 x[n-2] + \epsilon_n, \quad (44)$$

where \((\phi_1 = 0.9, \phi_2 = -0.8, \epsilon_n \sim \mathcal{N}(0,1))\). The choice of AR coefficients in Eq. (44) can be considered related to the under-damped SHO driven by white noise [31]. We simulate 1000 data points of this process to generate a discrete time series. We determine the memory power spectra and ZF-NMP1 using solely this time series with no a priori information about the AR coefficients or innovations, \(\epsilon_n\), which define the process. A realization of this process (and thus time series to be analyzed) is shown in Fig. 7.

The power spectrum of this process is determined from the time series using the ARMaxel parametric spectrum estimator. The technical details of this estimator are provided in Ref. [32] but as an overview it fits the data to an optimal order (p) auto regressive, order (q) moving average, or order (r, r-1) auto regressive moving average model determined by an information criteria. This criteria effectively provides a balance between rewarding the reduction in residual variance and punishing the increase in model order complexity. The parametric model that gives the smallest estimate of the prediction error is then selected and the estimated power spectrum is calculated using the fast Fourier transform. Once the power spectrum estimate is obtained, the higher-order memory power spectra and generalized NMP can be determined using Eqs. (13), (17),

FIG. 6. (Color online) Numerically determined memory power spectra for the ideal pole filter (m = 4,ω0 = 50). Notice that the higher-order memory power spectra get considerably flatter.

FIG. 7. (Color online) Sample path realization of the AR(2) process \([\phi_1 = 0.9, \phi_2 = -0.8, \epsilon_n \sim \mathcal{N}(0,1)]\) generated from Eq. (44). This discrete time series is used to generate the memory power spectra.
and (18). The estimated memory power spectra are shown in Fig. 8. Notice that similar to systems with a continuous power spectrum analyzed in Sec. IV, the higher-order memory power spectra appear to smear out the correlation structure observable in the power spectrum.

An estimate of the ZF-NMP$_1$ of this AR process can be obtained from the time series by estimating the power spectrum with the ARMAX algorithm and using Eqs. (13) and (20). This estimate (mean ± standard error) is averaged over 20 realizations (each 1000 data points) of the AR process to give

$$\hat{\epsilon}_1(0) = 0.368 \pm 0.0119.$$  \hfill (45)

This solution can be compared to the true ZF-NMP$_1$. The unnormalized power spectrum of this process is given by [33]

$$M_0(\omega) = \frac{\sigma^2}{1 + \phi_1^2 + \phi_2^2 - 2\phi_1(1 - \phi_2)\cos(\omega) - 2\phi_2\cos(2\omega)},$$  \hfill (46)

where $\sigma^2$ is the variance of the innovations. Using Eqs. (13), (20), and (46) the ZF-NMP$_1$ of this process can be calculated by numerical integration to be

$$\epsilon_1(0) = 0.359.$$  \hfill (47)

Therefore, it can be seen that with appropriate statistical averages (which are necessary given finite-time recordings of stochastic processes) the ZF-NMP$_1$ can be accurately estimated from the time series data alone.

This example highlights several key points that are not immediately clear in the analysis of the physically motivated systems considered in Sec. IV. First, this time series could be acquired without any knowledge of the underlying physics driving this system. This would make the Mori-Zwanzig interpretation of the non-Markovity (which requires partitioning the dynamical system into subsets of observables of interest and an interacting environment) extremely difficult to perform. This is in contrast to the signal processing approach introduced in this paper which interprets the non-Markovity spectrum in the concrete terms of operations on the measured power spectra. Second, this example provides a “real world” application of estimating the non-Markovity spectra where the underlying continuous power spectra is unknown and only discrete samples of the measured time series corrupted with noise are available. Problems of this nature are commonplace in signals analysis and thus it is important to identify that the closed form Eqs. (17) and (18) for the memory power spectra and generalized NMP are applicable to this class of problem. We refer the reader to Ref. [17] for a detailed description regarding the issues associated with interpreting the underlying continuous memory kernel from its discrete time estimate.

VI. CONCLUSIONS

The generalized non-Markov parameters have been used to successfully differentiate states (as defined by the degree of chaossity and randomness) of complex interacting systems. In this paper we have shown these parameters can be understood as a set of closed-form expressions that only depend on a nonlinear set of integral transform operations on the measured signal’s power spectrum. We have argued that the operations yielding the higher-order memory power spectra and generalized NMP veil the underlying correlation structure of the measured system in agreement with Ref. [17]. We have supported this argument with numerical simulation of four instructive stochastic processes: a SHO driven by white noise, band-limited white noise, the output of white noise fed into an ideal all pole filter and an AR(2) process with Gaussian innovations. These results suggest a sensitivity of the ZF-NMP$_1$ to the decay rate of the tail of the spectrum.

Last, we have shown that under the appropriate condition of $C^1$ or higher smoothness of the autocorrelation [or equivalently $O(\omega^{-4})$ or faster decay rates of the tail of the spectral function], the closed form expression for the ZF-NMP$_1$ can be reduced to depending solely on the spread and DC offset of the measured power spectrum. These results provide an alternative interpretation of the generalized NMP, which only depends on the measured signal and does not require knowledge of Mori-Zwanzig theory, nor interpretation of a complex relationship between a measured system and its environment. We have shown that these equations for the memory power spectra and generalized NMP can readily be applied to systems where only noisy discrete time samples are available. These simplified expressions of the NMP in light of its previous success in the analysis of complex systems provides insight into what properties of the spectrum could be used in future signal analysis of complex systems.
