26    Significant Points:

27    1. Ambient measurements of sub-1.0 hygroscopic growth factor ($GF$) and $f$(RH)

28    2. Measured in multiple regions based on three instruments

29    3. Sub-1.0 $GF$s and $f$(RH) are observed consistently in biomass burning plumes

30    4. Reasons include particle restructuring, optical effects, and volatilization

31

**Abstract**

This study reports on the first set of ambient observations of sub-1.0 hygroscopicity values (i.e., growth factor, ratio of humidified-to-dry diameter, $GF=D_{p,wet}/D_{p,dry}$ and $f$(RH), ratio of humidified-to-dry scattering coefficients, less than 1) with consistency across different instruments, regions, and platforms. We utilized data from (i) a shipboard humidified tandem differential mobility analyzer (HTDMA) during Eastern Pacific Emitted Aerosol Cloud Experiment (E-PEACE) in 2011, (ii) multiple instruments on the DC-8 aircraft during Studies of Emissions, Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys (SEAC⁴RS) in 2013, as well as (iii) the Differential Aerosol Sizing and Hygroscopicity Spectrometer Probe (DASH-SP) during measurement intensives during Summer 2014 and Winter 2015 in Tucson, Arizona. Sub-1.0 $GF$s were observed across the range of relative humidity (RH) investigated (75-95%), and did not show a RH-dependent trend in value below 1.0 or frequency of occurrence. A commonality between suppressed hygroscopicity in these experiments, including sub-1.0 $GF$, was the presence of smoke. Evidence of externally mixed aerosol, and thus multiple $GF$s, was observed during smoke periods resulting in at least one mode with $GF < 1$. Time periods during which the DASH-SP detected externally mixed aerosol coincide with sub-1.0 $f$(RH) observations. Mechanisms responsible for sub-1.0 hygroscopicity are discussed and include refractive index (RI) modifications due to aqueous processing, particle restructuring, and volatilization effects. To further investigate ambient observations of sub-1.0 $GF$s, $f$(RH), and particle restructuring, modifying hygroscopicity instruments with pre-humidification modules is recommended.

55

## Introduction

Aerosol-water interactions influence how particles scatter solar radiation, their ability to serve as cloud condensation nuclei (CCN), and where they deposit in the human respiratory system [*Dua and Hopke*, 1996]. These interactions are also important to account for with regard to remote sensing retrievals of aerosol particles due to biases that result from aerosol swelling in moist areas such as next to clouds, in addition to attempts of using retrieved columnar aerosol data to estimate surface fine particular matter ($PM_{2.5}$) [e.g., *Kim et al.*, 2015]. Representing the ability to take up water vapor at fixed relative humidity (RH), hygroscopicity is a property of particles dependent on size and composition. Improving the understanding of aerosol hygroscopicity will improve predictability of future climate, as aerosol interactions with water vapor and clouds are linked to the largest sources of uncertainty in estimates of the total anthropogenic radiative forcing [*IPCC*, 2013].

In order to study aerosol hygroscopicity in the atmosphere, a number of instruments have been developed. Traditionally, the Humidified Tandem Differential Mobility Analyzer [HTDMA; *Liu*, 1978; *Rader and Mcmurry*, 1986] has been used for sub-saturated aerosol water uptake measurements; however, the long sampling time required to scan through a complete size distribution is impractical for aircraft applications. The Differential Aerosol Sizing and Hygroscopicity Spectrometer Probe [DASH-SP, Brechtel Mfg. Inc.; *A. Sorooshian et al.*, 2008a] is a newer instrument designed specifically for aircraft-based, rapid, size-resolved measurements of aerosol sub-saturated hygroscopicity using two optical particle counters (OPCs) to measure scattering from a dried and a humidified channel. Both instruments quantify hygroscopic growth factor (*GF*), defined as the ratio of humidified particle diameter to a fixed, single diameter at dry

78 conditions ($GF = D_{p,wet}/D_{p,dry}$). Nephelometer-based instruments quantify hygroscopicity for bulk

79 aerosol using the parameter $f$(RH), which is the ratio of light scattering from all particle sizes in

80 humid (typically RH of ~80%) versus dry conditions (typically RH less than 20%). While the

81 nephelometer-based instruments are rapid and suited for aircraft measurements, two key

82 differences with the previous two techniques are that $f$(RH) data are not size-resolved and have

83 limitations in terms of probing RHs above 85% [*Kreidenweis and Asa-Awuku*, 2014].

84     While extensive research has reported on *GF* and $f$(RH) values extending from unity (i.e., no

85 growth upon hydration) to higher values, only a few studies based on laboratory work, summarized

86 below, have reported sub-1.0 hygroscopic growth, suggestive of particle size shrinkage upon

87 hydration. Sub-1.0 hygroscopicity results when the humidified diameter is less than the original

88 dry diameter ($D_{p,dry}$) for *GF* measurements, and when the total scattering of humidified ambient

89 air is less than dried ambient air for $f$(RH) measurements. In terms of the single-parameter kappa

90 (κ) developed by *Petters and Kreidenweis,* [2007], which is related to *GF* as shown by the

91 approximation in Equation 1, sub-1.0 hygroscopic growth would correspond to κ < 0:

$$[GF]^3 = 1 + \kappa \left( \frac{\frac{RH}{100\%}}{1 - \frac{RH}{100\%}} \right) \qquad (1)$$

92

93     A range of explanations for sub-1.0 hygroscopicity have been discussed in past laboratory-

94 based studies including surface-active organic species [*Petters and Kreidenweis*, 2013], slightly

95 soluble organic compounds [*Petters and Kreidenweis*, 2008], and elemental carbon restructuring

96 [*Tritscher et al.*, 2011]. The majority of the literature has been devoted to particle restructuring.

97 For example, flame-produced soot from diesel and propane combustion shows evidence of particle

98 restructuring at an RH as low as 35% [*Henning et al.*, 2012]. Using a similar source, *Weingartner*

99 *et al.* [1997] concluded the restructuring process was still occurring and had not reached steady

100   state with RH up to 80%. Soot from a propane diffusion flame can undergo morphological

101   transformations, from chain-like to compact structure, as coagulation time increases, which is

102   explained by Coulomb interactions between parts of the aggregated soot particle [*Onischuk et al.*,

103   2003]. Another study showed that soot restructuring in acetylene and ethylene burner emissions

104   occurs upon evaporation and is likely attributed to capillary effects [*Ma et al.*, 2013]. Hydrophilic

105   soot particles collapse into globules with increased RH [*Mikhailov et al.*, 2006], yet when diluted

106   with warm particle-free air, their fractal structure stays intact until humidification RH > 90%

107   [*Rissler et al.*, 2005].

108       Non-burner emitted particles also demonstrate restructuring behavior. *Jimenez et al.*

109   [2003] observed that diiodomethane ($CH_2I_2$) particles formed under dry conditions were fractal

110   agglomerates, until reaching higher RHs when they became more compact and dense particles.

111   Upon hydration, there is evidence that biomass burning combustion particles of 100 nm or larger

112   are more readily restructured [*Martin et al.*, 2013], and the decrease in mobility diameter upon

113   humidification is more pronounced for larger particles [*Pagels et al.*, 2009]. *Weingartner et al.*

114   [1995] found that organic particles above 100 nm shrank into a more compact structure at RH =

115   90% due to capillary forces induced on any asymmetrical part of the structure. *Lewis et al.* [2009]

116   reported that wood smoke from combustion of chamise and palmetto collapse to a more spherical

117   and compact shape upon exposure to high RH, while smoke from ponderosa pine, with lower

118   inorganic content did not show this behavior.

119       While many studies have reported on particle size shrinking upon hydration from fuel

120   burners, wood smoke, and soot, a number of laboratory studies focused on inorganic salts have

121   found similar evidence, indicating the mechanism is not limited to organic-containing particles.

122   Aggregated inorganic salt particles shrank after exposure to enhanced RHs (> 60%) and the degree

123   of particle shrinkage was greater for aggregates of larger initial size and larger increases in RH

124   [*Montgomery et al.*, 2015]; a potential mechanism governing the structural change was suggested

125   to be linked to surface tension owing to water adsorption within the aggregate structure. At low

126   RH (< 50%), restructuring from hydration of $(NH_4)_2SO_4$ has been shown to have stronger effects

127   on particle mobility diameter than the adsorption or absorption of water [*Mikhailov et al.*, 2009].

128   In a study of inorganic salts, observations of the structural rearrangement of $NH_4NO_3$, $(NH_4)_2SO_4$,

129   NaCl, and $NaNO_3$ indicated that particle size decreased by up to 10% due to chemical reactions

130   and evaporation upon hydration when exposed to RHs below each salts' respective deliquescence

131   RH [*Gysel et al.*, 2002; *Mikhailov et al.*, 2004].

132        Particle coating and photochemical aging affects the ability, degree, and onset of particle

133   restructuring.  Delayed and reduced hygroscopic growth has been observed with combustion

134   particles coated with $H_2SO_4$ [*Zhang et al.*, 2008], glutaric acid [*Xue et al.*, 2009], surfactant

135   organics [*Dusek et al.*, 2011], dioctyl sebacate (DOS) and oleic acid [*Ghazi and Olfert*, 2013],

136   anthropogenic secondary organic aerosol [*Schnitzler et al.*, 2014], and soot with a hydrophilic

137   coating [*Pagels et al.*, 2009]. Aging soot in the presence of isoprene results in increased mass with

138   decreased particle mobility diameter and increased effective density, as coating material fills in

139   void spaces and causes partial restructuring of fractal soot aggregates [*Khalizov et al.*, 2013].

140   Photochemical processing of fresh wood smoke was found to physically convert the fractal nature

141   of smoke particles into a more spherical shape in addition to concurrent chemical transformations

142   [*Giordano et al.*, 2013; *Giordano and Asa-Awuku*, 2014].

143        Particle morphological changes upon hydration, including shrinkage due to restructuring,

144   alters particle light absorption and scattering characteristics. Restructuring by neutralization

145   surface reactions has been suggested to explain reduction in light absorption cross section upon

146  hydration of laboratory generated mixtures of black carbon (BC) and brown carbon (BrC) particles

147  at low humidity; however, upon RH increase, continued water uptake by inorganic coatings can

148  lead to absorption enhancement [*Chen et al.*, 2015]. In polluted, humid conditions, it has been

149  observed that hygroscopic particles absorb water, growing in size and enhancing light scattering,

150  but mass absorption cross section decreases, likely due to shielding effects of absorbing aerosols

151  [*S Lee et al.*, 2012]. *Dennis-Smither et al.* [2012] observed that refractive indices of organic aerosol

152  increased during and after evaporation of volatile products, concluding that aging followed by

153  slow restructuring in particle morphology was responsible for this behavior.

154      The goal of this study is to report ambient observations of sub-1.0 hygroscopic growth (*GF*

155  and *f*(RH)), and consequently sub-0 $\kappa$, from three field projects: Eastern Pacific Emitted Aerosol

156  Cloud Experiment (E-PEACE) in 2011; Studies of Emissions, Atmospheric Composition, Clouds

157  and Climate Coupling by Regional Surveys (SEAC$^4$RS) in 2013; and observations from

158  measurement intensive periods at the Tucson Aerosol Characterization Observatory (TACO)

159  between 2014 and 2015.  All three field studies included measurements of aerosol hygroscopicity

160  as well as other chemical and meteorological observations. Possible causes for sub-1.0

161  hygroscopicity will be discussed in addition to suggested strategies for probing this phenomenon

162  in greater detail for future studies.

163

164  **2.      Experimental Methods**

165  **2.1      Field Observations and Instrumentation**

166  **2.1.1   E-PEACE Field Campaign**

167    E-PEACE was a multiplatform field study focused on the coastal zone of California during

168    July–August 2011, investigating aerosol-cloud-precipitation-radiation interactions [*Russell et al.*,

169    2013]. The project involved the use of the Center for Interdisciplinary Remotely-Piloted Aircraft

170    Studies (CIRPAS) Twin Otter, based in Marina, CA, and the R/V *Point Sur*, which conducted a

171    12-day research cruise (12–23 July). Specifics of the campaign and results are detailed elsewhere

172    [*Russell et al.*, 2013; *Wonaschütz et al.*, 2013; *Wang et al.*, 2014; *Jung et al.*, 2015; *Modini et al.*,

173    2015]. This work utilizes data only from the R/V *Point Sur*, on board which smoke generators

174    used gasoline and heated paraffin-type oil with low vaporization temperature (150˚C) to emit

175    smoke in the marine boundary layer. An organic plume of thick condensed smoke and vapor was

176    emitted into the marine atmosphere and measured from R/V *Point Sur* itself with an extensive

177    payload of instruments [*Russell et al.*, 2013].

178    Of most relevance from the R/V *Point Sur* instrument payload was an HTDMA, which

179    measured hygroscopic growth with two DMAs, one dry (RH < 8%) and one humidified at varying

180    RH settings (40, 70, 85, and 92%), with uncertainty in *GF* of ± 0.03 [*Lopez-Yglesias et al.*, 2014].

181    Dry particle diameters selected were 30, 75, 150, and 300 nm. To allow for more meaningful

182    intercomparisons with measurements from other experiments pertaining to our investigation, we

183    only use data for the two highest RH set points (85 and 92%) at dry sizes of 150 and 300 nm.

184    Smoke emissions emitted by the ship and then sampled by the ship on 17 July 2011 constitute a

185    key case study. Plume tracking, meteorological conditions, and results from other instruments on

186    board R/V *Point Sur* related to the smoke sampling can be found in *Wonaschütz et al*. [2013].

187    **2.1.2 TACO Measurement Intensives**

188    The Tucson Aerosol Characterization Observatory (TACO) is a rooftop laboratory on the

189    University of Arizona campus in inner city Tucson (30 m AGL, 720 m ASL; 32.2299°N,

110.9538°W), which has a metropolitan population of ~1 million [*U.S. Census Bureau*, 2011]. The observatory has been collecting long-term data relevant to aerosol particle properties and meteorology since 2011. Instrument results at TACO from various instruments in addition to DASH-SP, such as a Particle-Into-Liquid Sampler (PILS, Brechtel Manufacturing Inc.), Cloud condensation nuclei counter (CCNc, DMT Inc.), a semicontinuous OC/EC analyzer (Sunset Laboratory Inc., Oregon), Micro-Orifice Uniform Deposit Impactors (MOUDI, MSP Corporation), and single-stage filter samplers have been summarized elsewhere [*Youn et al.*, 2013; *Crosbie et al.*, 2015; *Sorooshian et al.*, 2015; *Youn et al.*, 2015].

During TACO, the DASH-SP measured size-resolved *GF*s at humidified RH values typically between 50–95% with dry channel measurements below 20% RH, and with $D_{p,dry}$ between 180 and 300 nm. The DASH-SP RH was controlled within 1.5% and the *GF* uncertainty was less than 3% [*Shingler et al.*, 2016]. The instrument data from TACO relevant to the current study is from the DASH-SP during summer intensive periods (27 May – 01 June 2014, 12–20 August 2014) and a winter intensive period (30 January – 12 February 2015). Instrument operating details, data processing procedures, and examples of its field deployment are presented elsewhere [*Sorooshian et al.*, 2008a, 2008b; *Hersey et al.*, 2009, 2011, 2013; *Shingler et al.*, 2016]. The instrument relies on a classification differential mobility analyzer (DMA) to select dried particles of a specific diameter prior to feeding the monodisperse aerosol stream to the following modules: a diffusion-based aerosol conditioning module in which particles are brought to equilibrium at a controlled RH, followed by detectors at the outlet end that either determine (i) the optical scattering distribution of dry, monodisperse particles selected by the DMA (used to determine the real component of refractive index, $RI_{dry}$, at 532 nm), or (ii) the optical scattering distribution of the particles after the RH conditioning module.

### 2.1.3 SEAC⁴RS Field Campaign

Based out of Houston, TX during August–September 2013, SEAC⁴RS incorporated three research aircraft to investigate numerous topics including (i) emission redistribution throughout the troposphere from deep convection, (ii) evolution of gases and aerosols in convective outflow and their implications for atmospheric chemistry, and (iii) how anthropogenic pollution and biomass burning emissions are affected by meteorology and cloud processing. Another focus was to validate/calibrate instrumentation as a test bed for future applications. Details of the SEAC⁴RS project and specifics on measurements pertaining to this work can be found elsewhere [*Toon et al.*, 2016] and all data are publicly available from the NASA Langley Research Center Atmospheric Science Data Center [*ASDC*, 2015].

This work focuses on in situ measurements from the NASA DC-8, utilizing all research flights from SEAC⁴RS with focus on three flights that targeted biomass-burning sampling: 6 August, 19 August, and 27 August. The DASH-SP on board the DC-8 measured size-resolved hygroscopic *GF*s of ambient aerosol particles at humidified RH values typically between 70–95% with dry channel measurements below 15% RH, and $D_{p,dry}$ between 175 and 350 nm [*Shingler et al.*, 2016]. Similar to TACO conditions, the DASH-SP RH was controlled within 1.5% and *GF* uncertainty was less than 3% for SEAC⁴RS measurements [*Shingler et al.*, 2016]. *f*(RH) data are obtained from the Langley Aerosol Research Group Experiment (LARGE) instrument package, specifically the tandem humidified nephelometers [TSI Inc, St. Paul, MN, USA; Model 3563; *Ziemba et al.*, 2013] at dry (RH 20%) and humidified (RH 80%) scattering channels. Number size distributions from the Laser Aerosol Spectrometer (LAS; $D_p$ between 0.1—6.3 μm) as part of LARGE were used in particle density calculations. DC-8 data are also used for acetonitrile from the Proton-Transfer-Reaction Mass Spectrometer [PTRMS; *de Gouw and Warneke*, 2007], black carbon (BC)

11

236  from the Humidified-Dual Single-Particle Soot Photometer [HD-SP2; *Schwarz et al.*, 2008], and

237  sub-micron aerosol chemical composition from the High Resolution Aerosol Mass Spectrometer

238  [HR-AMS; *DeCarlo et al.*, 2006; *Canagaratna et al.*, 2007], and biomass burning number fraction

239  of $PM_{2.5}$ from the Particle Analysis by Laser Mass Spectrometry [PALMS; *Lee et al.*, 2002].

240

## 3.    Results

### 3.1    Sub-1 Hygroscopicity Observations

243      Multiple pieces of evidence for sub-1.0 hygroscopicity are presented in order from E-

244  PEACE, TACO, and SEAC$^4$RS. Ship-based HTDMA measurements of *GF* during E-PEACE are

245  summarized in Figure 1, where it is shown that *GF* is clearly suppressed in smoke-influenced

246  samples as compared to background aerosol sampled outside of the ship-generated smoke plume.

247  *GF*s below 1.25 are only observed in smoke-influenced samples.   Additionally, numerous

248  observations of sub-1.0 *GF* are reported during smoke sampling, regardless of the dry particle

249  diameter. While more pronounced at a RH of 92%, reaching *GF*s as low as 0.77, sub-1.0 *GF*s are

250  observed at 85% as well, reaching a minimum value of 0.89.

251      Ground-based measurements of *GF* for $D_{p,dry}$ of 190–300 nm during TACO intensives (Fig.

252  2) indicate that higher values are observed during summer periods (above 1.15 at RH > 80%) with

253  suppressed *GF*s and sub-1.0 values during winter periods. The reduction of *GF* below 1.0 is not

254  more pronounced at any particular RH between 75–97%. Winter in the Tucson metropolitan area

255  is characterized by enhanced residential burning for heat.  As the area is surrounded by mountains

256  with strong boundary layer inversions during cold nights, residential burning emissions are trapped

257  in a shallow layer and often are not ventilated in periods of prolonged cooler temperatures [*Crosbie*

12

258 *et al.*, 2015], which leads to the highest year-round $PM_{2.5}$ mass concentrations of species linked to

259 biomass burning including elemental carbon, organic carbon, and water-soluble organic carbon

260 [*Youn et al.*, 2013]. While it cannot be proven unambiguously that sub-1.0 *GF*s in Tucson are due

261 to biomass burning, certainly the coincidence of burning during periods with these data points

262 supports the case for a potential link.

263 Hygroscopicity data from SEAC$^4$RS for $D_{p,dry}$ of 160–360 nm further provides evidence of

264 sub-1.0 *GF* values with most occurrences being at RHs between 80–90% and without any

265 systematic difference in value below 1.0 at any particular RH (Fig. 3). Similar to E-PEACE and

266 TACO, a difference in trends between biomass burning sampling and non-smoke sampling is

267 observed, with sub-1.0 points observed only during the former periods. *Shingler et al.* [2016] have

268 shown that wildfire emissions during SEAC$^4$RS coincide with suppressed *GF* and sub-1.0

269 observations.

270 From the three presented field studies, biomass burning (SEAC$^4$RS), residential burning

271 TACO), and simulated smoke emissions (E-PEACE) coincide with suppressed *GF* observations

272 compared to non-combustion sampling, and show evidence of sub-1.0 hygroscopicity. It is

273 reinforced that strict quality control measures have been implemented for each data set, and the

274 sub-1.0 observations in Figs. 1–3 have withstood those checks, including removing all in-cloud

275 sampling from SEAC$^4$RS and any periods with poor signal-to-noise ratio.

276 **3.2    Case Study: Aged Smoke Sampling**

277 In order to investigate sub-1.0 hygroscopicity in depth, a case study is highlighted from

278 SEAC$^4$RS during the 19 August 2013 research flight. A flight from this campaign is chosen for a

279 case study as it had the most complex suite of instruments as compared to the other campaigns and

280    the DC-8 was able to study biomass-burning plumes across a wider plume age range. The 19

281    August flight in particular offered excellent data coverage across multiple instruments of relevance

282    to this study. During this flight, the DC-8 probed an aged fire plume over Nebraska and Wyoming,

283    originating from Idaho and Wyoming fires as determined from the Emission Inversion method

284    [*Saide et al.*, 2015]. Figure 4 presents a time series of chemical composition, biomass burning

285    markers, aircraft altitude, ambient RH, and hygroscopicity measurements.  The biomass burning

286    markers utilized in this study are: (i) gas-phase acetonitrile, indicative of biomass burning

287    emissions at elevated concentrations (> 250 ppbv); (ii) AMS $f_{60}$, which is the fraction of organic

288    aerosol at *m/z* 60 (i.e., levoglucosan-like fragment in the instrument); (iii) BC; and (iv) PALMS

289    biomass burning (BB) fraction (i.e., number fraction in $PM_{2.5}$ containing biomass burning

290    material).

291         The periods of lowest *f*(RH) between 21:00–21:30 correspond to enhanced levels of all

292    four of the aforementioned biomass burning tracers. *GF* and $\kappa$ from DASH-SP are also lowest

293    during this time period, however, only a few points exhibited values of sub-1.0 or sub-0,

294    respectively. While the mass fraction of BC relative to total $PM_1$ ($MF_{BC}$) remains steady in and

295    out of biomass burning sampling (~1–2%), periods with *f*(RH) < 1 exhibit enhanced organic mass

296    fraction ($MF_{org}$ ~90%), with lower values (~70%) observed when *f*(RH) > 1. As $PM_1$ total mass is

297    elevated in biomass burning plumes (> 50 $\mu g\ m^{-3}$), the BC contribution to total mass is of the same

298    order of magnitude as inorganic species and the mass of BC increases by approximately a factor

299    of ten. This increase in BC mass could affect the total scattering of the aerosol, as well as the

300    DASH-SP size-resolved *GF* depending on the peak modal diameter of BC particles. Between

301    21:00–21:30, HD-SP2 measurements show that the mass-median diameter of BC cores is 175 nm

302    volume equivalent diameter, and the calculated BC-specific $\kappa$ is -0.03 $\pm$ 0.02. With DASH-SP

303  sampling at a fixed dry size of 250 nm during this plume intersection, theoretically, BC cores

304  would not be sampled. However, as LARGE $f$(RH) is a bulk scattering measurement, BC cores

305  would be sampled, possibly explaining $f$(RH) values were more frequently detected below 1.0 as

306  compared to $GF$ values.

307  The relationship between hygroscopic growth and biomass burning indicators is further

308  explored in Fig. 5 where it is shown that acetonitrile and $f$(RH) have an inverse relationship, which

309  asymptotes to $f$(RH) ~0.9 at the highest acetonitrile concentrations (0.55–0.65 ppbv). $f$(RH) values

310  were always sub-1.0 when acetonitrile levels exceeded 0.38 ppbv. The $GF$ and $\kappa$ relationship with

311  acetonitrile is less clear. As already noted, this could be due to the size-resolved nature of DASH-

312  SP measurements.

313  As literature suggests wetting of chain-like or aggregated particles can lead to a more

314  compact nature and higher density [*Weingartner et al.*, 1995; *Jimenez et al.*, 2003; *Onischuk et al.*,

315  2003; *Lewis et al.*, 2009], differences in particle density can be used as a plausible marker for

316  particle restructuring. Particle density is calculated using data for size distribution and $PM_1$ mass

317  fractions of organic, inorganic, and BC species. Figure 6 illustrates the relationship between

318  particle density and $f$(RH), which both are representative of bulk aerosol unlike the size-resolved

319  $GF$ measurements from the DASH-SP. $f$(RH) is shown to increase as a function of particle density.

320  A linear orthogonal distance regression (ODR) trend line is fit to the $f$(RH)-density scatterplot,

321  resulting in slope of 0.84 $cm^3$ $g^{-1}$ and intercept of 0.15. With $R^2$ of 0.5 (n = 747), 50% of the

322  variance in $f$(RH) is explained by particle density. While the predictive correlation between these

323  two parameters could be stronger, the results still support the notion that agglomerated and chain-

324  like particles collapse into more compact, denser particles.

325

## 4.    Discussion

Section 4.1 below demonstrates how a revised data processing strategy with DASH-SP data can handle cases of externally mixed aerosol in order to identify more cases of sub-1.0 hygroscopic growth than with previous data processing methods. Sections 4.2-4.3 focus on reasons as to why sub-1.0 hygroscopic growth data are observed in the various datasets presented in this work. One mechanism already discussed in Section 1 that the current dataset cannot provide direct evidence for, but is a likely explanation for at least a subset of the sub-1.0 data points, is that of particle restructuring. It is also possible that restructuring can occur concurrently with any combination of the other reasons discussed below.

### 4.1    External Mixtures

Atmospheric aerosols are assumed to be internally mixed due to atmospheric processing, both from cloud and photochemical processing. As a result, atmospheric aerosol instruments are often optimized for internal mixtures [*Seinfeld and Pandis*, 2012]. An external mixture is a heterogeneous mixture of aerosol particle populations, where each particle may have unique composition, whereas, an internal mixture is a chemically homogeneous mixture of aerosol particles. The subsequent discussion examines how a revised treatment of DASH-SP data to consider external mixtures can lead to possible sub-1.0 *GF* values.

To test the DASH-SP's capability to identify the presence of externally mixed aerosol, calibration standard solutions of $Na_2SO_4$, polystyrene latex particles (PSLs), and a mixture of the two were atomized and fed to the instrument, which sampled at a $D_{p,dry}$ of 240 nm with RH = 80%

16

347 (Fig. 7a–b). The dry RI ($RI_{dry}$) of the two number concentration modes observed in the dry OPC

348 channel correctly match the values of the individual standards, with $RI_{dry} = 1.47$ for $Na_2SO_4$ and

349 1.60 for PSLs. While individual standards produce one clear number concentration mode, and thus

350 one *GF*, according to the properties of that specific standard (Fig. 7a), a mixture of the two species

351 results in a more ambiguity since it usually is unclear as to which of the multiple modes in the

352 humidified size distribution should be assigned to a specific mode in the dry distribution (Fig. 7b).

353 As this was a controlled laboratory experiment, it is known with certainty how the two modes in

354 each distribution of Figure 7b match up. However, if this were a field measurement, it would be

355 unclear which humidified peak should be associated to which $RI_{dry}$ leading to four potential *GF*s

356 from the mixture sample scan (Fig. 7b). In the following discussion (Figs. 8–9), we define an

357 external mixture as being when two distinct $RI_{dry}$ are observed at a selected dry size.

358 Data have been selected from SEAC[4]RS (Fig. 5), TACO (Fig. 2), and smoke sampling

359 during E-PEACE (Fig.1) to illustrate evidence of external mixtures. The scans selected are

360 representative of the smoke sampling periods in each of these studies, with the caveat that TACO

361 data do not reflect a fresh smoke plume but rather an urban plume with smoke influence due to

362 residential heating. DASH-SP data from SEAC[4]RS (Fig. 8a), illustrate the presence of two $RI_{dry}$

363 at one $D_{p,dry}$ during a period of biomass burning sampling. Similarly, DASH-SP data from TACO

364 on 01 February 2015 during the wintertime reveal two $RI_{dry}$ are observed at one $D_{p,dry}$ during a day

365 with likely residential burning owing to low ambient temperatures (Fig. 8b).

366 While the DASH-SP scans in SEAC[4]RS and TACO show two clear modes, representative

367 of two distinct values of $RI_{dry}$, there are less defined modes in the humidified size distribution.

368 Unlike the laboratory tests with an external mixture of two known species, the exact chemical

369 composition of ambient air sampled is unknown, which complicates the matching of modes.

17

370  Consequently, there is uncertainty about how to match each $RI_{dry}$ with an associated humidified

371  channel mode. The weighted mean of the humidified distribution has been selected in these scans

372  (Figs. 8a–b), as was done for the field campaign datasets, details of which can be found in *Shingler*

373  *et al*. [2016]. Depending on $RI_{dry}$ associated with the weighted mean of the humidified OPC

374  distribution, one of two *GF*s is possible, and in these cases, the higher $RI_{dry}$ results in a sub-1.0

375  *GF*. This analysis suggests that instances of sub-1.0 *GF* could generally be underreported with

376  current post-processing algorithms (such as with the DASH-SP up to this point) that typically only

377  lead to one *GF* value per scan. That is to say, the sub-1.0 *GF*s shown in Fig. 8a–b, are not in

378  campaign-wide summary plots (Fig. 2–3). The reported *GF*s for DASH-SP scans in Fig. 8a and

379  8b, are 1.26 and 1.16, respectively, using the weighted mean approach of *Shingler et al*. [2016] for

380  the dry and humidified OPC distributions.

381      Figure 8c represents a HTDMA scan from E-PEACE during smoke sampling on 17 July

382  2011, where five *GF* modes were resolved using the multi-peak fitting package in Igor

383  (Wavemetrics, Inc.). Of note is that one of the *GF*s was 0.85. The HTDMA sampling time (~75

384  s) was longer than typical DASH-SP scanning times in smoke plumes (~ few seconds), which

385  means that confidence in the ability of the former instrument to accurately resolve multiple *GF*s

386  depends on whether the aerosol characteristics during the entire scan stay the same. This can be a

387  challenge for plumes of fresh emissions where the probably of externally mixed aerosol is higher

388  since moving platforms may struggle to stay in the plume for an entire scan. However, during this

389  particular scan the instrument was able to sample the plume continuously for the full scan duration.

390      To further investigate external mixtures during the case study flight on 19 August 2013

391  during SEAC$^4$RS, Fig. 9b shows a time series of dry and humidified OPC scans over the entire

392  flight with *GF*, κ, and *f*(RH). Changes in selected $D_{p,dry}$ are reflected in location of dry OPC

393    distributions. During the expanded period in Fig. 9b the DC-8 spent time in and out of biomass

394    burning plumes. This distinctive signature of being either in or out of the plume is evident in $f$(RH)

395    measurements of sub-1.0 hygroscopicity in the plume. Evidence of prolonged periods of the

396    DASH-SP sampling external mixtures is correlated with periods of $f$(RH) < 1, as seen in both

397    periods of sub-1.0 $f$(RH) in Fig. 9b. The effect of two populations of aerosol at one $D_{p,dry}$ supports

398    the claim the DC-8 sampled an externally mixed aerosol population during biomass burning

399    plumes on 19 August 2013. While sub-1.0 $GF$ is observed during the 19 August 2013 case study,

400    $f$(RH) < 1 is more common. One explanation for DASH-SP not observing sub-1.0 GF while $f$(RH)

401    < 1 could be due to DASH-SP measurements at a specific $D_{p,dry}$ combined with periods of

402    externally mixed aerosol.

403        The question remains as to how an external mixture affects LARGE $f$(RH) measurements

404    and what the difference is in chemical composition between the two peaks in DASH-SP's bimodal

405    distribution. It is worth noting that roughly 50% of pulse height observations in DASH-SP raw

406    data during periods of externally mixed aerosol are at the higher $RI_{dry}$, which has a similar RI to

407    BC or PSLs. Typical organic aerosol has an RI of 1.55, and elemental carbon has an RI of 1.8

408    [*Malm et al.*, 2005]. Other than there being a high concentration of BC, it has been suggested that

409    amorphous carbon spheres or "tar balls" with higher RI than simple organics could be responsible

410    for the second higher RI peak, particularly in $D_{p,dry}$ size range of this study [*Hand et al.*, 2005].

411    These tar balls are thought to consist of organic polymer material and are mostly insoluble in water

412    [*Posfai et al.*, 2004], unchanged by moderate RH or cloud processing. However, *Hand et al.* [2005]

413    suggested that at RH > 80%, Scanning Electron Microscope (SEM) analysis indicates the start of

414    "melting" of particle edges, with effective degradation of tar balls and wetting by RH > 92%

415    resulting in irreversible morphological changes.

## 4.2    Refractive Index Sensitivity

Since the DASH-SP data processing algorithm relies on the measurement of dry particle refractive index (real part), it is possible that a RI change, due to chemical modification in the DASH-SP after dry sizing, would result in an apparent change in wet size, without physical size changing. To probe this possibility, a sensitivity analysis of $GF$ $RI_{dry}$ was conducted with results shown in Fig. 10.  A representative humidified channel RH (85%) and OPC electrical pulse height ($PH_{wet}$: 30,000 in Fig. 10a-b, 20,000 in Fig. 10c-d) were explored; it is noted that the OPC reports electrical pulse heights which are subsequently converted into number concentration.  For a given $D_{p,dry}$, $RH_{dry}$, and fixed $PH_{wet}$, the effect of variations in $RI_{dry}$ on $GF$ and "resultant" wet diameter was calculated. With a fixed $PH_{wet}$, it is assumed that wet physical size does not change. Thus, the effect of RI (due to aqueous processing) on $GF$ is isolated. For a fixed $D_{p,dry}$ and wet physical size, a shift in RI produces a profound effect; in Fig. 10c, a 225 nm dry particle could have a $GF$ ranging from 0.9–1.25 over an RI range of 1.4–1.59. Thus, while physical size may remain unchanged by water uptake, aqueous chemistry shifting RI could result in a sub-1.0 value.

## 4.3    Evaporation and Phase Change

Sampling of aerosol to conduct hygroscopicity measurements is prone to evaporation of semivolatile compounds.  Thermo-kinetic modeling was recently conducted by *Shingler et al.* [2016] to investigate the potential effects of evaporation of semivolatile organic compounds (SVOCs) and ammonium nitrate within the measurement inlet and inside the DASH-SP system. They reported results for select organic and inorganic compounds of varying chemical structure and volatility for typical SEAC[4]RS operating conditions. Details of model set up, conditions, and validation can be found in *Shingler et al.* [2016]. Briefly, the Aerosol Inorganic-Organic Mixtures

20

438    Functional groups Activity Coefficients [AIOMFAC; *Zuend et al.*, 2008, 2011] model was utilized

439    to determine species activity coefficients and condensed phase concentrations. The output from

440    AIOMFAC was used in the kinetic multi-layer model for gas-particle interactions in aerosols and

441    clouds [KM-GAP; *Shiraiwa et al.*, 2012] to model transient mass transfer processes and gas-phase

442    concentrations during instrument sampling.

443    In this work, we are primarily concerned with additional losses due to particle evaporation

444    experienced from the entrance of the humidifier up to the size distribution measurement in the

445    humidified OPC.  By definition, if a humidified particle does not grow in size upon hydration, a

446    *GF* = 1 would result, and if this particle experiences evaporative losses, thus decreasing mass in

447    the particle phase in the humidifier and humidified OPC measurement, a sub-1.0 *GF* could result.

448    The particles modeled in *Shingler et al.* [2016] are characterized by plausible concentration ratios

449    of inorganic to organic species, in addition to relative amounts of low-volatility organic

450    compounds (LVOCs) to SVOCs (5% ammonium nitrate, 25% ammonium sulfate, 50% LVOCs,

451    and 20% SVOCs). Simulations were conducted for particles with $D_{p,dry}$ of 250 nm and with

452    instrument humidified channel RHs of 75%, 85%, and 93%, but for this discussion we focus on

453    85%.

454    Evaporative losses of ammonium nitrate for liquid-phase and semi-solid particles range

455    between 13.1–14.3% and 0.0–0.1%, respectively, the range depending on the reference ambient

456    temperature (modeled at 250, 295, and 310 K; representative of a range of tropospheric altitudes)

457    for both phases. Losses of organic species can range from near zero for low volatility compounds

458    (e.g., docosanoic acid ~0.01% for liquid and semi-solid phases) to complete evaporation to gas-

459    phase (e.g., chrysene, 5.6–11.2% for liquid and 0.0–0.1% for semi-solid particles) [*Shingler et al.*,

460    2016]. Losses are more severe for liquid phase particles than for semi-solid particles, as the bulk

461   diffusivity of water and organics is reduced in semi-solid particles. These reported evaporative

462   losses in the instrument at 85% RH would reduce a *GF* of 1.15 (without losses) to 1.11 with losses

463   and represent an upper limit of underestimation of *GF* values as the particle composition used in

464   this modelling analysis was more volatile than a semivolatile ambient aerosol [*Shingler et al.,*

465   2016].

466       Considering that the composition of wildfire biomass burning smoke has a higher organic

467   mass fraction than other airmasses (~90% and 70%, respectively, as shown in Fig. 4 and reported

468   in *Shingler et al.,* [2016]), these evaporative loss modeling results must be extrapolated to

469   conditions which lead to sub-1.0 *GF* and *f*(RH). As the volatility of biomass burning smoke can

470   vary based on biofuel and fire phase, (i.e., more volatile biomass burning organic aerosol is

471   produced in smoldering combustion than flaming combustion [*Huffman et al.*, 2009]), without

472   detailed chemical composition measurements during sampling, quantifying the evaporative losses

473   for aerosol near the *GF* = 1 threshold is not possible in this study. Assuming the loss estimates in

474   *Shingler et al.* [2016] are reasonable and represent an upper limit to reduction in *GF*, and the

475   modeled semivolatile composition within the particle phase is representative of the ambient

476   samples, it can be qualitatively assumed that a reported *GF* of 0.95 would be higher without

477   evaporative losses within the sampling inlet and DASH-SP system.  However, as there is no

478   significant dilution or temperature change in the *f*(RH) measurement technique, evaporative losses

479   are much less significant in *f*(RH) measurements compared to DASH-SP measurements of *GF*. As

480   *f*(RH) datapoints represent the majority of sub-1.0 hygroscopicity observations (Fig. 4 and 5), it is

481   unlikely that evaporative losses are the dominant contributing mechanism resulting in sub-1.0

482   observations.

483

## 5.    Conclusions

Combining hygroscopicity measurements from three different instruments across multiple field projects and observation platforms, this work presents the first observations of sub-1.0 hygroscopicity reported in the ambient environment. Ship-based HTDMA measurements reveal sub-1.0 $GF$s exclusively during sampling smoke-like particles in the marine boundary layer off the California coast. Ground-based DASH-SP data in Tucson, Arizona exhibit sub-1.0 $GF$s exclusively during winter, coincident with widespread residential wood burning. Aircraft-based data for DASH-SP $GF$ and LARGE $f$(RH) exhibit sub-1.0 hygroscopicity exclusively during wildfire biomass burning sampling. Detailed examination of a biomass burning focused flight during SEAC[4]RS indicate smoke plumes where acetonitrile exceeds 380 pptv result in sub-1.0 $f$(RH), with measurements leveling off at 0.9. Reduced particle density correlates with the lowest $f$(RH) values, with the majority of sub-1.0 observations occurring when particle density is less than 1.2 g cm$^{-3}$.

A new manual data processing technique is demonstrated with the DASH-SP that can help identify more cases of sub-1.0 $GF$ as compared to previous methods for both the current, previous, and future experiments. More specifically, the procedure focuses on identifying cases of externally mixed aerosol with support from laboratory tests. Observations from all three field campaigns by both the DASH-SP and HTDMA show that externally mixed aerosol, manifested as bimodal hygroscopicity profiles, were present during smoke-influenced sampling. Given current post-processing capabilities with DASH-SP data, quantitatively reporting multi-modal $GF$s is not yet possible; however, detailed case examples of specific scans show how multiple $GF$s are not uncommon with the lowest $GF$ sometimes being sub-1.0. It is not clear how externally mixed aerosol would affect $f$(RH) measurements, yet SEAC[4]RS observations indicate $f$(RH) < 1 when

507    DASH-SP observes two $RI_{dry}$ at one $D_{p,dry}$ size. External mixtures observed in this work are

508    consistent with literature reports of freshly emitted wood smoke from laboratory combusted

509    biomass fuels resulted in bimodal κ, indicative of chemical heterogeneity, or externally mixed

510    aerosol [*Carrico et al.*, 2010]. Future work will focus on further development of DASH-SP post-

511    processing to quantify more than one *GF* and examining the connection between external mixtures

512    and sub-1.0 *f*(RH) observations.

513    Potential explanations for sub-1.0 hygroscopicity were explored, including RI

514    modifications due to aqueous processing. A sensitivity analysis showed that aqueous processing

515    of particles without a change in physical size can alter RI in such a way to result in a sub-1.0 value

516    when using OPCs that rely on light scattering for detecting particle size. Interactions between

517    particle morphological changes upon hydration and light-scattering changes warrants further

518    exploration with biomass burning and very hydrophilic populations.

519    Evaporation of SVOCs within the DASH-SP measurement system could also contribute to

520    sub-1.0 hygroscopic observations, the degree of which would be dependent upon on the volatility

521    of biomass burning smoke, based on chemical composition and fire phase of biomass burning

522    emissions. The majority of sub-1.0 hygroscopicity observations are in the *f*(RH) dataset during

523    SEAC[4]RS, where substantial evaporative losses within the instrument are unexpected, thus

524    reducing the likelihood of evaporative losses being the dominant mechanism contributing to sub-

525    1.0 measurements.

526    While restructuring has been reported across a variety of sizes, RHs, combustion sources,

527    and particle coatings, to our knowledge, evidence has not been reported from ambient

528    measurements. While our datasets cannot allow for identification of this process as having

529 explained sub-1.0 hygroscopicity, it cannot be discounted as a likely contributor. Soot particle

530 morphology is important in climate models, as a recent study found diesel soot particles conducive

531 to forming ice crystals were more compact than those that formed supercooled droplets, with

532 enhanced single scattering albedo, thus reducing top-of-the-atmosphere direct radiative forcing by

533 ~63% [*China et al.,* 2015]. Additionally, better understanding particle restructuring is impactful

534 for mixing state models, as one possibility for deviations in model predictions of *GF* and

535 measurements is microscopic solid phase restructuring at increased humidity that is not accounted

536 for in hygroscopicity and mixing state models [*Lei et al.,* 2014]. To more robustly study this

537 mechanism in future field projects, we suggest hygroscopicity-measuring instruments develop a

538 prehumidification channel prior to instrument sizing modules, which can be easily switched on/off,

539 to hydrate and collapse particles. When sampling aerosol types vulnerable to restructuring such

540 as biomass burning smoke, a reasonable hypothesis would be that switching between

541 prehumidified and non-prehumidified channels should result in periods of sub-1.0 observations

542 only without prehumidification.
