10 Knowledge of the rate, distance and direction of dispersal within and among breeding areas is
11 required to understand and predict demographic and genetic connectivity and resulting
12 population and evolutionary dynamics. However dispersal rates, and the full distributions of
13 dispersal distances and directions, are rarely comprehensively estimated across all spatial
14 scales relevant to wild populations. We used resightings of European Shags *Phalacrocorax*
15 *aristotelis* colour-ringed as chicks on the Isle of May (IoM), UK, to quantify rates, distances
16 and directions of dispersal from natal to subsequent breeding sites both within IoM (within-
17 colony dispersal) and across 27 other breeding colonies covering 1045km of coastline
18 (among-colony dispersal). Additionally, we used non-breeding season surveys covering
19 895km of coastline to estimate breeding season detection probability and hence potential bias
20 in estimated dispersal parameters. Within IoM, 99.6% of individuals dispersed between their
21 natal and observed breeding nest site. The distribution of within-colony dispersal distances
22 was right-skewed; mean distance was shorter than expected given random settlement within
23 IoM, yet some individuals dispersed long distances within the colony. The distribution of
24 within-colony dispersal directions was non-uniform, but did not differ from expectation given
25 the spatial arrangement of nest sites. However, 10% of all 460 colour-ringed adults that were
26 located breeding had dispersed to a different colony. The maximum observed dispersal
27 distance (170km) was much smaller than the maximum distance surveyed (690km). The
28 distribution of among-colony dispersal distances was again right-skewed. Among-colony
29 dispersal was directional, and differed from random expectation and from the distribution of
30 within-colony dispersal directions. Non-breeding season surveys suggested that the
31 probability of detecting a colour-ringed adult at its breeding location was high at a north-
32 eastern UK scale (98%). Estimated dispersal rates and distributions were therefore robust to
33 incomplete detection. Overall, these data demonstrate skewed and directionally divergent
34 dispersal distributions across small (within-colony) and large (among-colony) scales, and
35 indicate that dispersal may create genetic connectivity but little among-colony demographic
36 connectivity within the study area.

37 **Key-words:** connectivity, demography, fat-tailed distribution, long-distance dispersal,
38 movement, philopatry

39 Dispersal of individuals within and among natal and subsequent breeding areas can create
40 demographic and genetic connectivity among proximate and distant locations, and
41 consequently influence population structure, dynamics and persistence (Hanski 1999, Clobert
42 *et al.* 2001, Nathan *et al.* 2008, Clobert *et al.* 2009). Accurate estimates of dispersal rates
43 within and among breeding areas, and the overall distributions of dispersal distances and
44 directions, are therefore required to understand observed population ecology and predict
45 future change (Rodenhuse *et al.* 1997, Broquet & Petit 2009, Clobert *et al.* 2009). Such
46 estimates, and understanding of underlying processes, are also required to parameterise
47 theoretical models that examine general ecological and evolutionary consequences of
48 dispersal (Chambers 1995, Kot *et al.* 1996, Chapman *et al.* 2007, Nathan *et al.* 2008,
49 Petrovskii & Morozov 2009). However, it is extremely challenging to accurately estimate
50 overall dispersal rates, distances and directions in wild populations, particularly for species
51 that can potentially disperse substantial distances (Koenig *et al.* 1996). The number of
52 systems for which comprehensive dispersal data exist is consequently limited (Clobert *et al.*
53 2001, Nathan *et al.* 2003, Doligez & Pärt 2008).

54 One common limitation is that many field studies measure dispersal within restricted areas
55 that are smaller than the distance over which individuals can potentially move (Koenig *et al.*
56 1996, Cooper *et al.* 2008, Doligez & Pärt 2008). Such studies can be valuable in quantifying
57 small-scale or local movements, and hence in dissecting local population structure and
58 regulation and underlying behavioural processes (Rodenhuse *et al.* 1997, Nathan *et al.* 2003,
59 Tavecchia *et al.* 2008, Sonsthagen *et al.* 2010). However, conclusions may not be valid when
60 extrapolated across larger spatial scales (Hawkes 2009). In particular, systematic observation
61 bias stemming from restricted study areas may cause long-distance dispersal and hence
62 overall dispersal rates and distances to be substantially underestimated (Baker *et al.* 1995,
63 Koenig *et al.* 1996, Nathan *et al.* 2003, Cooper *et al.* 2008). Some studies attempt to correct
64 for such spatial bias in detection rates by estimating the probability that a dispersed individual
65 will be observed as the proportion of available area that was surveyed at successive distances
66 from the point of initial observation (Baker *et al.* 1995, Koenig *et al.* 1996, Winkler *et al.*
67 2005, Doligez & Pärt 2008, Sharp *et al.* 2008). However, this method assumes that detection
68 probability per unit search area does not vary with distance, which may not be valid (Cooper
69 *et al.* 2008). Furthermore, directional dispersal could substantially affect population structure
70 and dynamics, and information on direction as well as distance is required to describe overall
71 spatial patterns of dispersal and linkage. Despite this, few field studies have quantified the

72 full distribution of dispersal directions or tested whether this distribution departs from
73 random expectation given the spatial distribution of available habitat (e.g. Coulson & Néve
74 de Mévergnies 1992, Matthysen *et al.* 2005, Sharp *et al.* 2008). Such estimates may also be
75 biased by arbitrary study area dimensions.

76 These difficulties, which result from spatially restricted observation effort and hence spatially
77 biased detection rates, are widely accepted to affect many empirical estimates of dispersal
78 rates, distances and directions (Koenig *et al.* 1996, Winkler *et al.* 2005, Cooper *et al.* 2008,
79 Doligez & Pärt 2008). However accurate estimates are required to design and parameterise
80 predictive models that involve dispersal processes (Kot *et al.* 1996, Hanski 1999, McCallum
81 2000, Petrovskii & Morozov 2009). Two continuous probability distributions, Gaussian
82 (normal) and negative exponential, are often used to approximate the decline in frequency of
83 individuals with increasing distance from a source (Chambers 1995, Kot *et al.* 1996,
84 McCallum 2000, Nathan *et al.* 2003, Chapman *et al.* 2007). Available empirical data,
85 however, suggest that true distributions of dispersal distances can show lower rates of decay
86 at large distances than expected under these models, resulting in ‘fat-tailed’ distributions (Kot
87 *et al.* 1996, Nathan *et al.* 2003, Chapman *et al.* 2007, Kesler *et al.* 2010). This lack of
88 congruence between basic model formulation and true dispersal distribution may cause
89 divergence between predicted and observed consequences for population structure and
90 evolutionary dynamics (Kot *et al.* 1996, Chapman *et al.* 2007). Individuals that lie within the
91 tails of such distributions are by definition uncommon, and few empirical studies cover
92 sufficiently large areas relative to a species’ typical dispersal distance with sufficiently high
93 detection probability to quantify the rate, distance and direction of long-distance dispersal
94 (Nathan *et al.* 2003, 2008). Full natal dispersal distributions have been most comprehensively
95 quantified in passive dispersers (Nathan *et al.* 2008), and in active dispersers that move over
96 relatively small areas or distances (e.g. $\leq 1\text{km}$, Stream Salamander *Gyrinophilus*
97 *porphyriticus*, Lowe 2010; $< 2\text{km}^2$, Tansy Beetle *Chrysolina graminis*, Chapman *et al.* 2007).
98 Kesler *et al.* (2010) estimated Red-cockaded Woodpecker *Picoides borealis* dispersal
99 distances within a *c.* 1000km^2 area, but this may still be small relative to the species’ potential
100 mobility. The frequency and magnitude of long-distance dispersal, and hence the degree to
101 which common model formulations may generally capture the full distributions of dispersal
102 distances and directions across diverse taxa, therefore remain unclear (Nathan *et al.* 2003,
103 2008, Chapman *et al.* 2007).

104 To determine the degree to which distributions of local dispersal distances and directions
105 relate to distributions that encompass the full dispersal range, both local and large-scale
106 dispersal need to be measured and then combined to generate overall distributions that
107 incorporate movement across both spatial scales (Hawkes 2009). This requires studies that
108 quantify dispersal rates, distances and directions by locating philopatric and dispersed
109 individuals across the full range of potential dispersal distances and directions within and
110 beyond specific breeding areas, where sampling and hence detection rates are high and
111 relatively uniform across the full range of spatial variation, and where the magnitude and
112 pattern of detection failure and resulting bias can be independently estimated (Baker *et al.*
113 1995, Koenig *et al.* 1996, Nathan *et al.* 2003, Cooper *et al.* 2008, Doligez & Pärt 2008).

114 We used individually marked European Shags *Phalacrocorax aristotelis* to quantify the rate
115 of dispersal from natal to subsequent breeding sites, and the distributions of dispersal
116 distances and directions, both within a focal breeding colony and across the full biologically
117 likely dispersal range from this colony. Furthermore, by locating marked individuals in non-
118 breeding (wintering) areas, we estimated the probability of detecting an individual at its
119 breeding location across a large geographical range and hence the degree of detection failure.
120 We thereby quantified small- and large-scale dispersal distributions, and compared observed
121 distributions to widely implemented model formulations.

122 **METHODS**

123 **Study system**

124 The European Shag (hereafter Shag) is a colonially breeding seabird that is endemic to rocky
125 coasts of the north-east Atlantic and Mediterranean (Wanless & Harris 2004). British Shags
126 of all ages are coastally distributed year-round (Harris & Swann 2002). They first breed aged
127 ≥ 2 years (Potts *et al.* 1980) and adults can be reliably distinguished from subadults by
128 plumage and behaviour (Snow 1960).

129 Shag demography has been studied for >30 years at a breeding colony on the Isle of May
130 (hereafter IoM; *c.*4km in circumference, 56°11'N 2°33'W), Firth of Forth, eastern Scotland,
131 (Aebischer 1995). Shag chicks have been ringed in all parts of the colony since 1997 with
132 alphanumeric British Trust for Ornithology (BTO) rings and plastic colour-rings engraved
133 with a unique three letter code. A mean of 650 chicks (± 365 SD, range=161-1208) was ringed

134 each year during 1997-2006, totalling 6496 individuals and comprising *c.*90% of individuals
135 fledged on IoM during this time. Colour-ring codes can be read in the field at distances of
136 $\leq 150\text{m}$, allowing individual Shags to be identified on breeding and wintering grounds
137 without recapture. The annual survival probability of breeding adults is $0.86 \pm 0.03\text{SE}$
138 (Frederiksen *et al.* 2008) meaning that adults commonly survive to breed in multiple years.

139 **Within-colony dispersal**

140 Shags nest on coastal rock ledges on IoM (Aebischer *et al.* 1995). Nest sites are discrete and
141 patchily distributed around the island's circumference. All nest sites are individually marked
142 and their locations are recorded to the nearest 10m using GPS. All nest sites were repeatedly
143 checked during the 2008 and 2009 breeding seasons (1 March-31 August) and the identities
144 of ringed breeding adults were recorded. Sexes were determined by voice, size and behaviour
145 (Snow 1960).

146 Dispersal within IoM was defined as the movement of an individual from its natal nest site
147 (in 1997-2006) to its observed breeding site in 2008 or 2009. Exact natal sites and hence
148 locations were known for a substantial proportion of colour-ringed adults found breeding on
149 IoM during 2008-2009 (69%, see Results). Dispersal rate was estimated as the number of
150 adult Shags colour-ringed as chicks on IoM found breeding at an IoM site other than their
151 natal site to the total number of these adults found breeding anywhere on IoM. Dispersal
152 distance for these individuals was estimated as the shortest distance around the IoM coastline
153 (coastal distance). Since Shags rarely cross land in flight (Harris & Swann 2002), this was
154 deemed more biologically relevant than Euclidean distance. In practice, coastal and
155 Euclidean distances were tightly correlated ($r=0.83$, $\text{d.f.}=284$, $P<0.0001$). Dispersal direction
156 was calculated as the direct bearing from an individual's natal site to its observed breeding
157 site. Since IoM has a roughly elliptical coastline within-colony dispersal in almost any
158 direction was possible, and multiple directions were possible for most distances. Breeding
159 adults that originated from natal sites that were less precisely known, typically due to less
160 comprehensive documentation during early study years, were excluded from these analyses.

161 Our working definition of dispersal (above) does not equate to natal dispersal defined as
162 movement from natal site to site of first reproduction (Greenwood & Harvey 1982). Our
163 dataset comprised breeding adults of various ages and therefore measured natal dispersal plus
164 any subsequent breeding dispersal between breeding sites. Ultimately, it is the combination of

165 these two processes, as described by our study, that influences demographic and genetic
166 connectivity and hence population and evolutionary dynamics. Phenomenological
167 understanding of these consequences therefore does not necessarily require the two dispersal
168 processes to be distinguished. However, to investigate the degree to which breeding dispersal
169 might bias inference of natal dispersal *sensu stricto* from our data, coastal distance was
170 calculated between the 2008 and 2009 breeding sites of adults (aged 2-12 years) that had
171 been ringed as chicks on IoM that bred in both years ($n=276$). These data showed that
172 breeding dispersal was highly restricted in both males and females (mean $15\text{m}\pm 66\text{SD}$,
173 median 0m , IQR $0\text{-}8\text{m}$). Indeed, 140 (51%) of the 276 adults bred at the same site in both
174 years, and 265 (96%) bred within 50m of their previous site. Breeding dispersal distances did
175 not differ significantly between males and females (Kolmogorov-Smirnov: $D=0.05$, $P=0.99$)
176 or between 2008 and 2009 breeding sites relative to an individual's natal site (Kolmogorov-
177 Smirnov: $D=0.04$, $P=0.99$). Furthermore, 70% of adults that changed breeding site between
178 2008 and 2009 moved $<5^\circ$ between these sites relative to their natal site. Breeding dispersal
179 directions did not differ significantly between sexes (Kolmogorov-Smirnov: $D=0.08$, $P=0.36$)
180 or between 2008 and 2009 breeding sites relative to an individual's natal site (Kolmogorov-
181 Smirnov: $D=0.06$, $P=0.99$). Previous analyses also showed that breeding dispersal is
182 restricted in Shags (Aebischer *et al.* 1995). These data suggest that breeding dispersal would
183 not greatly bias inference of natal dispersal distributions from our composite dispersal data.
184 Since the nest sites of individuals that bred in both 2008 and 2009 were clearly non-
185 independent (being identical in 51% of cases and $<50\text{m}$ apart in most others), a single
186 randomly selected breeding site from 2008 or 2009 was used to estimate dispersal distance
187 and direction from natal to subsequent breeding location for individuals that bred in both
188 years.

189 **Among-colony dispersal**

190 Dispersal away from IoM was defined as the movement of an individual that had been ringed
191 as a chick on IoM to an observed breeding location elsewhere. To locate dispersed adults, 26
192 colonies in addition to IoM were surveyed during the 2008 and/or 2009 breeding seasons, and
193 one further colony was surveyed in 2010 (Fig.1a, Table 1). Surveys were carried out by the
194 authors, assisted by other observers (see Acknowledgements). Colonies were identified
195 during a census of all UK Shag populations in 1998-2002 and ranged in size from <10 to
196 >500 breeding pairs at that time (Table 1; Wanless & Harris 2004), and fell within an overall
197 study area that was defined by long-term UK and European ring-recovery data. Specifically,

198 since 1997, 425 adult Shags ringed as chicks on IoM were recovered elsewhere, dead or alive
199 in any season, prior to the current study. These data do not themselves accurately describe
200 breeding locations or dispersal rates, but do help define the total geographical area relevant to
201 adult IoM Shags. All 425 recoveries occurred along the UK's east (North Sea) coast, ranging
202 from 427km north of IoM ($n=375$) to 355km south ($n=50$). Dead recovery data prior to 1985
203 showed similar patterns (Galbraith *et al.* 1986). This does not solely reflect the geographical
204 distribution of recovery reporting because numerous Shags ringed at other UK colonies have
205 been recovered elsewhere, including on north, south and west UK coasts and continental
206 Europe (Harris & Swann 2002). This weight of prior information suggests that dispersal of
207 IoM-ringed Shags to geographical regions other than North Sea colonies is unlikely or
208 extremely rare. The 27 surveyed colonies were consequently restricted to the North Sea.
209 However, they still encompassed a large geographical area relative to all previous ring
210 recoveries, from 690km north (16 colonies) to 355km south (11 colonies) of IoM, covering
211 1045km of coastline in total (Fig.1a). Approximately 90% of all breeding colonies along the
212 UK's North Sea coast were surveyed (as per Wanless & Harris 2004) during the main
213 incubation and chick-rearing periods (i.e. April-July). The remaining 10% comprised small
214 colonies and scattered breeding pairs. No breeding colonies exist between the Farne Islands
215 and Flamborough Head (*c.*100km and *c.*355km south of IoM respectively) or south of
216 Flamborough Head due to a lack of suitable nesting habitat. The most northerly and southerly
217 colonies surveyed therefore represent the approximate limits of breeding colonies along the
218 North Sea coast and encompass the maximum likely dispersal distance of IoM Shags (and
219 substantially exceeded the maximum distance observed, see Results).

220 At each surveyed colony as many adult Shags as possible were checked for colour-rings by
221 observation from land and/or boat. All adult Shags observed at a colony during the breeding
222 season were assumed to be breeding at that colony. No adults were observed at multiple
223 colonies within or between 2008 and 2009. There was therefore no evidence of among-
224 colony breeding dispersal. Not all adults observed during any one survey could be checked
225 for rings because their legs were obscured from view. These individuals were counted and
226 categorised as 'unchecked'. Checked adults were counted and categorised as 'unringed' or
227 'colour-ringed'. Ring codes were recorded and verified by repeat checking by the observer,
228 between observers or using digital photography. It was highly unlikely that all Shags
229 breeding at a particular colony would be present during a single survey and/or checked if
230 present. Therefore, to increase the probability that colour-ringed individuals would be

231 observed, multiple surveys of each colony were undertaken where possible. The total number
232 of individuals checked for colour-rings across all visits to each colony was estimated
233 (Supporting Information Appendix S1). To investigate whether the distribution of colour-
234 ringed adults found breeding simply reflected the distribution of observation effort we
235 quantified the correlation between the number of ringed adults observed and the total number
236 of adults estimated to have been checked across all surveyed colonies. Sex could not be
237 reliably determined for most adults observed away from IoM due to generally greater
238 observation distances and reduced opportunity for prolonged behavioural observations.

239 The observed dispersal rate away from IoM was estimated as the ratio of the number of adult
240 Shags that had been colour-ringed as chicks on IoM that were found at breeding colonies
241 away from IoM to the total number of these adults found at all colonies including IoM. The
242 distribution of dispersal distances was quantified using coastal distance between IoM and the
243 other 27 surveyed colonies. Coastal distance was calculated as above or as the shortest
244 distance across the water for distances $\leq 50\text{km}$ (since shags can cross such distances of open
245 sea, Harris & Swann 2002). Coastal distance was again tightly correlated with Euclidean
246 distance (Spearman's rank correlation coefficient: $r=0.99$, $P<0.0001$). Dispersal directions
247 were calculated as the bearing from IoM to each surveyed colony.

248 **Overall dispersal**

249 Data from all surveys within and outside IoM were combined to quantify the overall
250 distribution of dispersal distances and directions across the full range of individual dispersal.

251 **Analyses**

252 Individual-based randomisations were used to test whether observed distributions of dispersal
253 distances and directions differed from random expectation given the system's spatial
254 properties. For all adults observed breeding on IoM during 2008-2009 with known natal nest
255 sites, randomised dispersal distributions were generated by calculating distance and direction
256 between each adult's natal site and a breeding site that was randomly selected with
257 replacement from all nest sites used on IoM during 1997-2009 ($n=2024$). This process was
258 repeated 1000 times for each adult. Data were binned into 40x50m distance categories (0-
259 2000m), which were deemed biologically relevant based upon observed dispersal distances,
260 and averaged across randomisations for each distance category to produce the mean (\pm SD)
261 randomised distance distribution. The same method was used to produce a randomised

262 direction distribution, with data binned into 18x20° categories (0-360 degrees). Observed
263 distances and directions were binned into the same categories for comparison.

264 Similar methods were used to create randomised null distributions for dispersal among
265 colonies and overall. For colour-ringed adults observed breeding away from IoM during
266 2008-2010, random breeding colonies were selected with replacement from all surveyed
267 colonies. In the absence of accurate data quantifying site availability at surveyed colonies,
268 settlement probability was weighted by approximate colony size with settlement being three
269 times more likely at large colonies than small colonies (Table 1). Conclusions remained
270 robust when these weightings were altered, including equal weighting. Randomised dispersal
271 distances and directions were calculated and categorised by colony ($n=27$). Randomised
272 distributions for overall dispersal were generated by calculating distance and direction
273 between an individual's known natal site and a random breeding colony (including IoM)
274 selected with replacement. Individuals that were randomly allocated to IoM were assigned a
275 random breeding site within IoM. Distances were categorised by colony ($n=28$) and
276 directions were binned as before. Finally, to investigate whether observed dispersal directions
277 differed from expectation given constrained dispersal distances, randomisations were
278 repeated with destination colonies restricted to surveyed colonies located within the
279 maximum observed dispersal distance.

280 Since Shags occupy discrete breeding colonies, dispersal occurs in discontinuous rather than
281 continuous space. However, to quantify the degree to which the observed dispersal
282 distribution could be adequately captured by commonly used dispersal models, observed
283 distance distributions were tested against negative exponential and Gaussian distributions (the
284 latter reflected and centred on zero, Kot *et al.* 1996). Skew and kurtosis were calculated for
285 unreflected observed distance distributions (Joanes & Gill 1998; Chapman *et al.* 2007).
286 Values of >1 indicate distributions that are right-skewed and fatter-tailed than expected under
287 normality. Observed direction distributions were tested against a Rayleigh (circular)
288 distribution to determine whether they differed from uniformity. Circular-linear regressions
289 were used to quantify the relationship between dispersal distance (linear variable) and
290 direction (circular variable) and test whether distance was non-random with respect to
291 direction.

292 **Detection rate**

293 Despite our substantial large-scale survey effort, as with any field dispersal study, the
294 probability of detecting a colour-ringed breeding Shag was unlikely to be 1.0 and may have
295 varied among colonies (Supporting Information Appendix S2). To assess the degree to which
296 incomplete and uneven detection of breeding adults might bias estimated dispersal rates,
297 distances or directions, the number of colour-ringed adults that were alive but had not been
298 located at any breeding colony was estimated by undertaking winter (1 September-28
299 February) surveys during the 2008-2009 and 2009-2010 winters. During winter, Shags
300 congregate at roosts on skerries and piers that often include large numbers of individuals
301 fledged from and breeding at multiple colonies; individuals can winter substantial distances
302 (>150km) from their breeding colony (Supporting Information Appendix S3). The probability
303 of observing an individual in winter is therefore at least partly independent of its breeding
304 location. Any spatial bias in detection probability with respect to breeding location therefore
305 differs to some degree between summer and winter. Twenty winter roosts were surveyed,
306 ranging from 540km north to 355km south of IoM (Fig. 1b, Supporting Information Appendix
307 S3). All observed Shags were checked for colour-rings and identities of ringed adults were
308 verified using similar protocols as at breeding colonies.

309 The number of colour-ringed adults that were observed during winter surveys but not
310 observed breeding (N_U) was used to estimate the total number of colour-ringed adults that
311 were alive but had not been located breeding (N_X), as:

312
$$N_X = N_U / (N_{WTOT} / N_{STOT})$$
 eqn.1

313 where N_{WTOT} is the total number of colour-ringed adults observed during winter surveys that
314 had also been located breeding, and N_{STOT} is the total number of colour-ringed adults
315 observed breeding across all surveyed colonies (Supporting Information Appendix S2). This
316 expression assumes that the probability that an individual will be observed in winter is
317 independent of the probability that it was observed breeding in the summer. It therefore
318 provides an approximate estimate of the total number of individuals that remained undetected
319 during breeding season surveys. The N_X breeding adults that were estimated to have
320 remained undetected was used to estimate upper and lower limits to dispersal rate away from
321 IoM, as:

322 Upper limit = $(N_{SD}+N_X)/(N_{SD}+N_{SIoM}+N_X)$ eqn.2a

323 Lower limit = $N_{SD}/(N_{SD}+N_{SIoM}+N_X)$ eqn.2b

324 where N_{SD} is the total number of colour-ringed Shags observed breeding away from IoM
325 during 2008-2010 and N_{SIoM} is the total number of colour-ringed Shags observed breeding on
326 IoM during 2008-2009.

327 To estimate the degree to which incomplete detection of breeding adults might have caused
328 observed dispersal distributions to be poorly estimated, the estimated N_X undetected adults
329 were either allocated to IoM, or randomly allocated to one of the 27 other surveyed colonies,
330 with a probability weighted by colony size (Table 1). Randomisations were repeated 1000
331 times, summarised as before and compared to observed distances and directions. Upper and
332 lower limits to dispersal rate and distributions respectively assume that all N_X undetected
333 colour-ringed adults had dispersed from IoM, or that all bred on IoM (Supporting Information
334 Appendix S2).

335 Data from all surveys undertaken during 2008-2010 were combined for all analyses.
336 Analyses were run in Excel and R (v.2.12.2, R Development Core Team 2011). Circular
337 statistics were calculated using library ‘circular’ (Lund & Agostinelli 2011). Means are
338 presented $\pm 1SD$.

339 **RESULTS**

340 **Within-colony dispersal**

341 During the 2008 and 2009 breeding seasons 1511 observations were made of 938 individual
342 adult Shags breeding on IoM (Table 1). In total, 416 adult Shags that had been ringed as
343 chicks on IoM were located breeding on IoM. Exact natal nest sites were known for 285 of
344 these 416 individuals (69%). Only one individual (0.3%) bred at its natal site. The observed
345 dispersal rate within IoM was therefore 99.6%. This rate did not differ significantly from that
346 expected given random dispersal to any possible nest site ($\chi^2=1.77$, d.f.=1, $P=0.18$);
347 recruitment to the natal site occurred on 0.03% of random allocations.

348 Observed dispersal distances within IoM ranged from 0 to 1962m (mean 464±500m, median
349 249m, IQR 65-799m, $n=285$). Distributions did not differ significantly between males and
350 females (Kolmogorov-Smirnov: $D=0.25$, $P=0.16$; Fig.2a). Across both sexes, the distribution
351 of dispersal distances differed significantly from both negative exponential and Gaussian
352 (Kolmogorov-Smirnov: $D=0.13$, $P<0.0001$ and $D=0.48$, $P<0.0001$ respectively), and was
353 right-skewed and fat-tailed (skew=3.6, kurtosis=14.2). Randomised dispersal distances
354 ranged from 0 to 2048m (mean 756±512m, median 733m, IQR 276-1153m). Observed
355 dispersal distances tended to differ from random for females ($\chi^2=56$, d.f.=39, $P=0.06$; Fig.2c),
356 and differed significantly from random for males ($\chi^2=77$, d.f.=39, $P=0.006$; Fig.2b) and
357 across both sexes combined ($\chi^2=85$, d.f.=39, $P<0.01$); individuals bred closer to their natal
358 site than expected given random dispersal within IoM.

359 Some dispersal occurred in almost every direction within IoM (Fig.3a). However the
360 observed distribution of dispersal directions was bimodal and differed markedly from
361 uniformity (Rayleigh test: $z=0.18$, $n=285$, $P<0.0001$; Figs. 3a, 4a); 18% (51/285) of
362 individuals dispersed approximately SE (112.5-157.5°) from their natal site and 34%
363 (97/285) of individuals dispersed approximately NW (292.5-337.5°; Fig.3a). Observed
364 dispersal directions did not differ significantly between males and females (Kolmogorov-
365 Smirnov: $D=0.13$, $P=0.22$; Fig.3a). Randomised dispersal directions were also bimodal: 23%
366 and 36% of directions were approximately SE and NW respectively. This bimodal
367 distribution arises because the IoM is roughly elliptical and aligned approximately SE-NW.
368 The observed and randomised distributions of dispersal directions did not differ significantly
369 for either males ($\chi^2=10.9$, d.f.=17, $P=0.98$; Fig.3b) or females ($\chi^2=5.3$, d.f.=17, $P=0.99$;
370 Fig.3c) or across both sexes combined ($\chi^2=11.3$, d.f.=17, $P=0.98$). The observed
371 directionality of dispersal therefore did not differ from that expected given random movement
372 among nest sites. Dispersal distance was not strongly related to dispersal direction (circular-
373 linear regression: estimate=-0.08 radians/m, $t=0.50$, $P=0.31$, $n=285$).

374 **Among-colony dispersal**

375 During the 2008 to 2010 breeding seasons, 99 surveys at 27 colonies away from IoM resulted
376 in 7648 observations of an estimated c.3487 individual adult Shags (Table 1, Fig.5,
377 Supporting Information Appendix S1). A total of 44 colour-ringed adults that had been ringed
378 as chicks on IoM were located breeding at these colonies. The observed dispersal rate away
379 from IoM was therefore $44/(416+44)=9.6\%$. The number of colour-ringed adults found

380 breeding at a colony was not tightly correlated with the total number of adults estimated to
381 have been checked there across all surveys ($r = 0.18$, d.f.=26, $P=0.35$; Fig.5, Supporting
382 Information Appendix S1).

383 At least one colour-ringed adult was located at 12 of 27 surveyed colonies (Table 1, Fig.5).
384 Observed dispersal distances ranged from 16 to 170km (mean 62 ± 46 km, median 40km, IQR
385 35-99km, $n=44$). The observed distance distribution tended to fit negative exponential but
386 differed significantly from Gaussian (Kolmogorov-Smirnov: $D=0.23$, $P=0.015$ and $D=0.5$,
387 $P<0.0001$ respectively). The distribution was right-skewed and fat-tailed (skew=2.3,
388 kurtosis=3.9); 64% (28/44) of dispersed Shags were located at colonies within 50km of IoM.
389 Randomised dispersal distances ranged from 13 to 689km (mean 170 ± 4 km, median 100km,
390 IQR 50-229km). Observed distances differed significantly from random ($\chi^2=39$, d.f.=26,
391 $P=0.04$); most individuals dispersed to colonies that were closer to IoM than expected given
392 random dispersal across surveyed colonies. However, dispersers did not all move to the
393 closest colonies to IoM (Table 1).

394 The observed distribution of dispersal directions differed from uniformity (Rayleigh test:
395 $z=0.42$, $n=44$, $P<0.0001$; Fig.4b). Most individuals dispersed SW from IoM; 64% (28/44)
396 moved between 202.5 and 247.5° (Fig.4b). Furthermore, the observed distribution differed
397 from that expected given random settlement across all surveyed colonies ($\chi^2=38$, d.f.=26,
398 $P=0.05$) and across only those colonies up to the maximum observed dispersal distance
399 ($\chi^2=35$, d.f.=17, $P=0.005$). This indicates that the observed directionality of dispersal did not
400 solely reflect the spatial distribution of surveyed colonies. Observed dispersal directions
401 varied significantly with dispersal distances (circular-linear regression: estimate=0.015
402 radians/km, $t=5.33$, $P<0.0001$, $n=44$); Shags moved furthest towards the NE. However,
403 randomised distances and directions were also significantly related (circular-linear
404 regression: estimate=0.017 radians/km, $t=2.52$, $P=0.005$) indicating that this distance-
405 direction relationship simply reflects the system's spatial structure.

406 **Overall dispersal**

407 Since the distributions of dispersal distances and directions within IoM did not differ between
408 males and females and most Shags observed away from IoM could not be reliably sexed, the
409 dispersal distributions for Shags observed within ($n=285$) and away from IoM ($n=44$) were
410 combined ($n=329$).

411 The full observed distribution of dispersal distances ranged from 0-170km (mean 9 ± 27 km,
412 median 0.32km, IQR 0.08-1km, $n=329$; Fig.6). It differed significantly from both negative
413 exponential and Gaussian (Kolmogorov-Smirnov: $D=0.85$, $P<0.0001$ and $D=0.13$, $P<0.0001$
414 respectively) and was right-skewed and fat-tailed (skew=4.8, kurtosis=20.0). Randomised
415 dispersal distances ranged from 0 to 689km (mean 3 ± 26 km, median 0.64km, IQR 0.27-
416 1.05km) and differed significantly from observed ($\chi^2=478$, d.f.=27, $P<0.0001$) demonstrating
417 highly significant philopatry to and within the IoM colony.

418 The full observed distribution of dispersal directions was bimodal; 17% (56/329) of Shags
419 dispersed approximately SE and 30% (98/329) dispersed approximately NW (Fig.4c). This
420 distribution differed significantly from that expected given random dispersal to any nest site
421 or surveyed colony ($\chi^2=230$, d.f.=17, $P<0.0001$), and to any nest site or surveyed colony
422 within the observed dispersal range ($\chi^2=45$, d.f.=17, $P=0.002$). The overall distribution of
423 dispersal directions did not, therefore, simply reflect the system's spatial structure. Neither
424 observed distances (circular-linear regression: estimate=0.49 radians/km, $t=0.89$, $P=0.18$) nor
425 randomised distances (circular-linear regression: estimate=1.34 radians/km, $t=0.46$, $P=0.33$)
426 were significantly related to dispersal direction.

427 **Detection rate**

428 A total of 195 adults that had been ringed as chicks on IoM were resighted at roosts during
429 the winters of 2008-2009 or 2009-2010, and were observed up to 430km from their known
430 breeding colony (Supporting Information Appendix S3). These included 178 (43%) of 416
431 individuals observed breeding on IoM, and 13 (30%) of 44 individuals observed breeding at a
432 different colony. These proportions did not differ significantly ($\chi^2=0.96$, d.f.=1, $P=0.33$). The
433 remaining four individuals were not observed breeding at any colony, giving $N_U=4$. The total
434 number of undetected breeding-age adults was therefore estimated to be small ($N_X\approx 9$, eqn.1).
435 The lower and upper limits to the rate of dispersal away from IoM were therefore estimated
436 as *c.*9% and 11% respectively (eqns.2a & b).

437 The overall observed distributions of dispersal distances and directions did not differ
438 significantly from those created when $N_X=9$ undetected adults were randomly allocated to
439 nest sites on IoM (distance: $\chi^2=0.02$, d.f.=27, $P=0.99$, direction: $\chi^2=2.19$, d.f.=17, $P=0.97$), or
440 to surveyed breeding colonies away from IoM (distance: $\chi^2=3.89$, d.f.=27, $P=0.99$; direction:
441 $\chi^2=0.39$, d.f.=17, $P=0.99$; Supporting Information Appendix S2). Estimated dispersal rates

442 and distributions were therefore broadly robust to the small estimated degree of incomplete
443 detection in our study, and hence to the maximum potential degree of spatial bias in
444 detection.

445 **DISCUSSION**

446 Understanding the ultimate consequences of dispersal for population structure and dynamics
447 requires accurate estimation of the rate, distance and direction of movements between natal
448 and subsequent breeding locations, both within single breeding areas and across a population
449 or species' full potential dispersal range (Rodenhouse *et al.* 1997, Frederiksen & Petersen
450 1999, Broquet & Petit 2009, Clobert *et al.* 2009). We estimated within-colony, among-colony
451 and overall dispersal rates, distances and directions for Shags, a species with substantial
452 dispersal potential, by locating adults that had been colour-ringed as chicks on the Isle of
453 May (IoM) breeding on IoM and at other colonies across a large geographical scale. We
454 additionally used winter surveys to estimate the degree of incomplete detection of breeding
455 adults, and hence consider resulting error and bias in estimated dispersal distributions.

456 **Within-colony dispersal**

457 The Isle of May is a discrete island land mass. Its Shag population is monitored annually;
458 most fledglings are ringed and adults identified with little internal spatial bias. The within-
459 colony dispersal rate and full distributions of dispersal distances and directions were therefore
460 estimated with little potential bias stemming from arbitrary boundaries or spatially
461 heterogeneous sampling. The internal dispersal rate, defined as observed breeding away from
462 an individual's natal nest site, was close to 100%. This did not differ from expectation
463 assuming unconstrained dispersal among all known nest sites. The high internal dispersal rate
464 may therefore simply reflect high nest availability rather than necessarily implying specific
465 avoidance of, or constraints on, occupying the natal site. Equally, there was no evidence that
466 Shags bred on their natal site more than expected by chance.

467 However, despite the high internal dispersal rate, dispersal distances within IoM were shorter
468 than expected given random dispersal in males and females (medians of 205m and 258m
469 versus 736m and 730m respectively; Fig.2). Dispersal was therefore restricted at a
470 biologically small spatial scale. Since Shags can forage up to 15km away from their nest
471 while breeding (Wanless *et al.* 1991) and move up to *c.*400km during winter (Supporting

472 Information Appendix S3) this relative philopatry cannot reflect a physical inability to
473 disperse throughout the colony; the entire circumference of IoM is only 4km. Several other
474 studies have demonstrated restricted within-colony dispersal for highly vagile species (e.g.
475 Black-legged Kittiwakes *Rissa tridactyla*, Coulson & Néve de Mévergnies 1992; Western
476 Gulls *Larus occidentalis*, Spear *et al.* 1998; Black Guillemots, *Cephus grylle*, Frederiksen &
477 Petersen 1999; Wandering Albatross *Diomedea exulans*, Charmantier *et al.* 2011). Such
478 strong natal philopatry can lead to genetic structuring and demographic asynchrony at small
479 spatial scales (e.g. Tavecchia *et al.* 2008, Sonsthagen *et al.* 2010). However, despite their
480 overall tendency to breed relatively near their natal site, a substantial proportion of Shags
481 dispersed greater distances within IoM (e.g. 48/285 dispersed ≥ 1 km, including both males
482 and females; Fig.2). Any within-colony genetic structure is therefore likely to be eroded by
483 gene flow (Mills & Allendorf 1996).

484 Directional dispersal could substantially alter population processes beyond those resulting
485 from specific dispersal rates and distances (Kot *et al.* 1996, Clobert *et al.* 2001, Matthysen *et*
486 *al.* 2005, Sharp *et al.* 2008). An individual's dispersal direction is inevitably constrained by
487 the location of its natal site relative to other potential breeding sites. Since IoM has a roughly
488 elliptical coastline, individual Shags could potentially disperse in multiple directions from
489 any natal site. Furthermore, across the whole colony combined, some individuals had
490 opportunity to disperse in every direction. In fact, the observed distribution of dispersal
491 directions was bimodal rather than uniform, but did not differ from that expected given
492 random dispersal among nest sites. The observed directionality of dispersal can therefore be
493 explained by local landscape structure rather than necessarily implying preferential
494 directional movement by individual Shags.

495 Dispersal distances and directions within IoM were very similar in males and females. This
496 contrasts with the general observation that females often disperse longer distances in birds
497 (Greenwood 1980), but is consistent with studies on Western Gulls (Spear *et al.* 1998) and
498 Lesser Kestrels (*Falco naumanni*, Serrano *et al.* 2003). A previous study on IoM Shags did
499 detect non-significant female-biased dispersal over a larger spatial scale (Aebischer 1995).
500 However, this study took place when the IoM population was much larger than it was in
501 2008-2009, and followed a period of rapid increase. This indicates that general conclusions
502 regarding sex-biased dispersal cannot necessarily be drawn from single studies that are
503 restricted in time or space (Lawson-Handley & Perrin 2007).

504 **Among-colony dispersal**

505 The rate and pattern of long-distance dispersal could profoundly affect population and
506 evolutionary dynamics. One basic aim in ecology is therefore to accurately quantify dispersal
507 rates, distances and directions among breeding areas on a large spatial scale. Such data are
508 challenging to collect because long-distance dispersal may be rare and search areas may be
509 large (Baker *et al.* 1995, Koenig *et al.* 1996, Nathan *et al.* 2003, Cooper *et al.* 2008).
510 Estimated dispersal rates, distances and directions will be prone to error and bias if some
511 individuals remain undetected and these individuals are non-random with respect to breeding
512 location (Baker *et al.* 1995, Koenig *et al.* 1996). We minimised these ubiquitous problems by
513 surveying most Shag breeding colonies across a substantial area relative to the total likely
514 dispersal range from IoM (Table 1, Fig.1). Since colonies are restricted to coastline and
515 islands, the search area did not increase non-linearly with distance from IoM (as would occur
516 in a fully two-dimensional landscape, Lowe 2010). Overall, approximately 28% (2126/7648;
517 Table 1) of all observations of breeding Shags and 32% (1107/3487; Table 1) of the
518 estimated total number of individuals checked away from IoM were further away from IoM
519 than the furthest observed disperser. Therefore, while the occurrence of rare long-distance
520 dispersal over even greater distances than those surveyed cannot be ruled out, our search area
521 substantially exceeded the likely and detected dispersal range. The number of dispersers
522 located at each colony away from IoM was not correlated with the number of individuals
523 estimated to have been checked there (Table 1, Supporting Information Appendix S1)
524 suggesting that observed disperser locations did not solely reflect the distribution of
525 observation effort across surveyed colonies. Furthermore, our surveys of marked adults both
526 at breeding colonies and on separate wintering grounds enabled us to estimate breeding
527 season detection failure with relatively independent spatial bias. The use of independent
528 cross-season observations to validate dispersal estimates has been proposed but rarely
529 implemented (Doligez & Pärt 2008). Our winter observations indicated that the probability of
530 detecting a IoM-ringed Shag at its future breeding location was very high (460/469=98%) at
531 a north-east UK scale. The estimated number of undetected breeders was therefore too few to
532 substantially alter the main conclusions regarding the distributions of dispersal distances and
533 directions, and indicated that the observed dispersal rate of *c.*10% was robust to $\pm 1\%$ (see
534 also Supporting Information Appendix S2). Although the estimated breeding season detection
535 failure was small in the current study, our use of cross-season observations illustrates one
536 means by which the long-standing problem of how to quantify overall detection failure in
537 large-scale dispersal studies could be resolved (Doligez & Pärt 2008).

538 Observed dispersers moved to colonies that were much closer to IoM than expected if
539 dispersal occurred at random across all surveyed colonies, demonstrating that dispersal was
540 spatially restricted among colonies as well as within the focal IoM colony (and hence at two
541 very different spatial scales). Most dispersing Shags moved SW from IoM, but the longest
542 movements were to the NE. This broad relationship between distance and direction mirrored
543 the geographical distribution of surveyed colonies. These patterns imply that it may be
544 distance rather than direction *per se* that shapes the overall dispersal distribution. However
545 the distribution of among-colony dispersal directions did differ from random expectation,
546 even after accounting for distance. This indicates that among-colony dispersal does have a
547 non-random directional component in Shags.

548 Shag dispersal away from IoM (c.10%) occurred at a relatively low rate compared to avian
549 dispersal studies that attempted to correct for bias stemming from restricted study areas (e.g.
550 83% in Lesser Kestrels *Falco naumanni*, Serrano *et al.* 2003 and 80% in Tree Swallows
551 *Tachycineta bicolor*, Winkler *et al.* 2005). In other seabirds, natal colony return rates have
552 been estimated to vary widely, from ca.10% in Northern Fulmars (*Fulmarus glacialis*,
553 Ollason & Dunnet 1983) to ca.80% in Wandering Albatrosses (Inchausti & Weimerskirch
554 2002). The number of observed dispersed Shags never exceeded c.9% of the total adults
555 estimated to have been checked at any colony, and was typically substantially less than this
556 (Table 1). Dispersal from IoM to any other individual colony may consequently be
557 proportionally too infrequent to cause substantial demographic coupling. However, since just
558 one disperser per generation can be sufficient to homogenise genetic variation across
559 populations (Mills & Allendorf 1996), such movements may be sufficient to erode genetic
560 structure.

561 **Overall dispersal**

562 Ecological and evolutionary models of movement commonly assume either Gaussian or
563 negative exponential dispersal functions (Chambers 1995, Kot *et al.* 1996, McCallum 2000,
564 Chapman *et al.* 2007). These functions fitted our data relatively poorly since they failed to
565 account for long-distance dispersal; ‘fat-tailed’ distributions of dispersal distances were
566 observed at within-colony and among-colony scales and overall. Since Shags are restricted to
567 coastal breeding colonies they do not occupy continuous space. Indeed, distributions of
568 dispersal directions were non-uniform across both spatial scales, violating another standard
569 assumption of phenomenological dispersal models.

570 These results concur with the growing evidence that dispersal typically does not represent a
571 single process across multiple spatial scales (e.g. Kot *et al.* 1996, Ronce 2007, Petrovskii &
572 Morozov 2009, Kesler *et al.* 2010). Distances and directions were constrained differently by
573 the geography and dimensions of habitat across scales. Within-colony dispersal data therefore
574 did not accurately predict dispersal distributions across larger spatial scales, demonstrating
575 the need to quantify movements across the full extent of dispersal, rather than extrapolating
576 from finite or arbitrary study sites (Nathan *et al.* 2003, Hawkes 2009).

577 Genetic and demographic connectivity ultimately stem from the spatial distributions of all
578 breeding attempts made by individuals from specific origins (as we measured for Shags
579 originating on IoM). However, full comprehension of the ecological and evolutionary causes
580 of dispersal may require mechanistic as well as phenomenological understanding of observed
581 dispersal distributions (Nathan *et al.* 2008, Clobert *et al.* 2009, Hawkes 2009). Considering
582 stepwise movements between natal and breeding colonies may not be appropriate in Shags,
583 because the range of individual winter movements covers numerous potential breeding
584 colonies (Supporting Information Appendix S3). Observed dispersal may therefore reflect
585 departure and settlement decisions rather than constraints on transience (Hénaux *et al.* 2007;
586 Clobert *et al.* 2009, Hawkes 2009), which may in turn reflect local ecology. Current dispersal
587 away from IoM is unlikely to be driven by local nest site or food availability. The current
588 IoM population is small compared to the recent maximum (1916 pairs in 1987 versus 465 in
589 2009; Aebischer & Wanless 1992) and breeding success is relatively high (1.90-2.02 chicks
590 fledged per pair in 2008-2009 compared to the mean for 2000-2009 of 1.35 and the long-term
591 mean of 1.01; Newell *et al.* 2010). A key next step is to link quantitative data on dispersal
592 distances and directions with individual traits of dispersers and the demographic and
593 ecological properties of destination colonies that are and are not selected in order to
594 investigate the causes and predict the long-term consequences of dispersal (Nathan *et al.*
595 2008, Clobert *et al.* 2009).

596 We thank the National Trust (Farne Islands), Forth Seabird Group (Forth Islands), Scottish
597 Seabird Centre (Craigleith and Fidra), Fair Isle Bird Observatory (Fair Isle), Royal Society

726 **SUPPORTING INFORMATION**

727 Additional Supporting Information may be found in the online version of this article.

728 Supporting Information **Appendix S1.**

729 Estimation of the total number of adult shags checked for colour-rings on the Isle of May
730 and at other breeding colonies.

731 Supporting Information **Appendix S2.**

732 The degree to which incomplete detection of breeding adult shags on Isle of May or
733 elsewhere might have caused estimated distributions of dispersal distances and directions to
734 be biased.

735 Supporting Information **Appendix S3**

736 Winter roost sites surveyed for colour-ringed adult shags during 2008-2010, and winter
737 locations of observed individuals.

Table 1. Colonies surveyed for breeding colour-ringed shags during 2008-2010 including; the maximum number of shags checked on one survey (Survey Maximum), the cumulative number of observations over all surveys at that colony (Total Observed), the total number of individual shags estimated to have been checked at that colony (Total Checked; Supporting Information Appendix S1), and the total number of colour-ringed adults located at that colony (Number Colour-Ringed). Colonies are listed by increasing distance away from the IoM (Distance (km)). *The IoM was surveyed throughout each breeding season (see Methods). Breeding colony size (Size) was categorised as 1 (<50 pairs), 2 (50-100 pairs) or 3 (\geq 100 pairs). N.B. The total number of individual shags checked at a colony (Total Checked) may be lower than indicated total breeding colony size.

Figure legends

Figure 1 Location of (a) Isle of May (IoM) and 27 other breeding colonies and (b) 20 winter roost sites that were surveyed for colour-ringed Shags. Marker colour indicates colony size (see Table 1; white = size 1, grey = size 2, black = size 3). Colony codes are defined in Table 1.

Figure 2 (a) Proportional distribution of distances from natal to observed breeding site within Isle of May for 159 male and 126 female Shags, and the proportions of observed versus randomised dispersal distances (\pm SD) for (b) males and (c) females.

Figure 3 (a) Proportional distribution of directions from natal to observed breeding site within Isle of May for 159 male and 126 female Shags, and the proportions of observed versus randomised dispersal directions (\pm SD) for (b) males and (c) females.

Figure 4 Distributions of dispersal directions for (a) within Isle of May (IoM) (b) outside IoM and (c) within and outside IoM combined. Wedge size represents the number of Shags dispersing in a particular direction.

Figure 5 Total number of adult Shags estimated to have been checked at each colony away from Isle of May (primary y axis), and the total number of colour-ringed adult Shags observed at each colony (secondary y axis).

Figure 6 Overall distribution of observed dispersal distances both within and outside Isle of May. Note the break in the x-axis.
