Introduction: The enstatite (E) chondrites are enigmatic but important for understanding the evolution of the terrestrial planets. They have highly reduced mineral assemblages in which enstatite (near pure in composition) is the dominant silicate, metal is abundant and contains >2.5 wt. % Si in some EH3s, elements which are generally lithophile in most chondrites occur as sulfide and some E3s contain nitrides and carbides [1,2,3]. Notably, stable isotope compositions are similar to the Earth-Moon [4,5,6]. Aside from E chondrite clasts in the Kaidun breccia [7,8], the enstatite chondrites are dry, lacking evidence of ever having hydrous minerals, distinguishing them from most other chondrite groups and suggesting they formed relatively close to the sun, inside of the snow line. Compared to other chondrite groups, the E3s are also matrix-poor, with EH3s having ~4-12 vol. % and EL3s ≤5 vol % matrix [9,10]. Here we present a study of NWA 8785, a remarkable new EL3 chondrite with an FeO-rich, fine-grained matrix. Our goals are to understand E chondrite matrix and the evolution and alteration history of the EL3 parent body.

Results: NWA 8785 was studied in polished sections. It contains (in vol. %) sharply bound chondrules (47%), metal/sulfide-rich nodules (13%), mineral fragments (8%) and rare refractory inclusions all surrounded by a fine-grained FeO-rich matrix (32%) (Fig. 1a), the highest matrix abundance known among EL3 chondrites. Chondrules range in size up to 2mm with most 500-700 μm, close to the mean EL3 chondrule size of 520 μm reported by [11]. All chondrule textures are present but are dominantly pyroxene-rich (PP and RP) varieties. The metal-rich nodules in NWA 8785, common in all EL3s [12, 13], are unlike those in other EL3 chondrites. They contain enstatite, silica, graphite and sulfides as in other EL3s but are texturally, and in some cases mineralogically, different; intergrowths of enstatite laths characteristic of nodules in other EL3s are less common, suggesting a different origin for the NWA 8785 nodules. Matrix, much more abundant than in other EL3s, is littered with mineral (enstatite, Na-rich plagioclase, FeS and FeNi) and lithic (chondrule) fragments up to 50 μm in size surrounded by a fine grained (sub-micrometer) FeO-rich mixture (Fig. 1b, c) showing variable amounts of SiO₂, MgO and FeO, likely a product of alteration (TEM and XRD are underway to decipher the mineralogy of the fine-grained matrix component in NWA 8785). This contrasts sharply with matrix in other E3s which is composed of silica and enstatite, with metal and sulfide as major components. Additionally, in one matrix area, a 30 μm spinel-rich inclusion was found, consisting of MgAl₂O₄ spinel surrounded by sodalite, a common alteration product in refractory inclusions in CV chondrites.

Discussion: NWA 8785 is an unusual EL3 chondrite with an FeO-rich, fine-grained matrix unlike matrix found in any other E3 chondrite, except for the E3 clasts in the Kaidun breccia which show various degrees of aqueous alteration [8]. The NWA 8785 matrix, more abundant than in other EL3s, may have been the carrier of ices that accreted to the parent body, resulting in alteration. Further study of this altered material and alteration fluids may advance our understanding of the of E chondrite - Earth-Moon relationship.
