Summary

Freshwater availability is changing worldwide. Here we quantify 34 trends in terrestrial water storage (TWS) observed by the Gravity Recovery and Climate Experiment (GRACE) satellites during 2002-2016 and categorize their drivers as natural interannual variability, unsustainable groundwater consumption, or climate change. Several of these trends had been lacking thorough investigation and attribution, including massive changes in northwestern China and the Okavango delta. Others are consistent with climate model predictions. This observation-based assessment of how the world's water landscape is responding to human impacts and climate variations provides a blueprint for evaluating and predicting emerging threats to water and food security.

Main Text

Groundwater, soil moisture, surface waters, snow, and ice are dynamic components of the terrestrial water cycle[1, 2, 3]. They are not static on an annual basis (as early water budget analyses supposed), yet absent hydroclimatic shifts or significant anthropogenic stresses they typically remain range-bound. Recent studies have identified locations where terrestrial water storage (TWS; the sum of these five components) appears to be trending below previous ranges, notably where ice sheets or glaciers are diminishing in response to climate change[4, 5] and where groundwater is being withdrawn at an unsustainable rate[6, 7, 8].

Accurate accounting of changes in freshwater availability is essential for predicting regional food supplies, human and ecosystem health, energy generation, and social unrest. Groundwater is particularly difficult to monitor and manage because aquifers are vast and unseen, yet groundwater meets the domestic needs of roughly half of the world's

52 population[9] and boosts food supply by providing for 38% of global consumptive irrigation
53 water usage[10]. Nearly two-thirds of terrestrial aquatic habitats are being increasingly
54 threatened[11] while the precipitation and river discharge that support them are becoming
55 more variable[12]. A recent study[11] estimates that almost 5 billion people live in areas where
56 threats to water security are likely, a situation that will only be exacerbated by climate
57 change, population growth, and human activities. The key environmental challenge of the
58 21st century then may well be one of globally-sustainable water resources management.

59 Much of our knowledge of past and current freshwater availability comes from a
60 limited set of ground-based, point observations. Assessing changes in hydrologic
61 conditions at the global scale is exceedingly difficult using in situ measurements alone, due
62 to the cost of installing and maintaining instrument networks, gaps in those networks, and
63 a lack of digitization and sharing of what data do exist[13]. Satellite remote sensing has
64 proven crucial to monitoring water storage and fluxes in a changing world, enabling a truly
65 global perspective that spans political boundaries[14]. In particular, since its launch in 2002,
66 the GRACE mission[15] has tracked ice sheet and glacier ablation, groundwater depletion,
67 and other TWS changes[16, 17, 18, 19]. On a monthly basis GRACE can resolve TWS changes
68 with sufficient accuracy over scales that approximately range from 200,000 km^2 at low
69 latitudes to 90,000 km^2 near the poles[1]. However, due to GRACE's coarse spatial
70 resolution, inability to partition component mass changes, and the brevity of the time series,
71 proper attribution of the TWS changes requires comprehensive examination of all available
72 auxiliary information and data, which has never before been performed at the global scale.

73 Here we map TWS change rates around the globe based on 14 years (April 2002 –
74 March 2016) of GRACE observations (Figure 1). The GRACE data were processed using

an advanced mass concentration[20] ("mascon") approach that enables improved signal resolution relative to the standard spherical harmonic technique[21]. Best fit linear rates of change after removing the seasonal cycle (referred to herein as "apparent trends") are presented in Table 1 for 34 study regions. For context, the largest man-made reservoir in the U.S., Lake Mead, has a capacity of about 32 Gt; during the study period all but one of the 34 regions lost or gained more water than that and eleven of them lost or gained more than ten times that amount. The reported uncertainty bounds are typically low because error in the removal of glacial isostatic adjustment (GIA) signals is the only major source of noise in the secular signal; low uncertainty does not, on its own, imply that the apparent trends existed before the GRACE period or will continue into the future. The coefficient of determination (r^2), representing the "goodness of fit" of the regressed linear trends, is included in Table 1 to quantify the strength of the apparent trends relative to non-secular interannual variability. It is hence a useful but by no means conclusive piece of evidence for predicting whether the trend will be fleeting or enduring, reflecting the cohesiveness of the TWS time series tendencies in Figures ED1-ED4. We attribute the trends to natural variability, direct human impacts, or climate change and forecast the likelihood that they will continue based on 1979-2016 precipitation data from the Global Precipitation Climatology Project version 2.3 (GPCP)[22] (see Figures ED5-ED8), an irrigated area map[23], satellite-based lake level altimetry time series[24], Landsat imagery, and published reports of human activities including agriculture, mining, reservoir operations, and inter-basin water transfers. Further, for each region we provide the median climate model prediction of precipitation changes between 1986-2005 and 2081-2100, under the Representative Concentration Pathways 8.5 W/m^2 (RCP8.5; "business as usual") greenhouse gas

emissions scenario from the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report[25]. We chose the high-end scenario because it accentuates regional differences, which are more important for this analysis than absolute magnitudes. Figure 2 presents maps of the IPCC, GPCP, and irrigated area data.

Global Scale

By far the largest TWS trends occur in Antarctica (region 1; -127.6 ±39.9 Gt/yr averaged over the continent), Greenland (region 2; -279.0 ±23.2 Gt/yr), the gulf coast of Alaska (region 3; -62.6 ±8.2 Gt/yr), and the Canadian archipelago (region 4; -74.6 ±4.1 Gt/yr), where the warming climate continues to drive rapid ice sheet and glacier ablation[4, 5, 26, 27]. Positive trends in sub-regions of Antarctica and Greenland result from increasing snow accumulation[28]and millennial-scale dynamic thickening processes[29, 30]. Excluding those four ice-covered regions, one of the most striking aspects of changing TWS illuminated by Figure 1 is that freshwater seems to be accumulating in far northern North America (region 5) and Eurasia (region 6) and in the wet tropics, while the greatest non-frozen freshwater losses have occurred at mid-latitudes[8, 31]. The observed trends are consistent with increasing rates of precipitation during the period and the prediction of IPCC models that precipitation generally will decrease in mid-latitudes and increase in low and high latitudes by the end of this century[25]. They also complement recent studies that identify increasing rates of precipitation in the tropics and increasing water storage and river discharge in the high Arctic[12, 32]. However, because the rates of TWS change (0.45 ±0.43 cm/yr and 0.17 ±0.12 cm/yr in regions 5 and 6) and coefficients of determination

120 (0.52 and 0.10) are small, while GIA related errors are relatively large, we cannot state
121 definitively that these high latitude tendencies are real trends.

122 A second distinguishing characteristic of the map is that it reveals a clear 'human
123 fingerprint' on the global water cycle. As seen in Figure 2, freshwater is rapidly
124 disappearing in many of the world's irrigated agricultural regions[6, 10, 33, 34, 35, 36, 37, 38]. A
125 third aspect of the global trend map is natural interannual variability; many of the apparent
126 trends are likely to be temporary, caused by oscillations between dry and wet periods
127 (themselves driven by El Nino / La Nina and other climatic cycles) during the 14-year
128 study period[39, 40].

129

130 **Eurasia**

131 The hotspot in northern India (region 7) was among the first non-polar TWS trends to
132 be revealed by GRACE[41, 42]. It results from groundwater extraction to irrigate crops
133 including wheat and rice in a semi-arid climate. Fifty-four percent of the area is equipped
134 for irrigation. We estimate the rate of TWS depletion to be 19.2 ±1.1 Gt/yr, which is within
135 the range of GRACE based estimates from previous studies of differently-defined northern
136 India regions[41, 42, 43]. The trend persists despite precipitation being 101% of normal
137 (compared with the 1979-2015 GPCP annual mean for the region) during the study period,
138 with an increasing trend of 15.8 mm/yr. That extractions already exceed recharge during
139 normal years does not bode well for groundwater during future droughts. The contribution
140 of Himalayan glacier mass loss to the regional trend is minor[41, 42].

141 The increasing trend in central and southern India (region 8; 9.4 ±0.6 Gt/yr) likely
142 reflects natural variability of (mostly monsoon) precipitation, which was 104% of normal

143 with an increasing rate of 3.7 mm/yr (0.4%/yr). The r^2 value is low (0.24), yet both trends
144 are consistent with the IPCC-RCP8.5 predicted 23% precipitation increase by 2100.
145 The increasing trend in east-central China (region 9) is caused by a surge in dam
146 construction and subsequent reservoir filling across that region[44]. Best known is the Three
147 Gorges Dam Reservoir, which was filled to its design capacity of 39.3 Gt between June
148 2003 and October 2010[45]. The 14-year regional trend, 7.8 ±1.6 Gt/yr, did not change
149 appreciably after the Three Gorges Dam Reservoir was filled. That can be explained by
150 both the prevalence of other dam projects and greater precipitation after 2010 (971 mm/yr)
151 than before (928 mm/yr). Further, seepage from dams tends to raise the regional water
152 table, which can continue for years before the system equilibrates[46]. If precipitation trends
153 towards an 8% increase by the end of this century, as predicted, then the observed TWS
154 trend may persist even after the current dam building boom, though probably at a slower
155 pace.
156 Satellite altimetry and Landsat data indicate that the majority of lakes in the Tibetan
157 Plateau have grown in water level and extent during the 2000s, owing to a combination of
158 elevated precipitation rates and increased glacier melt flows[47] that is difficult to
159 disentangle. From 1997 to 2001 the average annual precipitation in region 10 was 160
160 mm/yr, well below the 2002-2015 average of 175 mm/yr, thus the observed increase in
161 TWS (7.7 ±1.4 Gt/yr) may reflect replenishment after a prolonged dry period. Additional
162 surface water storage would have been partially offset by glacier retreat and warming-
163 enhanced evaporation. GIA may further complicate the partitioning of the GRACE derived
164 mass change signal over the Tibetan Plateau[48], but some have argued that the GIA
165 contribution is negligible[49]. The latter study noted that interannual mass variability in the

region during the GRACE period is large relative to the inferred trend[49]. We concur (r^2 = 0.67) and conclude that there is no basis to extrapolate the apparent TWS trend into the future. In fact, it appears to have reversed in 2013 (Figure ED2). Although IPCC-RCP8.5 predicts a 20% increase in precipitation by 2100, it is probable that warming-induced glacier mass losses will begin to exceed surface water gains, particularly if the fraction of frozen precipitation decreases.

Region 11 lies to the west of the city of Urumqi in northwestern China's Xinjiang province. During the study period TWS depletion was intense: -5.5 ±0.5 Gt/yr from an area of only 215,000 km^2. Precipitation data indicate drought was a nonfactor. The glaciers of the Tien Shan mountain range, whose central third lies within region 11, are melting rapidly[49], but not rapidly enough to explain all of the mass loss. Groundwater is being withdrawn to support irrigated agriculture across the province[50, 51] and possibly to dewater coal mines[52]. However, region 11 is contained within an endorheic basin. Hence the additional surface water produced by ice melt and groundwater abstraction cannot flow far, yet the elevations of the five lakes within that basin either declined or were stable during the study period, and GRACE did not detect significant TWS increases in other parts of the basin. We conclude that region 11 is losing glacier ice and possibly groundwater which ultimately become evapotranspiration, both in irrigated agricultural areas to the north, south, and west of the mountains and as evaporation from the desert floor to the south[50]. Details are provided in the supplementary Methods.

The vast agricultural region surrounding Beijing (region 12) is heavily irrigated (52%). Previous GRACE-based studies offered a wide range of estimates of groundwater depletion from the North China Plain aquifer (see the supplementary Methods for details), which is

encompassed by region 12 and supports much of that irrigation. Here we estimate a TWS change rate of -11.3 ±1.3 Gt/yr for region 12. During the GRACE period annual total precipitation held steady, about 10 mm/yr above the 1979-2015 mean, following two dry years and a wet year during 2001-2003. All evidence suggests that this trend is human induced and likely to continue until groundwater becomes scarce or regulations are put in place to reduce consumption rates.

The negative trend that extends across East India, Bangladesh, Burma, and southern China (region 13), -23.3 ±1.9 Gt/yr, may be explained by a combination of intense irrigation[53] (25%) and a decrease in monsoon season precipitation during the period. Annual total precipitation was well above normal from 1998 to 2001, resulting in elevated TWS. During the GRACE period, precipitation declined at a rate of -10 mm/yr (-0.7%/yr), and the annual accumulations were below average from 2009 to 2015. This is the third most heavily irrigated of the study regions, so TWS decline is likely to continue, though perhaps at a slower rate given that rainfall should normalize eventually and a 15% increase in rainfall is predicted by 2100.

Decreasing water storage in the Middle East has been quantified using GRACE by previous studies[54, 55, 56]. Here we split the affected area into two regions, northwest Saudi Arabia (region 14; -10.5 ±1.5 Gt/yr) and the northern Middle East (region 15; including eastern Turkey, Syria, Iraq, and Iran; -32.1 ±1.5 Gt/yr). The declines result from a combination of recent drought and consequent increases in groundwater demand. Average precipitation during the study period was 78% and 96% of the 1979-2015 means in regions 14 and 15, with a slight declining trend (-1%/yr) in both. While the irrigation dataset indicates that less than 1% of region 14 is irrigated, Landsat imagery reveals the appearance

and expansion of crop irrigation over the past three decades, supplied by non-renewable groundwater. However, the Saudi government ended their domestic wheat production program in market year 2014-15[57]. Thus while some farms have continued to operate, it is likely that the depletion rate in region 14 will diminish, and TWS may already be stabilizing (Figure ED2).

Region 15 has experienced a more complicated recent water history[54, 58]. Turkey's construction of 22 dams upstream on the Tigris and Euphrates Rivers in the last 3 decades has significantly decreased the rate of flow into Iraq and Syria. Combined with long-term drought, this has forced widespread over-reliance on groundwater for both domestic and agricultural needs and largely explains the large negative TWS trend[54, 59]. Surface and groundwater depletion is likely to continue in a stepwise fashion, with periods of near-stability during normal to wet years and rapid declines during drought years.

To the north, an adjoining zone of TWS depletion (region 16; -18.1 ±1.3 Gt/yr) extends from the Ukraine through western Russia and into Kazakhstan. As before, the root cause is competition for scarce water resources, exacerbated by drought. Fifteen percent of the area is irrigated, including fertile croplands that are vital to Russia. Precipitation during the period was 97% of normal with a decreasing trend of 6 mm/yr (1%/yr). As in region 15, surface and groundwater depletion in region 16 is likely to continue as it has, stepwise, with substantial declines during drought years (2008, 2012, and 2014) and lesser recoveries in normal to wet years.

The water demands of regions 15 and 16 place severe pressure on the Aral and Caspian Seas[60] (regions 17 and 18). The demise of the Aral Sea is well known. Our estimate of the mass change in what remains of it is -2.2 ±0.1 Gt/yr. Water level fluctuations in the

Caspian Sea have previously been attributed to meteorological variability[8] and direct evaporation from the Sea[61]. We find that annual discharge from the Volga River explains 60% of the variance in annual mean Caspian Sea level compared with 18% explained by evaporation from the Sea. Interannual variations in Volga River discharge are nearly three times as large as interannual variations in evaporation, and the former are controlled by both precipitation changes and the water demands of crops that cover 37% of the basin. Using crop production data and other information we establish that the -23.7 ±4.2 Gt/yr rate of change of water mass in the Caspian Sea observed by GRACE was caused in part by diversions and direct withdrawals of water from the rivers that sustain it (see the supplemental Methods for details), mirroring the circumstances that doomed the Aral Sea. The Caspian Sea contains about 78,000 Gt of water, so at the current rate it will survive for three more millennia, but a receding shoreline could be an issue.

Three mass changes that are prominent in Figure 1 in Eurasia are not associated with TWS at all. Crustal deformation accompanying the 2004, magnitude 9.1 Sumatra-Andaman earthquake caused two of the mass changes, the dipole positive and negative trends in Sumatra and the Malay Peninsula, respectively[62]. The 2011, magnitude 9.0 Tohoku earthquake caused the negative trend in Japan[63].

North America

Ongoing GIA processes centered near Hudson Bay, where the Laurentide ice sheet was thickest 20-95 thousand years ago, require a correction of the mass rates observed by GRACE of up to 5-6 cm/yr (equivalent height of water)[64, 65]. However, GIA models are imperfect and thus there is large uncertainty in the apparent decreasing TWS trend in

central Canada (region 19) and some evidence that it may reflect an overcorrection of GIA[66]. Nevertheless, here we estimate the rate to be -7.0 ±6.4 Gt/yr. Loss of water would be consistent with a recent study that concluded Canada's subarctic lakes are vulnerable to drying when snow cover declines, and that recent bouts of drying may be unprecedented in the past 200 years[67]. On the other hand, precipitation has been 102% of normal during the GRACE period, and a 17% increase is predicted by the end of the century.

The wetting trend in the northern Great Plains (region 20), 20.2 ±4.8 Gt/yr, arises from a combination of deep drought during 2001 to 2003, which greatly depressed water levels at the start of the GRACE period, followed by nine of the next eleven years having greater than average precipitation, including flooding in 2010-11[68]. The trend is likely to diminish over time although a 7% increase in precipitation is predicted by 2100.

A historically severe drought centered in southern California (region 21) that began in 2007 (ignoring a wet 2010) and consequent increases in groundwater demand[69, 70] conspired to diminish TWS at a rate of -4.2 ±0.4 Gt/yr. While atmospheric rivers during 2016-2017 replenished California's surface waters and policy changes have been enacted, it is doubtful that aquifer storage will recover completely absent significant usage reductions, in part because dewatering of aquifer materials can cause compaction of sediments, reducing aquifer capacity irrevocably[71]. In the Central Valley, which accounts for one third of the vegetables and two thirds of the fruits and nuts grown in the U.S., annual water demands for agriculture have exceeded renewable water resources since the early 20th century[71]. Groundwater well observations that extend back to 1962 suggest that each successive drought causes groundwater levels to step down to a new normal range without full recovery[71], as in regions 15 and 16. Declining winter snowpack in the Sierra

Nevada Mountains, including a 500-year low in 2015[72], is a major concern because it is the main source of the region's surface water supply and groundwater recharge.

Sporadic droughts[73] in region 22, which encompasses parts of the southern High Plains and Texas, produced an apparent trend of -12.2 ±3.6 Gt/yr during the GRACE period. In this case we forecast partial replenishment. Large precipitation variations caused TWS to seesaw between high and low (Figure ED7). Heavy rains that led to flooding in parts of Texas and Oklahoma in May and October of 2015 and again in June of 2016 ended the most recent drought and reduced the linear rate of TWS decline during the GRACE period. On the other hand, withdrawals of groundwater that exceed recharge in the central and southern High Plains aquifer, to support irrigated agriculture, have persisted for decades[74] and will continue until the resource is exhausted or management policies change. The fringes of the aquifer have already run dry in places, and recent estimates predict that the southern High Plains aquifer could be depleted within 30 years[74]. Despite this situation, entrenched water rights are likely to preserve the status quo until the damage forces the hands of policymakers and stakeholders.

South America

Melting of the Patagonian ice fields (region 23) has previously been documented using altimetry[75] and GRACE[76]. Based on our analysis (see the supplemental Methods for details), TWS loss is occurring at a rate of -25.7 ±5.1 Gt/yr. In a warming world, melting of the Patagonian ice fields will continue until they are exhausted.

The magnitude 8.8 Maule (Chile) earthquake that occurred on 27 February 2010 is partly responsible for the apparent trend in Central Argentina[77] (region 24). A model has

not yet been developed to properly separate its effect from TWS variations after that date (Figure ED3). TWS had previously been declining at a rate of -8.6 ±1.2 Gt/yr. The region received substantially elevated precipitation in five of the six years between 1999 and 2004, producing a TWS surplus at the start of the GRACE period. Multi-year drought began in 2009, resulting in the observed April 2002 to February 2010 negative trend. TWS appears to have begun recovering (Figure ED3) in response to above-normal precipitation in 2014 and 2015 (Figure ED7), and we envisage that it will return to mean wetness conditions over time.

TWS increased during the GRACE period in central and western Brazil and its neighbors (region 25) at a rate of 51.9 ±9.4 Gt/yr. The region received less than average rainfall in every year from 2001 to 2005, followed by greater than average rainfall in six of the next ten years. As a result, TWS recovered from the early-period drought[78] and exhibited a massive but transitory increasing trend which may have already ended (Figure ED3). The magnitude is explained by both the size of the region and the intensity of the Amazon water cycle[79]. Still, we note that southern Brazil is a hotbed of dam construction[44], and it is possible that the filling of reservoirs contributed to the upward trend. Eastern Brazil (region 26) recently has suffered from a major drought[80], including well below normal rainfall in 2012, 2014, and 2015, causing TWS to plunge at a mean rate of -16.7 ±2.9 Gt/yr during the GRACE period. In both cases, assuming precipitation rates revert towards (or oscillate around) their long term means, the observed trends should fade. In fact, owing to the recent strong El Nino, 2015 was the driest year in the 37-year record for region 25 (Figure ED7), which may portend a reversion to average TWS.

Africa

Six apparent trends stand out in Africa. In southern Africa, a powerful wetting trend, 29.5 ±3.5 Gt/yr, encompasses the western Zambezi basin, the Okavango delta, and areas west to the coast (region 27). This region experienced a remarkable change in its hydroclimate. Area averaged annual rainfall was less than 970 mm in every year from 1979 to 2005. That threshold was exceeded five times from 2006 to 2011. A permanent climatic shift was previously speculated based on a significant decrease in annual precipitation between 1950-1975 and 1980-2005[81]. With ten years of additional hindsight, it appears that the region may simply have endured a prolonged drought from the late 1970s to the early 2000s. Thus, we attribute the GRACE period trend to natural variability[82]. Though TWS appears to have peaked in 2012 (Figure ED4), considering that the previous wet and dry periods lasted upwards of 25 years it is plausible that the wetting trend could resume.

An apparent trend of 21.9 ±3.9 Gt/yr occurs along the headwaters of the White Nile and Blue Nile Rivers, including Lakes Tanganyika and Victoria (region 28). Altimetry data indicate that during the study period both lakes experienced minimum water levels in 2006 and that their annual mean levels increased by 62 and 40 mm/yr on average, all of which is consistent with the TWS time series. Together, the two lake level trends equate to less than a quarter (4.8 Gt/yr) of the observed TWS trend. Considering that, rainfall would seem to be the primary driver of TWS variations, while management of the large lakes[83] and dam building in the northern part of the region[84] also contribute. However, rainfall is not particularly well correlated with either TWS or lake levels. The lack of correlation may be indicative of inaccuracies stemming from the sparsity of rain gauges in

350 the region. The observed rainfall trend was negligible during the period, but a 12% increase
351 is predicted by 2100. The northern part of region 28 encompasses the Grand Ethiopian
352 Renaissance Dam on the Blue Nile River at Ethiopia's northwest border with Sudan, which
353 Egypt has strongly denounced because of the possibility of reduced flow through the Nile.
354 Construction of the dam began in 2011 and is ongoing. Filling of the 74 km^3 reservoir will
355 likely produce a temporary increasing TWS trend in its immediate vicinity.
356 TWS has been increasing in tropical western Africa (region 29) at a rate of 24.1 ±2.1
357 Gt/yr. Precipitation was 3% below normal in 2000-2002 and 3% above during the rest of
358 the GRACE period. This appears to be the primary cause of TWS accumulation, though
359 the possible contribution of the many dams being built in this part of Africa[44] is unknown.
360 Interannual variability of rainfall is substantial in the region[85], so disregarding the dams, it
361 is likely that the rate of change of TWS will oscillate around zero over the coming decades.
362 By 2100 rainfall is predicted to decrease by 6%, hence the dam construction may be timely.
363 Decreasing TWS (-7.2 ±1.0 Gt/yr) in region 30, which extends from the coast of central
364 Africa into the northern Congo River basin, seems to be caused by natural interannual
365 variability, though it has been suggested that the surface runoff rate has been enhanced by
366 deforestation[84]. Between 1999 and 2002 rainfall averaged 4% above normal, while it
367 averaged 1% below normal during the rest of the GRACE period, including two very dry
368 years in 2014 and 2015. The decrease in TWS also happens to be consistent with the
369 postulated negative correlation between TWS in the Amazon and Congo basins[86], which
370 further implicates large scale climatic oscillation as the ultimate driver[85].
371 The negative trend along the coast of southeastern Africa (region 31), -12.9 ±2.3 Gt/yr,
372 reflects a recent severe drought[79] which has caused major food shortages. Rainfall was 4%

below average during the GRACE period, including annual accumulations that were below normal in five of the last eight years and barely above normal in the other three. Water levels in Lake Malawi, which is in the center of the region, are well correlated with regional TWS. The lake declined at a mean rate of 78 mm/yr during the period, accounting for 2.3 Gt/yr of the observed TWS trend. Thus it is likely that the apparent trend is primarily caused by natural variability[84], though a 6% decrease in rainfall is predicted during this century.

A weak negative trend, -11.7 ±2.9 Gt/yr, extends across arid Africa north of 19°N excluding Morocco (region 32). The coefficient of determination is not large at 0.45, nevertheless, precipitation during the GRACE period was 7% above normal, which suggests that the consumptive use of fossil groundwater to stimulate agriculture and economic development is the cause[55, 84, 87]. Three studies[6, 10, 36] estimated recent rates of consumptive groundwater use across North Africa to be 7.8, 15.7, and 4.1 Gt/yr, bracketing our TWS depletion estimate.

Australia

Australia appears to be bipolar with respect to water storage during the GRACE era, with wetting in the east and north and drying in the northwest. The worst drought in over 100 years afflicted eastern Australia during 2001-09[88]. It is likely that groundwater was more heavily consumed during that time to compensate for reduced availability of surface waters. Recovery from the drought began with heavy rains in 2010 and transitioned to severe flooding in 2011, with so much water stored on the continent in 2012 that global mean sea level temporarily declined[89]. The shift from dry to wet conditions caused the

apparent wetting trend in region 33, 19.0 ±2.8 Gt/yr, but most of that water had already been shed by 2016 (Figure ED4). North Western Australia received greater than normal rainfall during every year from 1997 to 2001, including the two wettest years in the GPCP record in 2000 and 2001. Thus region 34 began 2002 near maximum TWS capacity, and it gradually returned to average[90] (-8.9 ±1.2 Gt/yr) with 99% of normal precipitation during the GRACE period. It is possible that aquifer dewatering associated with Pilbara's mining industry also contributed, but reliable data are not available to confirm and quantify that contribution. We can only justifiably conclude that natural variability is the primary explanation for both Australian trends.

Implications and Discussion

GRACE has revealed significant changes in freshwater resources occurring across the globe, and has enabled them to be quantified at regional scales, unimpeded by sparse measurements or restrictive data access policies. Some of these changes are manifestations of human water management that, prior to GRACE, were known only anecdotally, including TWS depletion in northern India, the north China plain, and the Middle East (regions 7, 12, 14-16), or not at all, as in northwestern China (region 11). They portend a future in which already limited water resources will become even more precious. Others correlate well with global warming and predicted future precipitation changes, including worldwide ice sheet and glacier melt (regions 1-4, 23) and TWS increases in the northern high latitudes (regions 5-6). Apparent TWS trends in about one-third of the study regions represent partial cycles of longer term interannual oscillations, and may well fade or reverse over the decades (see green dots in Figure 1). While we have made every effort to

419 attribute the apparent trends properly, all will require continued observation to better
420 understand their causes and constrain their rates.

421 The GRACE data provide motivation for multilateral cooperation among nations,
422 states, and stakeholders, including development of transboundary water sharing
423 agreements, to balance competing demands and defuse potential conflict[33]. Government
424 policies that incentivize water conservation could help to avert a "tragedy of the commons"
425 scenario, i.e., opportunistic competition for groundwater outweighing the altruistic impulse
426 to preserve the resource. Northern India, the North China Plain, the Middle East, and the
427 area surrounding the Caspian Sea are already on a perilous path, while California, in
428 response to severe drought and alarming groundwater declines in the Central Valley,
429 recently passed legislation to regulate groundwater consumption.

430 In many regions, crop irrigation on massive scales has been supported by unsustainable
431 rates of groundwater abstraction[6, 33, 33, 34, 91]. In the face of aquifer depletion, population
432 growth, and climate change, water and food security will depend upon water saving
433 technologies and improved management and governance. The success of such an approach
434 in arid Israel[92] proves that a comprehensive water conservation strategy can work, and there
435 are encouraging signs in Saudi Arabia (as previously discussed) and parts of India[93] as
436 well. Meanwhile, as China looks to improve living standards for its 1.38 billion residents,
437 it will continue to face daunting water management decisions, many related to massive
438 geoengineering and water diversion projects that are likely to trigger political tensions.

439 The GRACE data also call attention to regions where continued monitoring will be
440 essential for distinguishing, understanding, and quantifying climate change impacts on the
441 water cycle[94, 95] and groundwater[96, 97] in particular. This is important for two reasons. First,

verification of emerging hydroclimatic trends such as increasing northern high latitude precipitation would raise confidence in the ability of climate models to predict water cycle consequences of climate change[98]. Second, a redistribution of freshwater from dry to wet regions, as has been forecast, could exacerbate disparities between the water "haves" and "have nots" and associated political instability, migration, and conflict. Most groundwater depletion is occurring within Earth's mid-latitudes, resulting in a positive drying feedback that is accelerating water losses and the severity of related socioeconomic issues[33].

New and future satellite remote sensing missions that extend the long term record of global, hydrological observations will be essential for continued assessment of changing freshwater availability[99]. In particular, the GRACE Follow On mission (planned to launch in early 2018), while affording a small increase in spatial resolution/accuracy[100], will enable surveillance of the trends described here and improved disentanglement of natural TWS variability from hydroclimatic change. Awareness of changing freshwater availability (e.g., Figure 1) is the first step towards addressing the challenges discussed here, through improved infrastructure, water use efficiency, lifestyle and water management decisions, and policy.

Table 1. TWS trends and supporting information. Location, area, GRACE terrestrial water storage trend (April 2002 – March 2016) and uncertainty, coefficient of determination (r^2) of the fitted linear trend, percentage of the area equipped for irrigation[23], trend in precipitation[22] (January 2002 to March 2016) after removing the seasonal cycle, annual mean precipitation (2003-2015) as a percentage of the long term (1979-2015) annual mean[22], and median predicted change in precipitation between 1986-2005 and 2081-2100 in the IPCC high end greenhouse gas emissions scenario[25] for each of the 34 study regions. *The TWS Trend in Region 24 is for April 2002 – February 2010 only.

Figure Captions

Figure 1. Annotated map of terrestrial water storage trends. Trends in TWS (cm/yr) based on GRACE observations from April 2002 to March 2016. The cause of the trend in each outlined study region is briefly explained and color coded by category. The trend map was smoothed with a 150 km radius Gaussian filter for the purpose of visualization, however, all calculations were performed at the native 3° resolution of the data product.

Figure 2. Trends in terrestrial water storage and supporting data maps. (Bottom to top) TWS trends (cm/yr); percentage of area equipped for irrigation[23] (%); trend in precipitation[22]; mean annual precipitation (2003-2015) as a percentage of the long term mean[22]; IPCC predicted change in precipitation[25]. Areas outside of the study regions are shaded.

Methods

GRACE data have traditionally been processed by solving for gravity anomalies in terms of Stokes coefficients[101, 102, 103, 104, 105, 106]. These solutions suffer from correlated errors that manifest as longitudinal striping in the gravity solution, requiring tailored "destriping" and smoothing post-processing filters to remove[107]. While largely successful in removing errors, the post-processing also damps and smooths real geophysical signals[101]. Recent advances in GRACE data processing have shown that solving for gravity anomalies in terms of mass concentration (`mascon') functions with carefully selected regularization results in superior localization of signals on an elliptical Earth[4, 21, 108, 109]. For instance, mascon solutions correlate better with in-situ ocean bottom pressure recorders than spherical harmonic solutions[21, 109], improve the spatial resolution of mass changes in Greenland[29], and were used to detect changes in the Atlantic Meridional Overturning Circulation[110]. Currently, there are three publicly available GRACE mascon solutions: Jet Propulsion Laboratory mascons RL05M.1 version 2[21, 111] (JPL-M), Center for Space Research mascons RL05M[109] (CSR-M), and Goddard Space Flight Center mascons version 2.3b[4] (GSFC-M). JPL-M parameterizes the gravity field with 4,551 equal-area 3° mascon elements, while CSR-M and GSFC-M both parameterize the gravity field in terms of 1° mascon elements (~41,000 mascon elements are solved for in each solution). The implementation details of each mascon solution differs, but we note that the JPL solution has the unique characteristic that each 3° mascon element is relatively uncorrelated with neighboring mascon elements, while the 1° mascon elements in the CSR and GSFC are highly correlated with their neighbors. Three degrees corresponds approximately to the 'native' resolution of GRACE, and being uncorrelated with one another in the retrieval

allows for a quantitative understanding of leakage errors when aggregating mass anomalies within a hydrological basin[112]; in fact, no literature yet exists on quantifying leakage errors in 1° mascon solutions. As such, in this manuscript, we use the JPL RL05M GRACE mascon solution for trend analysis and mapping; however, we use all (i.e., JPL-M, CSR-M, and GSFC-M) mascon solutions to derive uncertainties.

The JPL RL05M GRACE mascon solution parameterizes each monthly gravity field in terms of 4,551 equal-area surface spherical cap mass concentration functions, and uses a regularization approach that implements both spatial and temporal correlations to remove correlated errors during the gravity inversion. A Coastline Resolution Improvement (CRI) filter is used to separate between land and ocean mass within mascons that span coastlines[112]. GRACE does not produce a reliable estimate of the Earth's oblateness (C_{20} coefficient), and as such, we follow the standard protocol of using Satellite Laser Ranging to provide this estimate[113]. Further, GRACE gravity field anomalies are measured in the center of mass Earth reference frame, and therefore need to be augmented with a 'geocenter' estimate to capture all surface mass changes[114]. GIA corrections are made using the updated ICE-6G_D model[64, 65], with an exception for Antarctica, for which we reduce the fitted rate of mass change by 9.2 Gt/yr based on a regional model[115] that potentially provides a better GIA estimate for Antarctica[116]. Finally, corrections are made to the C_{21} and S_{21} coefficients[117] in order to fully remove the pole tide from the GRACE data. Jumps in the background atmosphere and ocean dealiasing product are corrected as well[118].

Prior to computing the best fit linear trend from a TWS time series, the seasonal cycle was removed as follows. First, missing months of data were filled by linear interpolation.

849 Next, the mean monthly seasonal cycle was computed by averaging all Januarys, all
850 Februarys, etc. Finally, for each month in the original, non-gap-filled time series, the mean
851 for the corresponding month of the year was subtracted. The first step, gap filling, was
852 necessary because, for example, the month of May was under-sampled in the second half
853 of the study period, which caused the mean May to be biased in locations where a consistent
854 trend existed (i.e., most of the regions of this study).

855 Trend error estimates account for both systematic and random GRACE measurement
856 errors as well as systematic GIA model error. GRACE measurement error is taken to be
857 the 1-sigma standard deviation between trend estimates obtained from JPL-M, CSR-M,
858 and GSFC-M. Given the specific basin boundaries used in this study, we find JPL-M to
859 have more pronounced trends (both positive and negative) than CSR-M and GSFC-M,
860 which is consistent with previous conclusions[119]. This spread is due to a fundamental
861 difference in the spectral content between the 3° mascons and 1° mascons, implying that
862 leakage characteristics are different when aggregating mass anomalies over a particular
863 region (somewhat counter-intuitively, the 3° mascons 'focus' more signal than the 1°
864 sampled mascons). In essence, the 'smooth' nature of the 1° mascon solutions (CSR-M
865 and GSFC-M) results in significant damping of signal over our regions of interest due to
866 leakage across the basin boundaries. For a more direct comparison of the three solutions
867 over our regions of interest, we matched the spectral content of JPL-M to that of CSR-M.
868 The regularization of the CSR mascon solution is based on a 200 km Gaussian smoothed
869 representation of a regularized spherical harmonic solution[109]; hence, it is expected that the
870 final mascon solution will inherit some of these spectral characteristics. Thus, we smooth
871 JPL-M with a Gaussian filter with a 200 km radius, and compare trend estimates of the

872 smoothed version of JPL-M to CSR-M and GSFC-M. The agreement is now significantly
873 better, and trends in the smoothed version of JPL-M are now also damped similarly to
874 CSR-M and GSFC-M (see Figure ED9 for an example). Analog analysis has been
875 performed before by others in studying mass variations over the Caspian Sea[120]. We use
876 the 1-sigma standard deviation of trend estimates obtained from the smoothed version of
877 JPL-M, CSR-M, and GSFC-M to derive the GRACE measurement errors. GIA model
878 error is taken to be the 1-sigma spread between four competing GIA models[64, 65, 121, 122, 123,
879 124] that implement two distinct loading histories, four distinct viscosity profiles, and
880 different implementation of physics. The uncertainty on the trend for any region is given
881 by the root sum of squares combining the GIA model error (which only manifests as a
882 trend) and the GRACE measurement error.

883 Time series for the Aral and Caspian Seas (regions 17 and 18) were calculated by
884 applying a set of gain factors to the GRACE data. Gain factors act to redistribute mass
885 within each individual mascon (at sub-mascon resolution), allowing for exact averaging
886 kernels to be applied to a region of interest and retrieval of accurate, unbiased (by leakage)
887 mass change values[112,125]. These particular gain factors were derived[112] via a combination
888 of total column soil moisture output from the Noah land surface model driven by the Global
889 Land Data Assimilation System[100] (which does not include sea water variations) along with
890 altimetry data[127] over the Seas.

891 Recent variations in Caspian Sea Level have been attributed by previous studies to
892 natural meteorological variability[8] and direct evaporation from the sea surface[61]. We tested
893 these two theories and a third, agricultural water consumption. Flow in the Volga River,
894 which delivers roughly 80% of the runoff to the Caspian Sea, is controlled by a series of

eleven dams[128]. Among other purposes these ensure a steady supply of water for crop irrigation[128]. Data to quantify interannual variations in irrigation extent, intensity, or volumes in the Caspian Sea drainage basin during the study period were not available. Estimates of Russian wheat, maize, rice, and soybean annual production[129] (in tons) during 1992-2015 were obtained from the Organisation for Economic Co-operation and Development (OECD). According to the irrigation dataset[23], the Volga River basin, which drains to the Caspian Sea, includes 3% irrigated crops and 37% rain-fed crops by area, and it accounts for about half of all Russian crop production, so the latter is a fair but imperfect indicator of agricultural water demand in the basin. Yearly total production was normalized by subtracting the 24-year mean and dividing by the standard deviation. Normalization was similarly performed on annual time series of GPCP precipitation[22] over the Caspian Sea and Volga River drainage basins, Volga River discharge, reanalysis based Caspian Sea evaporation[130], and changes in Caspian Sea level from satellite altimetry[24]. Correlation coefficients (and significance levels) between normalized Caspian Sea level change and its significant drivers (Figure ED10) were 0.78 (Volga River discharge; $p<0.001$), -0.47 (crop production; $p=0.02$), -0.43 (Caspian Sea evaporation; $p=0.04$), and 0.41 (Caspian Sea drainage basin precipitation; $p=0.05$). Correlation coefficients (and significance levels) between normalized Volga River discharge and significant drivers were 0.52 (Volga River basin precipitation; $p=0.01$) and -0.40 (crop production; $p=0.06$). Notably, the correlation between crop production and precipitation was negligible, suggesting that irrigation effectively mitigates the impact of drought. Interannual variations in Caspian Sea evaporation do, indeed, contribute significantly to Caspian Sea level changes. However, annual Volga River discharge variations are better correlated with

918 annual changes in Caspian Sea level, they are larger than variations in Caspian Sea
919 evaporation (standard deviation of 48 Gt vs. 18 Gt, compared with 38 Gt mean magnitude
920 of annual Caspian Sea level change), and they are controlled by both precipitation and
921 rising agricultural water demand[128]. We therefore conclude that all three factors
922 contributed to the observed water loss (-23.7 ±4.2 Gt/yr based on GRACE, ignoring steric
923 effects; -25.4 Gt/yr based on satellite altimetry) during 2002-2015.

924 For the Gulf Coast of Alaska and Patagonian Ice Fields (regions 3 and 23) it was also
925 necessary to increase the rates of mass loss (by 7 Gt/yr and 9 Gt/yr, respectively) to account
926 for Little Ice Age GIA[31]. Note the full GIA corrections to Antarctica, the Gulf Coast of
927 Alaska, and the Patagonian Ice Fields are not incorporated into Figures ED1 and ED3.

928 The irrigated area percentages (Table 1) were computed by area-weighted averaging of
929 the individual pixel values of irrigation intensity[23] (%) within each study region.
930 Precipitation trends (mm/yr) were computed based on monthly data[22] as above for TWS,
931 except that there were no gaps to fill. Precipitation trends (%/yr) and precipitation
932 percentages of normal were computed using the 1979-2015 annual mean precipitation
933 totals for each region. Predicted precipitation changes were computed as area weighted
934 averages from the IPCC dataset[25] over the study regions. The precipitation maps in Figure
935 2 were computed as above but on a pixel by pixel basis.

936 The explanation for the mass loss trend in northwest China (region 11), -5.5 ±0.5 Gt/yr,
937 is complex. Drought was not a factor given that precipitation was 10% above normal and
938 stable during the period. Two recent studies[131, 132] estimated the rate of glacier loss over
939 the entire Tien Shan mountain range to be -5.4 ±2.9 Gt/yr and -7.5 ±3.4 Gt/yr based on Ice,
940 Cloud and Land Elevation Satellite (ICESat) observations from 2003 to 2009. These

941 estimates are somewhat smaller than our GRACE based estimate of TWS decline in region
942 11 during that period (-8.3 ±0.8 Gt/yr), despite region 11 encompassing less than half of
943 the area of glacier melt[131]. Thus we conjecture that an additional catalyst for mass loss
944 must exist. Xinjiang province is one of the world's largest producers of coal, having an
945 estimated 2.2 trillion tons of reserves[133]. Reported rates of coal removal and burning
946 themselves are more than an order of magnitude smaller than the GRACE-observed mass
947 loss[133], but mining involves dewatering of the aquifers that the mines intersect. Consequent
948 groundwater depletion in the area is possible[52] but unconfirmed. Adding to the complexity,
949 region 11 lies within a larger, endorheic basin, meaning that water pumped from the ground
950 or melting from glaciers will remain as surface water, become groundwater recharge,
951 and/or evapotranspire, as opposed to flowing to the ocean. However, based on satellite
952 altimetry data, the elevations of the five lakes within the surrounding endorheic basin did
953 not increase during the study period. All either declined or did not change significantly.
954 The two lowlands into which region 11 drains (one northwest, one southeast) have
955 GRACE-based trends of 0.3 and -0.6 Gt/yr (both insignificant). Ultimately
956 evapotranspiration must account for the water lost from region 11. The average annual
957 precipitation in region 11 is 194 mm/yr, making it the fourth driest of the 32 study regions.
958 The endorheic basin is extensively irrigated, including 7% of region 11, and irrigation
959 intensity is likely rising in support of Xinjiang province's population growth (18.2 million
960 to 21.8 million between 2000 and 2010)[51]. Massive amounts of surface water from Lake
961 Bosten and the Kongque River (both southeast of region 11) are transferred via aqueducts
962 southward to the Tarim River in order to support farming in the arid plains, yet the Tarim
963 River runs dry before reaching its natural terminus, Lop Nor lake[50]. To summarize, the

Tien Shan mountain glaciers in region 11 are shrinking due to global warming. Groundwater may be declining due to agricultural withdrawals and/or mining operations, but the latter is unconfirmed. Because region 11 lies within an endorheic basin, neither glacier melt nor groundwater pumping can alone explain the observed TWS depletion. The corollary is that the resulting additions to surface water are balanced by desert- and irrigation-enhanced evapotranspiration.

As noted in the main text, previous GRACE based studies of the North China Plain (region 12), while agreeing that groundwater depletion associated with intense irrigation was the cause, offered a wide range of estimates of the TWS or groundwater trend. Specifically, put into common units, these estimates equated to -8.3 Gt/yr over a 370,000 km^2 area[134], -35 Gt/yr over a 2,086,000 km^2 area[135], -2.33 Gt/yr over a 370,000 km^2 area[136], and -14.09 Gt/yr over a 1,500,000 km^2 area[137], compared with our estimate of -11.3 Gt/yr over a 876,004 km^2 area.

Data Availability

Specific sources of data used in this study were the following. The primary GRACE TWS dataset is JPL Mascon RL05M.1 version 2 was accessed 3 February 2017 from https://grace.jpl.nasa.gov/data/get-data/jpl_global_mascons/. Additional GRACE TWS datasets used to estimate errors were CSR RL05 Mascon version 1 accessed 20 September 2017 from http://www2.csr.utexas.edu/grace/RL05_mascons.html and GSFC Mascon version 2.3b accessed 5 October 2017 from https://neptune.gsfc.nasa.gov/gngphys/index.php?section=413. Primary GIA data used in this study were the ICE-6GD model accessed 1 December 2017 from

http://www.atmosp.physics.utoronto.ca/~peltier/data.php and the IJ05_R2 GIA correction for Antarctica accessed 3 February 2018 from http://onlinelibrary.wiley.com/doi/10.1002/jgrb.50208/full. Additional GIA data used to compute GIA model error included ICE-6G_ANU_D accessed 3 February 2018 from http://onlinelibrary.wiley.com/doi/10.1002/2017JB014930/full, the A et al. (2013) GIA model accessed 16 December 2013 from ftp://podaac-ftp.jpl.nasa.gov/allData/tellus/L3/pgr/, and the Paulson et al. (2007) GIA model accessed 3 February 2018 from https://academic.oup.com/gji/article/171/2/497/2018541. Atmosphere and ocean dealiasing product jump corrections were accessed 13 June 2016 from ftp://podaac-ftp.jpl.nasa.gov/allData/grace/docs/. GPCP version 2.3 precipitation data were accessed 23 September 2016 from https://www.esrl.noaa.gov/psd/data/gridded/data.gpcp.html. Global Rain-fed Irrigation and Paddy Croplands version 1 data were accessed 12 September 2016 from http://ftp-earth.bu.edu/public/friedl/GRIPCmap/. Global Reservoirs/Lakes elevation version TPJO.2.3 data were accessed 29 July 2016 from https://ipad.fas.usda.gov/cropexplorer/global_reservoir/. IPCC 5th Assessment Report (RCP8.5) predicted precipitation change data were accessed 1 September 2016 from https://www.ipcc.ch/pdf/assessment-report/ar5/wg1/WG1AR5_AnnexI_FINAL.pdf. Russian crop production data were accessed 16 August 2017 from https://data.oecd.org/agroutput/crop-production.htm. Latent heat flux (evapotranspiration) data for the Caspian Sea and its drainage basin were extracted from MERRA2 Land Surface Diagnostics version M2TMNXLND_5.12.4, accessed 19 September 2017 from https://disc.sci.gsfc.nasa.gov/datasets/M2TMNXLND_5.12.4/summary. Volga River

discharge observations are restricted from public access, but a time series of normalized annual discharge values was provided to M.R. by Valentina Khan of the Hydrometeorological Research Center of the Russian Federation.

The JPL RL05M GRACE solution used in this study is identical to that which is available from the NASA/JPL GRACE Tellus website with exception that we implemented a different GIA model, a correction to the pole tide, and corrections to the background atmosphere/ocean dealiasing model. These adjustments are available from D.N.W. upon request. Data analyzed to create Figure ED9 are available from D.N.R. upon request. Excel spreadsheets containing the data and calculations used to create Table 1 and Figure ED10 are available from M.R. upon request.

Code Availability

GRACE based TWS time series for the study regions were prepared, including GIA adjustments, C_{21} and S_{21} coefficient replacements, and corrections due to jumps in the atmosphere and ocean dealiasing products, using MATLAB scripts. These are available upon reasonable request from D.N.W. TWS time series analyses, including trend estimation and r^2 computation, were performed within Excel spreadsheets, which are available from M.R. upon reasonable request.

Extended Data Captions

Figure ED1. Non-seasonal TWS anomalies: global regions. Time series of monthly TWS anomalies (departures from the period mean) from GRACE, after removing the mean seasonal cycle, averaged over each of study regions 1-6 (panels a-f), as equivalent heights of liquid water (cm). Note that the y-axes vary among panels.

Figure ED2. Non-seasonal TWS anomalies: Eurasia. As in Figure ED1, for regions 7-18 (panels a-l).

Figure ED3. Non-seasonal TWS anomalies: North and South America. As in Figure ED1, for regions 19-26 (panels a-h).

Figure ED4. Non-seasonal TWS anomalies: Africa and Australia. As in Figure ED1, for regions 27-34 (panels a-h).

Figure ED5. Annual precipitation totals: global regions. Time series of annual precipitation totals (mm) averaged over each of study regions 1-6 (panels a-f), based on GPCP v.2.3. Note that the y-axes vary among panels.

Figure ED6. Annual precipitation totals: Eurasia. As in Figure ED5, for regions 7-18 and the full drainage basins of the Aral and Caspian Seas (panels a-n).

Figure ED7. Annual precipitation totals: North and South America. As in Figure ED5, for regions 19-26 (panels a-h).

Figure ED8. Annual precipitation totals: Africa and Australia. As in Figure ED5, for regions 27-34 (panels a-h).

Figure ED9. Comparison of TWS trends (cm/yr) over India (January 2003 – March 2016) from three GRACE mascon solutions. JPL-M 3° (panel a), CSR-M 1°

(b), GSFC-M 1° (c), and JPL-M smoothed with a 200 km radius Gaussian filter and plotted at 1° (d). Notice the similarity between the latter three trend maps, whose regional trend amplitudes have all been dampened by smoothing.

Figure ED10. Comparison of normalized anomalies of Caspian Sea level changes and three primary drivers. Normalized anomalies of (1) changes in annual mean Caspian Sea level, (2) Volga River discharge, (3) Russian total crop weight, and (4) Caspian Sea evaporation. Precipitation (Figure ED2) is the other primary driver. Sea level change is positively correlated with Volga River discharge is and negatively correlated with Russian crop weight and evaporation.

Author Correction: Emerging trends in global freshwater availability

M. Rodell, J. S. Famiglietti, D. N. Wiese, J. T. Reager, H. K. Beaudoing, F. W. Landerer & M.-H. Lo

Correction to: *Nature* https://doi.org/10.1038/s41586-018-0123-1, published online 16 May 2018.

In Fig. 2 of this Analysis, the tick-mark labels on the colour bars in the second and third images from the top were inadvertently swapped. In addition, the citation at the end of the sentence, "On a monthly basis GRACE can resolve TWS changes with sufficient accuracy over scales that range from approximately 200,000 km^2 at low latitudes to about 90,000 km^2 near the poles" should be to ref. [4] not ref. [1]. These errors have been corrected online.
