1 General introduction

1.1 General remarks

THIS thesis is entitled ‘Digital Twin of Analogue Man: Development of a Computational Modelling Platform to Assess Heart-Vessel Interaction in Humans’. The concept of using ‘twins’ is not new. For many years, plastic replicas of skeletons (i.e. ‘physical twins’) have been used in the classroom as well as in the general practitioner’s office to explain aspects of the human skeletal anatomy. Physical twins were also used during NASA’s *Project Apollo* in which two identical spacecraft were built, one to remain on the basis, which allowed engineers to recreate the conditions of the spacecraft during missions [11].

Digital twin technology is a novel concept originating from manufacturing industry [17]. A digital twin refers to a virtual or computational model containing a comprehensive physical and functional description of a component, product or system [11].

In this thesis, we apply the digital twin concept to cardiovascular research on the haemodynamic interaction between the heart and blood vessels. To emphasise the role of computational modelling, we first provide a timeline that outlines the technological developments that drive clinical data integration for improved interpretation.

1.2 History of cardiovascular haemodynamics and imaging studies

Already in ancient times, palpation of blood vessels has been performed as a method to diagnose disease. Ancient physicians and priests used the concept of measuring the ‘state’ of the heart through pulsating ‘canals’ in the head, hand and fingers [12]. It was the Greek physician Galen (129 – c. 210), who extensively characterised the cardiovascular system as being comprised of networks of arteries and veins. At that time, there was still no notion of the circular blood flow. Much later, William Harvey (1578–1657) was first to mention the blood circulation in his book *De Motu Cordis*, published in 1628. In contrast to Galen’s understanding, Harvey discovered that 1) the arterial pulse is the result of an actively contracting heart and is not caused by intrinsic contraction of the arterial wall itself, 2) there exists a pulmonary circulation in which the right ventricle pumps blood through the lungs to the left ventricle, instead of venous blood passing through invisible pores in the interventricular septum, and 3) blood is continuously cycled through the body (i.e. the cardiovascular system is a closed-loop system), rather than being produced in the liver, distributed to the body, and vanished subsequently [2].

The first direct blood pressure measurements were performed by Stephen Hales (1677–1761) in England [30]. Hales performed arterial pressure measurements by inserting a brass cannula into a horse’s carotid artery, which was connected to a glass tube to read out the height of the column of blood (Fig. 1.1). Hales’s work spawned further developments for recording the arterial pressure waveform

into the 1800s, which resulted in Scipione Riva-Rocci's method using an upper arm cuff to non-invasively measure the actual blood pressure in humans (first described in 1896). The early version of this device was capable of measuring peak (i.e. systolic) blood pressure. A few years later, following the discovery of the Korotkoff sounds in Russia, Riva-Rocci's method was improved to also include diastolic blood pressure measurements, based on simultaneous auscultation of the artery distally to the blood pressure cuff [10].

Figure 1.1: Reconstruction of Stephen Hales's method of *in vivo* blood pressure measurement, as performed in the carotid artery of a sedated horse. Reproduced with permission from Special Collections, University of Otago, Dunedin, New Zealand.

Other advances in cardiovascular research that took place around the 1900s include the invention of X-ray imaging. X-ray now allowed to obtain structural information of the heart and major blood vessels. An even greater breakthrough was the introduction of the electrocardiogram that provides functional information and is still used as the ground truth modality in emergency rooms and doctor's offices all over the world [3]. Cardiac ultrasound was invented in the 1950s and was at that time limited to describing the position of a cardiac structure over time (i.e. a so-called M-mode image). It took until the 1970s for ultrasound scanners to appear to acquire two-dimensional images (i.e. B-mode) of the heart [44].

Vascular ultrasound emerged around the same time as cardiac ultrasound. Vascular research topics using ultrasound include assessment of the mechanical properties of arteries by studying arterial wall deformation under blood pressure pulsations [16, 19]. Although most vascular ultrasound applications

are non-invasive, intra-vascular methods using a transducer-mounted catheter are available to accurately evaluate the extent of atherosclerosis in arteries [46]. Among important clinical applications of vascular ultrasound is duplex ultrasound which provides two-dimensional greyscale images of blood vessels combined with a colour-coded map of the local blood flow velocity [13]. Currently, duplex ultrasound is a first-line imaging modality to assess amongst others carotid stenosis severity [28].

A more detailed assessment of significant stenoses can be obtained using computed tomography (CT) imaging [28]. CT is a minimally-invasive imaging technique based on acquiring multiple X-ray images at different angles and focal planes of a tissue [49]. Using a filtered back-projection algorithm, pioneered by the Austrian mathematician Johann Radon in 1917, the series of one-dimensional projections can be reconstructed into a two-dimensional image of the tissue [49]. In contrast to using duplex ultrasound for carotid stenosis assessment, CT additionally renders the three-dimensional structure of stenotic lesions, as reconstructed from multiple two-dimensional images. Furthermore, CT allows for characterisation of vessel wall composition (e.g. assessment of coronary calcium content).

Magnetic resonance imaging (MRI), based on the tissue-specific response of hydrogen nuclei to a magnetic field disturbance is a non-invasive imaging modality offering an anatomically detailed overview of the heart and blood vessels [49]. Furthermore, phase-contrast MRI is now widely used in cardiovascular MRI, providing a time-resolved quantitative assessment of blood flow in blood vessels as well as within the heart [23, 31].

Today, the variety of measurement devices (ultrasound machines, MRI scanners and blood pressure measurement devices) allow for a comprehensive and multi-faceted collection of clinical data. In theory, the multitude of clinical data enables researchers and clinicians to better understand and exploit the mechanisms of cardiovascular disease. However, interpretation of data is hindered by issues around mutual dependencies in the data, reliability, and accuracy, which makes correct diagnosis-making difficult [21]. Below, three illustrative examples of studies that are confronted with challenges regarding data interpretation are presented.

1. *Cardiac diastolic function studies:* In non-invasive settings, cardiac ultrasound is used for estimation of left ventricular (LV) filling pressure and diagnosis of diastolic dysfunction [34]. The E/e' ratio, based on Doppler ultrasound measurements of early mitral inflow velocity (E) and mitral annular early diastolic velocity (e'), has been proposed as index for filling pressure [34]. However, meta-analysis of studies performing both cardiac ultrasound and cardiac catheterisation (i.e. considered gold standard) suggested that the E/e' ratio alone has limited value for assessment of LV filling pressure [42].
2. *Arterial stiffness studies:* Various arterial stiffness parameters (e.g. pulse pressure, regional pulse wave velocity or local distensibility) have been

proposed as risk factors for cardiovascular diseases [45]. However, arterial stiffness measures as such do not discriminate underlying changes in arterial wall constituent properties (e.g. in collagen, elastin, or smooth muscle) [39]. Therefore, evaluation of changes in constituent properties is highly relevant for the development and monitoring of treatment [18].

3. *Heart-vessel interaction studies*: Presence of left ventricular hypertrophy (LVH) is an important risk factor for cardiovascular disease and mortality [29]. Concentric left ventricular remodelling and LVH are common findings in hypertensive patients [15]. Therefore, consideration of LV afterload in relation to LV structure and function — as governed by heart-vessel interaction — is important for research regarding LVH. Despite the multitude of clinical data, it is controversial to what extent (ageing-induced) changes in afterload are resulting from earlier arrival of reflected waves or from reduced arterial compliance [7, 32, 37]. Hence, the afterload aspects striking ‘the killing blow’ to the LV remain unclear.

A solution to these challenges may be the development of elaborate *statistical* models that consider many variables and include interactions between variables. However, statistical modelling alone offers only a limited interpretation of causality, because these models are dependent on the population and circumstances they are based on [1, 21]. In the field of biomedical engineering, computational models to capture *physical* and *physiological* relations, are being developed and applied [21, 36, 41]. In this thesis, we develop and assess physics-based computational models to interpret and estimate characteristics of heart-vessel interaction.

1.3 Computational models of cardiovascular haemodynamics and their clinical applications

1.3.1 Models of the circulation

Many physiological relationships related to cell, tissue, organ or the whole system can be approached by a mathematical relation. A computer model, composed of a network of applied physiological relationships, may simulate the cardiovascular system. As such, cardiovascular models are well-suited to test new hypotheses about mechanisms of cardiovascular diseases. Most cardiovascular models can roughly be assigned to three categories [43]. The first category consists of computationally expensive three-dimensional (3D) solid mechanics models, computational fluid dynamics models and fluid-structure interaction models, describing local stresses and strains, pressures and flow velocity fields, or all of the aforementioned physical quantities, respectively (Fig. 1.2) [9, 14, 25]. The second category is formed by computationally inexpensive zero-dimensional (0D) lumped parameter models, assuming uniform distributions of pressure and flow within entire compartments, e.g. the pulmonary circulation (Fig. 1.2). As such, lumped parameter models fail to take into account spatial variation of pressure and flow. The third is an intermediate category of the computationally expensive 3D models and

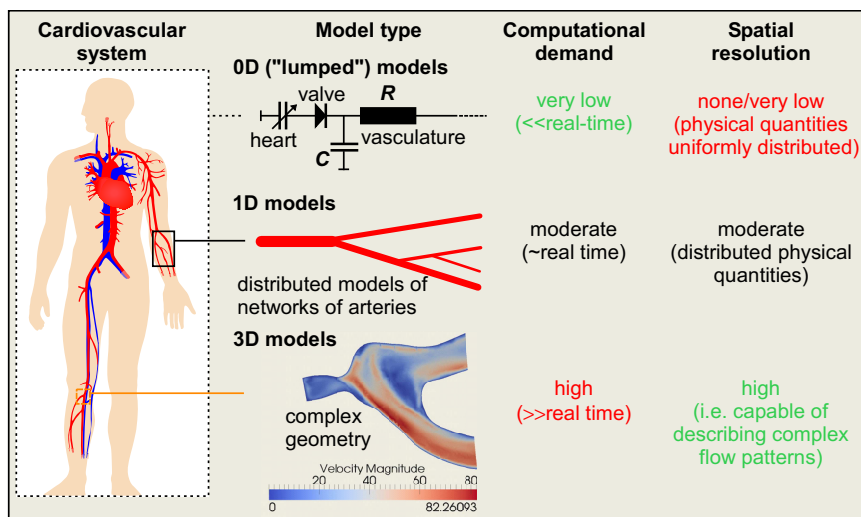

Figure 1.2: Dimensionality in cardiovascular modelling. Zero-dimensional (0D) or ‘lumped’ models consisting of a limited number of model parameters, (e.g. describing vascular resistance (R) and compliance (C)), consider uniform distributions of physical quantities (e.g. pressure or flow), have a low computational demand (e.g. run faster than real-time), but lack spatial detail. One-dimensional (1D) or ‘distributed’ models allow calculation of physical quantities along a single spatial direction at the cost of a moderate increase in computational demand. Three-dimensional (3D) models offer the highest spatial resolution, capable of calculating complex patterns of physical quantities.

simplified 0D models, comprising of one-dimensional (1D) distributed models that simulate wave transmission in networks of blood vessels (Fig. 1.2) [26, 40].

As a general rule, the choice of model dimensionality is determined by the required spatial and temporal resolution, which in turn is determined by the research question or clinical application [43].

In this thesis, we consistently use 0D models of cardiac mechanics and distributed models of wave transmission. The CircAdapt platform, an in-house developed cardiovascular model, has been successfully applied so far for simulating haemodynamics and LV adaptation processes during valvular pathologies and cardiac conductance disorders [27, 38, 48]. Its cardiac model describes a simplified cardiac geometry and assumes the cardiac chambers to be surrounded by contractile cardiac walls consisting of myofibres [48]. The myofibres are described using the one-fibre model [5], which relates myofibre stress to cavity pressure using the assumption that myofibre stress is homogeneously distributed within the myocardial wall. Furthermore, instead of relying on input from imaging techniques such as ultrasound or MRI, cardiac geometry (i.e. wall thicknesses and cavity volumes) is determined using cardiac adaptation rules [6]. A current limita-

tion of the CircAdapt model is that it does not yet contain a description of vascular wave transmission, which is believed to be important in studies on heart-vessel interaction (Section 1.2).

1.3.2 Patient-specific model-based characterisation of cardiovascular structure and function

In daily clinical practice, treatments are often based on the ‘one-size-fits-all’ paradigm in which results from clinical trials are used to define cut-off values for risk-stratification and clinical decision-making. Often, cut-off values are based on *statistical* associations between a clinical measure (e.g. systolic blood pressure by arm cuff) on the one hand, and a clinical end-point (e.g. heart failure or stroke) on the other. For some diseases like acute myocardial infarction, cut-off values exist that are useful for clinical decision-making [4, 47]. However, for complex diseases such as heart failure, cut-off values may lack precision because of the multi-factorial nature of the disease or the *indirect* description of a cut-off value as a marker for disease. Imputation or tuning computational models with or to a (subset of) clinical data could improve clinical decision-making. To this end, roughly two modelling approaches can be distinguished.

Forward approach

Personalised modelling can be performed using a forward approach [24, 33, 39], by substituting generic or population-averaged model parameters with their patient-specific counterparts, obtained or derived using measurements. Such a personalised model provides additional *direct* information on the state of the cardiovascular system by simulating variables (e.g. pressures, flows and material stresses) that cannot be routinely measured.

Inverse approach

An inverse approach [8, 24, 39] may be employed in which model parameters are tuned so that model simulations and patient measurements agree. In case the model parameters represent e.g. passive or active properties of tissue, such fitting procedure provides model-based estimates of those properties based on patient measurements. In previous works, the inverse approach has been proposed to facilitate a constitutive interpretation of clinical arterial stiffness measurements [39].

Limitations of patient-specific modelling

Difficulties with respect to patient-specific modelling are 1) a lack of clinical data available for model parametrisation, 2) measurement uncertainty associated with the clinical data, and 3) a mismatch between available clinical data and required clinical data to unambiguously estimate the unknown model parameters.

1.4 Aim and outline of this thesis

The aim of this thesis is to develop and evaluate a computational modelling platform to assess heart-vessel interaction. The developed models were employed in two use-cases concerning patient-specific modelling: 1) non-invasive computational methods to allow screening for LV diastolic abnormalities and 2) non-invasive identification of arterial wall mechanical properties to assess the effect of (novel) vascular drugs on cardiovascular system dynamics. The structure of this thesis is as follows.

In **Chapter 2**, we perform a meta-analysis of clinical intervention studies with arterial and LV structure/function as (primary) outcomes. This study serves as an important starting point to investigate heart-vessel interaction. In this review, we aim to evaluate, using clinical evidence, the current pathophysiological paradigm that links arterial stiffening and LV hypertrophy/failure [50].

In **Chapter 3**, we extend the existing CircAdapt computational model with a module describing arterial and venous wave transmission. The extended model is subjected to a relevant test-case, simulating the effect of systemic arterial hypertension on 1) global arterial and venous haemodynamics, and 2) changes in local wave dynamics at the level of the aorta. In **Chapter 4**, we use the newly extended circulatory model to critically evaluate the augmentation index (AIx). The AIx is a well-known and widely reported metric, deemed to capture the effect of increased cardiac workload due to wave reflections. However, its validity as a proxy for wave reflection magnitude has been questioned [22].

In **Chapter 5**, we model the adaptive capacity of blood vessels, making them respond to flow and pressure stimuli by changes in radius and wall thickness of blood vessels. We integrate the adaptation rules into a previously developed pulse wave propagation model [26], and assess whether the PWP-adaptation framework could be utilised to extrapolate incomplete patient-specific data sets. Model-based estimates are compared to dedicated ultrasound and MRI measurements, as obtained in ten healthy volunteers.

In **Chapter 6**, we employ the extended CircAdapt model to non-invasively estimate LV end-diastolic pressure (p_{ed}) and compliance (C_{ed}) from routine measurements of blood pressure and echocardiographic recordings. This approach could improve the currently used method of assessing increased LV filling pressure, which reportedly lacks specificity, i.e. echocardiographic $E/e' \neq p_{ed} \neq C_{ed}$ [42].

In **Chapter 7**, we model carotid arterial wall mechanics using a constitutive model that simulates stress-strain behaviour of the arterial collagen and elastin [20]. For constitutive interpretation of clinical arterial stiffness data, an inverse approach is utilised which enables estimation of constitutive properties. According to modelling standards [35], we perform uncertainty quantification to determine uncertainty in model-estimated constitutive property estimation.

This thesis concludes with a general discussion in **Chapter 8**, where we put the developments in the context of a multi-scale modelling platform and its utility for further mechanistic studies into heart-vessel interaction.

2.1 Abstract

Vascular research demonstrated that pulse wave velocity (PWV), a measure of arterial stiffness, is inherently blood pressure-dependent. Considering the hypothesised pathophysiological chain of increased arterial stiffness leading to increased blood pressure load with consequent left ventricle hypertrophy (LVH) development, we conducted a systematic review of antihypertensive and lifestyle intervention studies to determine the association between on the one hand changes in arterial stiffness and blood pressure, and on the other hand changes in LV mass (LVM).

Using PubMed, EMBASE, Cochrane and Web of Science, we identified 23 studies, containing 2573 patients. Studies reported changes in arterial stiffness (assessed by means of PWV), systolic- and diastolic blood pressure (SBP, DBP), and LVM index (LVMI), respectively.

Statistically significant reductions in SBP, PWV and LVMI were reported in 16, 14, and 20 studies, respectively. Pooled analysis of studies showed that the proportion in SBP reduction did not correlate significantly to the proportion in reductions of the other two variables. On the other hand, we found a significant positive correlation ($r=0.61$, $p=0.003$) between arterial stiffness and LVM, expressed as a relevant reduction in LVMI of 6.9 g/m^2 per 1.0 m/s reduction in PWV.

Our findings provide evidence that a decrease in arterial stiffness is associated with reduction of LVM. To investigate whether there exists a causal relation between LVH due to arterial stiffness increases and in turn blood pressure load increases, future studies should strive for a multiple follow-up design and use of blood pressure-independent or corrected stiffness indices.

2.2 Introduction

CURRENTLY, cardiovascular disease (CVD) is the number one killer of humans worldwide, responsible for 17.9 million deaths (approximately 30% of all deaths) each year [49]. In the elderly, CVD accounts for even more than 80% of all deaths [50]. High arterial blood pressure is a key determinant of CVD [24] and is the leading attributable factor for developing heart failure [39]. Elevated isolated systolic blood pressure (SBP) is becoming increasingly relevant in the ageing population as 60% of people aged 60 years or older have elevated SBP (i.e. SBP>140 mmHg) [34].

The (age-related) stiffening of arteries has been identified as a key determinant and precursor of elevated SBP [18, 21, 28]. The main contributors to elevated SBP are believed to be decreased (central) arterial compliance and increased systolic wave reflection (i.e. earlier arrival of reflected pressure wave) [28]. Increased myocardial afterload due to elevated SBP affects the way the left ventricle (LV) adapts and becomes hypertrophic [12]. Recently, the ESH/ESC guidelines for the management of hypertension have emphasised the importance of increased arterial stiffness (assessed as pulse wave velocity (PWV)) and LV hypertrophy (LVH) (assessed as LV mass index (LVMI)) in determining overall cardiovascular risk [26].

A pattern of increased arterial stiffness, high blood pressure, and LVH is frequently observed in smaller observational, cross-sectional studies [5, 30, 44]. Due to design and study size, such studies are seriously limited in identifying causality. Furthermore, arterial stiffness measurements are inherently blood pressure-dependent [36], complicating the causative interpretation of observed changes in both arterial stiffness and LV structure and function.

Considering the current pathophysiological paradigm linking arterial stiffening, elevation of SBP, and development of LVH/LV failure [47], our aim was to review the available randomised controlled trials (RCTs) and cohort studies, reporting intervention-induced changes in blood pressure, arterial stiffness and LV structure/function as primary outcomes. We evaluated whether intervention-induced changes in arterial stiffness correlated with improvement in LV structure and function. In our meta-analysis, we included the orders of magnitude of changes in PWV and of changes in LVM, in relation to changes in SBP and DBP.

2.3 Methods

2.3.1 Protocol and registration

In this study, we applied the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) statement for studies evaluating medical interventions [23].

2.3.2 Search strategy and study selection

We extensively searched the PubMed, EMBASE, Cochrane and Web of Science databases using the following search strategy: (((((((((((Heart Failure, Diastolic) OR Heart Failure, Diastolic) OR diastolic dysfunction) OR isolated systolic hypertension) OR pulse pressure) OR Blood pressure))) AND (((((((Hypertrophy, Left Ventricular) OR Hypertrophy, Left Ventricular) OR left ventricle hypertrophy) OR cardiac hypertrophy) OR cardiomegaly) OR cardiomegaly))) AND (((((((blood pressure) OR blood pressure) OR hypertension) OR high blood pressure) OR hypertension))) AND (((((((arterial stiffness) OR vascular stiffness) OR vascular stiffness) OR pulse wave velocity) OR pulse wave analysis) OR pulse wave analysis) OR distensibility)))) AND (((((physical activity*) OR motor activity) OR Motor activity) OR (((((((revalidation) OR Exercise) OR Exercise) OR Life Style) OR Life Style) OR Therapeutics) OR Therapeutics) OR medical treatment) OR medication))))). The starting date was determined as 1 January 1990 and the search was updated till 20 April 2017. The reference lists and citations of the obtained articles were handsearched for additional searches. Articles were included in this systematic review if they fulfilled the criteria described below (Fig. 2.1):

1. English-written randomised controlled trials (RCTs), prospective observational studies or case-control studies, investigating both an intervention- and control group, examining i) the relationship between arterial stiffness and (diastolic) heart failure in isolated systolic hypertension, or ii) the effects of medication, several compounds and lifestyle (diet or exercise) on blood pressure, arterial stiffness and cardiac structure/function, in human follow-up studies (subjects acting as their own controls).
2. Individuals with isolated systolic hypertension and/or heart failure. No restrictions on age were enforced. Both sexes were included.
3. Studies investigating (primary) outcome measures (see summary measures) Studies were excluded a) if populations with kidney haemodialysis/peritoneal dialysis were examined, b) if the estimated glomerular filtration rate (eGFR) was lower than 30 ml/min/1.73 m², c) if there were no ventricular or vascular changes reported, or d) if the studies were classified as retrospective cohort- and/or cross-sectional studies. Additionally, review articles and case reports were not eligible for inclusion.

2.3.3 Study selection and data extraction

When eligibility criteria and the search strategy were realised by three investigators (K.M.W, A.A.K. and K.D.R.), selection screening, based on title and abstract according to the *a priori* retrieved inclusion- and exclusion criteria, was conducted. In case of mismatch between the investigators, inclusion of an article was based on agreement by consensus during the selection screening.

Figure 2.1: Search and selection of studies.

Full-text publications were reviewed by two investigators (K.M.W. and M.H.G.H.) if eligibility criteria were satisfied. Study characteristics, risk of bias within studies and results/conclusions of individual studies were reviewed independently of each other.

From the selected studies, when available, the following data were extracted: i) study methods (design, data collection, time period), ii) participant characteristics (inclusion/exclusion, size, origin, setting), iii) intervention/placebo treatment (type, dose, duration), and iv) outcome measures. In case of a mismatch between first and second reviewer, agreement was achieved by consensus.

2.3.4 Risk of bias

Two reviewers (K.M.W. and M.H.G.H.) independently assessed risk of bias to ascertain the validity of the included studies. If present, discrepancies were resolved by agreement based on consensus. Using the online Cochrane handbook for writing systematic reviews [15], sequence generation, allocation concealment, randomisation, blinding of participants and personnel, proportion of drop-outs,

Table 2.1: Overview of arterial stiffness measured.

Name	Abbreviation	Regional or single-point PWV	Studies [ref. no.]
Carotid-femoral pulse wave velocity	cfPWV	regional	[2, 4, 13, 14, 31, 42]
Brachial-ankle pulse wave velocity	baPWV	regional	[1, 38, 41, 45]
Aortic pulse wave velocity	aoPWV	single-point	[8, 19, 32, 43]

similarity between therapies, selective outcome reporting and sponsors influence were assessed for RCTs. Prospective observational studies were assessed by the Newcastle Ottawa Scale [46], in which selection-, comparability- and exposure parameters were rated.

2.3.5 Summary measures

Primary outcome measures were changes in i) arterial stiffness and compliance, ii) blood pressure, iii) pulse pressure, iv) LV hypertrophy, LV mass (LVM) and LV mass index (LVMI), (v) diastolic heart failure, and particularly relations between those variables. The included studies report on the one hand regional pulse wave velocities (i.e. cfPWV and baPWV, based on transit time) and on the other hand single-point aortic stiffness. These studies did not utilise carotid measurements. Subsequently, from aortic stiffness estimates, we obtained estimates of aoPWV using the Bramwell-Hill equation [6]. In case compliance (CC) was reported we used $PWV = (A_0/\rho CC)^{1/2}$, whereas if distensibility (DC) was reported, we used $PWV = (1/\rho DC)^{1/2}$ (see *, Table 2.A1). Here, A_0 is the diastolic cross-sectional area, defined $A_0 = 0.25 \pi \text{ diameter}^2$ and ρ blood density, assumed 1050 kg/m^3 .

In total, six studies reported cfPWV, four studies reported baPWV and five studies reported aortic distensibility or compliance as arterial stiffness outcome, respectively (Table 2.1). Although pulse pressure was included in our search strategy, we did not include these results in our analysis to avoid it being interpreted as arterial stiffness measure.

2.3.6 Outcome of interest and statistical analysis

For each study, we extracted average primary outcomes measures per treatment arm. The outcomes were analysed for homogeneity via statistical analyses. Data were visualised using scatter plots, whereas weighted Pearson's correlation coefficients and linear regression coefficients were calculated to explore between-study associations between changes in PWV and SBP, LVMI and SBP, and LVMI and PWV, respectively.

To internally validate our findings, we performed a sensitivity analysis of the correlation and regression parameters by repeating the statistical analyses after omission of studies not specifically reporting the effect of antihypertensive medication. Additionally, we repeated the statistical analyses using only the data from RCTs. A p -value < 0.05 was considered statistically significant. All statistical analyses were performed using SPSS version 24 (IBM Corp, Armonk, NY, USA).

2.4 Results

2.4.1 Study selection

Using our search strategy, we identified 386 potentially relevant articles from PubMed ($n=221$), EMBASE ($n=1$), Cochrane ($n=50$) and Web of Science ($n=114$). A flow diagram of the study selection process is shown in Fig. 2.1. Eventually, 23 articles with a total of 2573 subjects met the inclusion- and eligibility criteria and were included in this systematic review.

2.4.2 Risk of bias

The quality of the different included studies varied. For RCT-studies (Table A1), the domains 'allocation concealment', 'blinding of participants and personnel' and 'blinding of outcome assessment' constitute a plausible risk of bias for most studies, which negatively influenced the outcome for these individual studies, and could lead to high risks of performance bias. On the other hand, most studies demonstrated adequate 'sequence generation', 'follow-up of patients' and 'similarity of therapies'. In addition, low chance of publication bias was indicated, via adequate exclusion of 'undesirable influences of sponsors' and 'selective-free outcome reporting'.

For cohort studies (Table A2), the domains 'selection', 'comparability' and 'exposure' were adequate indicating low risk of bias. Two studies [33, 40] constituted overall a significantly higher risk of bias, and therefore, extra attention is needed when interpreting those results.

2.4.3 Study characteristics

The characteristics of included studies are summarised in Table 2.2 and Table 2.3. Fourteen studies were qualified as RCTs, while the other nine were prospective observational cohort studies. The follow-up period ranged from three months to 4.8 years for all English-written studies. The number of participants ranged from $n=20$ to $n=873$. Mainly, essential hypertensive patients with or without cardiac and/or vascular alterations were included in studies in single-centre tertiary care centres in European and East Asian countries. The main exclusion criteria were cerebrovascular- and/or renal disorders.

The majority of the trials used antihypertensive drugs, such as angiotensin II receptor blockers (ARBs), angiotensin converting enzyme inhibitors (ACEIs), calcium channel blockers (CCBs), diuretics, and beta-blockers (BBs), while other trials examined the effects of either weight loss, physical training, surgery, treatment with agalsidase beta or high doses of allopurinol. Outcome measures included changes in vascular stiffness, pulse pressure, LVM and LV diastolic function parameters, and correlations between those variables.

Table 2.2: Characteristics of included randomised controlled trial studies (RCTs).

Authors	Country	Design	Follow-up	No. patients	Inclusion criteria	Exclusion criteria	Treatment (per arm 1,2,3)	Outcome measures
Au et al. [2]	Canada	RCT	3 mo	n=32	Healthy active males, already performing RET ≥ 2 years	BMI≥30 kg/m ² , history of smoking, supplements other than protein	1: HR-RET, 2: LR-RET	BP, HR, FFM, % body fat, LVMI, LVMI, cPWV, carotid artery distensibility
Beaussier et al. [4]	France	RCT	3 mo	n=164	Essential hypertension, patients resistant to 2-3 types of AHT drugs, including diuretics	Secondary hypertension, history of cardiovascular disease/stroke in the past 3 months, AF, uncontrolled DMT2, GFR <40 ml/min	1: Spirinolactone, furosemide, amloride, 2: Amipril, bisoprolol	BP, cPWV, echoCor, LVMI
Vizzardi et al. [43]	Italy	RCT	6 mo	n=51	HF, LVEF<40%, prior RAAS and beta-blockers treatment for ≥6 months	CAD or myocardial infarction	Spirinolactone	BP, aortic strain, aortic distensibility
Mancusi et al. [27]	Norway	RCT	58 mo	n=873	Patients aged 55-80 years, SBP of 160-200 mmHg or DBP of 95-115 mmHg, LVH based on ECG criteria	Not further described	Losartan/atenolol	BP, echoCor, LVMI, LVMI
Ripley et al. [32]	UK	RCT	6 mo	n=34	BP>140/90 mmHg, LVH confirmed by ECG and CMR criteria	Secondary hypertension, peripheral vascular disease, renal insufficiency, cardiac arrhythmias, malignancy, contraindication to MRI	1: Valsartan, moxonidine, 2: Bendroflumethiazide, amlodipine	BP, aortic distensibility, aopPWV, LVMI, LVMI
Jekell et al. [20]	Sweden	RCT	12 mo	n=115	Essential hypertension with LVH, and DBP of 90-115 mmHg	LVEF<45%, secondary hypertension, renal insufficiency, CHF, valvular heart disease	Irbesartan/atenolol	BP, echoCor, RWT, SV
Takami and Saito [38]	Japan	RCT	24 mo	n=52	Hypertensive outpatients aged 36-75 years, SBP≥140 mmHg and/or DBP≥90 mmHg	Current olmesartan use, secondary hypertension, arrhythmia, CHF, history of stroke or CAD, valvular heart disease, renal insufficiency, mental disorders	1: Olmesartan, azelnidipine, 2: Olmesartan, amlodipine	BP, echoCor, LVMI, E/e', E/A, baPWV
Rekhranj et al. [31]	UK	RCT	9 mo	n=33	CAD, previous MI, AP, BP<150/90 mmHg, LVH	Current alopurinol/zathiopine use, renal insufficiency, HF, gout	Allopurinol	cPWV, FMD, tonometry
Tomiyama et al. [41]	Japan	RCT	30 mo	n=113	SBP<180 mmHg and/or DBP<110 mmHg	Glucose ≥125 mg/dL, LVEF<50%, creatinine ≥2mg/dL, AHT, ABI<0.95, DMT2	1: Candesartan, 2: Amlodipine	BP, echoCor, E/A, LVMI, baPWV
Edwards et al. [11]	UK	RCT	10 mo	n=56	Patients aged 18-80 years, stage 2, renal failure, ACE/ARB treatment >6 months	AP, MI, HF, DMT2, vascular disease, AF, renal failure, anaemia	Spirinolactone	BP, aopPWV, cPWV, LVMI, LVMI
Malafro et al. [25]	Italy	RCT	3 mo	n=27	Patients with chronic systolic heart failure, clinically stable for 3 months	AF, mitral surgery, prior LV aneurysm repair, defibrillator implantation	Physical training	Stress-test, cardiopulmonary test, echoCor, LVMI
Anan et al. [1]	Japan	RCT	10 mo	n=31	Ambulatory SBP>135 mmHg or ambulatory DBP>85 mmHg	Secondary hypertension, prior AHT, organic heart disease (other than LVH), use of statins, DMT2	1: Valsartan, 2: Perindopril 3: Valsartan, perindopril	BP, echoCor, baPWV, BNP, LVMI, PWT, E/A
de Luca et al. [9]	International	RCT	12 mo	n=214	SBP≥160 mmHg and <210 mmHg, DBP>95 mmHg and <110 mmHg	Use of other types of AHT drugs	1: Perindopril, indapamide, 2: Atenolol	BP, LVMI
Topouchian et al. [42]	France	RCT	6 mo	n=69	DBP of 95-114 mmHg	Stroke, renal/cardiac failure	1: Verapamil, 2: Trandolapril, 3: Trandolapril, verapamil	BP, cPWV, LVMI, LVMI

Abbreviations: A = late ventricular filling velocity, A' = late diastolic velocity of mitral annulus, ABI = ankle-brachial index, ACE = angiotensin converting enzyme inhibitor, AD = arterial/aortic distensibility, AF = atrial fibrillation, AHT = antihypertensive treatment, AP = angina pectoris, ARB = angiotensin receptor blockers, baPWV = brachial pulse wave velocity, BMI = body mass index, BNP = brain natriuretic peptide, BP = blood pressure, CAD = coronary artery disease, cPWV = carotid-femoral pulse wave velocity, CHF = congestive heart failure, CMR = cardiovascular magnetic resonance, DBP = diastolic blood pressure, DMT2 = diabetes mellitus type 2, E = early ventricular filling velocity, E' = early diastolic velocity, ECG = electrocardiogram, FFM = fat-free mass, GFR = glomerular filtration rate, FMD = flow mediated dilatation, HF = heart failure, HR-RET = high-repetition resistance exercise training, HT = hypertension, LR-RET = low-repetition resistance exercise training, LV = left ventricular, LVEF = left ventricular ejection fraction, LVH = left ventricular hypertrophy, LVMI = left ventricular mass, MI = myocardial infarction, RAAS = renin-angiotensin-aldosterone-system, RWT = relative wall thickness, SBP = systolic blood pressure, SV = stroke volume.

Table 2.3: Characteristics of included cohort studies.

Authors	Country	Design	Follow-up	No. patients	Inclusion criteria	Exclusion criteria	Treatment	Outcome measures
Kwon et al. [22]	South-Korea	Cohort	6 mo	n=325	Outpatients aged 18-75 years, SBP<180 mmHg, DBP<110 mmHg, normal ECG	Previous/current use of AHT drugs, DMT2, CHF	Follow-up after AHT	echoCor, E/A, E/e', BP, ABPM, arterial distensibility
Watanabe et al. [45]	Japan	Cohort	12 mo	n=49	SBP≥140 mmHg and/or DBP≥90 mmHg, ≥ 3 months of CCB treatment without effect	Secondary hypertension, previous CVD, renal failure, HF	Follow-up after telmisartan	BP, echoCor, LVMI, bpPWV
Collin et al. [8]	France	Cohort	54 mo	n=30	Fabry disease patients, at least one cardiac and arterial characterisation performed before initiation of agalsidase-beta treatment	Current use of agalsidase-beta, ESRD/kidney transplant, renal insufficiency	Follow-up after agalsidase-beta	BP, echoCor, vascular ultrasound, cPWV
Mizuguchi et al. [29]	Japan	Cohort	13.5 mo	n=35	SBP≥140 mmHg and/or DBP≥90 mmHg	AF, CAD, HF, stroke, secondary hypertension, CHD, cardiomyopathy, DMT2	Follow-up after telmisartan	BP, echoCor, vascular ultrasound
Ruvolo et al. [33]	Italy	Cohort	3 mo	n=20	Male patients aged 18-60 years, BP>130/85 mmHg, LV concentric remodelling and/or increased aortic stiffness	IHD, renal failure, DMT2, unable to perform bike test, arrhythmias, valvular heart disease	Follow-up after hydrochlorothiazide, valsartan	BP, echoCor, vascular stiffness, LVMI, SV
Hashimoto et al. [14]	Japan	Cohort	12 mo	n=61	Untreated hypertensive patients, SBP≥140 mmHg and/or DBP≥90 mmHg	Secondary hypertension, CHD, HF, AF, stroke, renal insufficiency, current use of vasoactive drugs	Follow-up after AHT	echoCor, WSA, PWA, LVMI
Hashimoto et al. [13]	Japan	Cohort	12 mo	n=43	SBP≥140 mmHg and/or DBP≥90 mmHg	Secondary hypertension, renal insufficiency, major cardiovascular complications, current use of vasoactive drugs	Follow-up after AHT	BP, LVMI
Ikonomidou et al. [19]	Greece	Cohort	36 mo	n=56	Morbid obesity; BMI ≥40 kg/m ²	Current use of AHT, lipid decreasing, thyroid, and blood glucose lowering medications, cardiovascular medications, auto-immune diseases	Follow-up after bariatric surgery	BP, aortic distensibility, LVMI, LVMI
Tomiyama et al. [40]	Japan	Cohort	24 mo	n=90	Essential hypertension patients, BP<140/90 mmHg for last 6 months, ≥ 2 years of CCB treatment	Presence of CVD or serious health issues	Follow-up after AHT	BP, LVMI, cIMT

Abbreviations: A = late ventricular filling velocity, a' = late diastolic velocity of mitral annulus, ABPM = ambulatory blood pressure measurements, AF = atrial fibrillation, AHT = antihypertensive treatment, BMI = body mass index, BP = blood pressure, CAD = coronary artery disease, CCB = calcium channel blocker, cPWV = carotid-femoral pulse wave velocity, CHF = congestive heart failure, cIMT = carotid intima-media thickness, CVD = cardiovascular disease, DBP = diastolic blood pressure, DMT2 = diabetes mellitus type 2, E = early ventricular filling velocity, e' = early diastolic velocity, ECG = electrocardiogram, ESRD = end-stage renal disease, HF = heart failure, HT = hypertension, IHD = ischaemic heart disease, LV = left ventricle/left ventricular, LVH = left ventricular hypertrophy, LVMI = left ventricular mass, LVMI = left ventricular mass index, PWA = pulse wave analysis, RWTV = relative wall thickness, SBP = systolic blood pressure, SV = stroke volume, WSA = wave separation analysis.

2.4.4 Studies with vascular and ventricular outcome variables

A total of 13 studies reported values on changes in SBP, PWV and LVMI after intervention (Fig. 2.2).

Figure 2.2: Effect of intervention on mean changes in systolic blood pressure (Δ SBP), pulse wave velocity (Δ PWV) and left ventricular mass index (Δ LVMI). Studies are listed according to magnitude of Δ PWV, from largest (top-left) to smallest (bottom-right). Ten of the thirteen studies had antihypertensive medication as intervention (circles, triangles), while three (squares) had other interventions, as indicated. Symbols indicate treatment arms (i.e. closed circle= arm 1, open circle= arm 2, triangle= arm 3). Abbreviations: ACEI: angiotensin converting enzyme inhibitor; ARB: angiotensin-receptor blockers, BB: beta-blockers, CCB: calcium channel blockers. *No quantitative change in SBP reported but narratively reported as '(Central) systolic blood pressure and pulse pressure were not reduced,...'

The remaining 10 studies, reporting only one or two of the outcome variables, are not displayed in Fig. 2.2 (data given in Table 2.A1). At study level, changes in SBP seemingly correlated with reductions in both PWV and LVMI. Ripley et al. [32] reported no substantial differences between the change in SBP, PWV and LVMI among treatment arms (Fig. 2.2). Conversely, three studies [1, 38, 41] reported considerably different PWV reductions within treatment arms, despite a similar reduction in SBP. Takami and Saito [38] consisted of two treatment arms comparing two types of ARB, CCB combination treatment, whereas Anan et al. [1] consisted of three treatment arms comparing between ARB and ACEI treatment as well as ARB, ACEI combination treatment. Tomiyama et al. [41] consisted of an ARB treatment arm and a CCB treatment arm, respectively. Furthermore, in studies consisting of two or more treatment arms it appeared that the study arm with the highest reduction in PWV and SBP, consistently corresponded to the treatment arm with the highest reduction in LVMI.

2.4.5 Blood pressure in relation to vascular- and ventricular changes

Table 2.4 shows changes in PWV and LVMI stratified by mean changes (Δ) in SBP and DBP, defined by pressure ranges $\Delta\text{DBP} \geq -7$ mmHg versus $\Delta\text{DBP} < -7$ mmHg, and $\Delta\text{SBP} \geq -13$ mmHg versus $\Delta\text{SBP} < -13$ mmHg, respectively. The choice of the pressure ranges was based on twice the intra-session standard deviation for DBP and SBP, as reported earlier [36]. We found that greater reductions in blood pressure (both SBP as DBP) were indicative for greater PWV reductions, whereas for LVMI reductions this pattern only appear to hold for greater DBP-changes (Table 2.4).

Table 2.4: Blood pressure changes and associated changes in arterial stiffness and ventricular mass index.

BP change [mmHg]	Δ PWV [m/s]	Δ LVMI [g/m ²]
Δ DBP ≥ -7	-0.9 (-3.2, -0.14)	-7.3 (-22, -2.8)
Δ DBP < -7	-2.0 (-3.7, -0.6)	-11.0 (-35, -3.9)
Δ SBP ≥ -13	-0.8 (-2.4, -0.14)	-13.0 (-24, +4.5)
Δ SBP < -13	-2.0 (-3.7, -0.7)	-8.0 (-35, -2.8)

Changes are presented as median (minimum, maximum). Abbreviations: ΔDBP and ΔSBP denote changes in diastolic and systolic blood pressure, whereas ΔLVMI and ΔPWV denote changes in left ventricular mass index and pulse wave velocity, respectively.

2.4.6 Pooling of data and correlations between SBP, PWV and LVMI within studies reporting all three variables

We pooled and plotted ΔSBP , ΔPWV and ΔLVMI data to explore potential associations among these outcome measures (Fig. 2.3).

Figure 2.3: Scatter plots of mean changes in left ventricular mass index (Δ LVMI), pulse wave velocity (Δ PWV), and systolic blood pressure (Δ SBP). Studies with two or more treatment arms were plotted as separate data points. Markers indicate treatment type, i.e. the prescribed antihypertensive drug class or combination of classes, respectively. Abbreviations: ACEI: Angiotensin converting enzyme inhibitor, ARB: Angiotensin-receptor blockers, BB: beta-blockers, CCB: Calcium-channel blockers. Symbols: r : Pearson correlation coefficient. p : statistical significance level.

Regarding SBP, the proportion in reduction did not correlate significantly to the proportion in reductions of the other two outcome measures (i.e. Δ PWV vs. Δ SBP: $r=0.23$, $p=0.29$; Δ LVMI vs. Δ SBP: $r=-0.05$, $p=0.81$). However, we found a significant positive correlation between changes in Δ PWV and Δ LVMI (Fig. 2.3, $r=0.61$, $p=0.003$). Furthermore, linear regression of Δ PWV on Δ LVMI suggested a 6.9 g/m^2 decrease in LVMI per 1 m/s decrease in PWV ($95\% \text{CI}=[1.9;11.8] \text{ g/m}^2/\text{m/s}$).

The analyses were repeated following omission of the non-antihypertensive treatment studies [2, 8, 19, 25]. Briefly, this caused only minor changes in the correlation and regression parameters ($r=0.57$, $p=0.013$, and $B=6.5 \text{ g/m}^2/\text{m/s}$, $95\% \text{CI}=[1.6;11.4] \text{ g/m}^2/\text{m/s}$, respectively). Similarly, we found minor changes

in the correlation and regression parameters when using only data from RCTs ($r=0.62$, $p=0.010$, and $B=6.6 \text{ g/m}^2/\text{m/s}$, $95\%CI=[1.9;11.4] \text{ g/m}^2/\text{m/s}$). Given the limited amount of data points available for regression analysis (Fig. 2.3), we chose not to evaluate quadratic instead of linear associations, since this would result in overfitting. We explored possible mutual relationships between types of ΔPWV (i.e. as assessed by cfPWV, baPWV and aoPWV) with both ΔSBP and $\Delta LVMI$ (Fig. A1).

Our analysis did not demonstrate statistically significant associations. Nevertheless, in particular $\Delta baPWV$ and $\Delta aoPWV$, but not $\Delta cfPWV$, showed trends with $\Delta LVMI$ ($r=0.62$, $p=0.10$; $r=0.83$, $p=0.08$; $r=0.26$, $p=0.54$, respectively). Furthermore, $\Delta cfPWV$ and $\Delta aoPWV$, but not $\Delta baPWV$ showed trends with ΔSBP ($r=0.59$, $p=0.07$; $r=-0.85$, $p=0.07$; $r=0.14$, $p=0.74$, respectively), indicating that a larger power (in future studies) might possibly lead to significant correlations. In the above analyses a limited amount of data points was available (Fig. A1).

2.5 Discussion

2.5.1 Key findings

Our systematic review of well-controlled clinical intervention studies provides evidence that a decrease in arterial stiffness could contribute to the reduction of LVM in (hypertensive) patients. However, we could not obtain convincing evidence supporting the causative pathophysiological [arterial stiffening — elevated SBP — LV hypertrophy/ failure]-chain.

A major complication is that arterial stiffness measurements such as PWV are inherently blood pressure-dependent [36, 37]. In the present review, we found studies showing a significant decrease in PWV in excess of $\approx 0.5 \text{ m/s}$, which is typically the measurement variability order of magnitude, and in excess of 1 m/s , which our group identified as the change in PWV expected for a change in diastolic blood pressure of 10 mmHg [36]. As such, some of the observed significant changes in PWV may partially or fully be attributable to a change in blood pressure, without a change in intrinsic arterial stiffness.

We did not find a study that was appropriately designed to disentangle pressure-independent arterial stiffness effects from plain blood pressure lowering, nor are we aware of a study that extensively described SBP, PWV and LVMI changes over many time-points. We expect that changes in PWV precede changes in LV mass. There were several studies included reporting arterial stiffness and ventricular structure at multiple time-points [8, 19, 38, 41]. However, only data from Collin et al. [8] suggested that a change in PWV could precede a change in LV mass. Despite the present analysis, therefore, it remains cumbersome to assess the direct effect of antihypertensive treatment on LV structure and function as well as test the hypothesised causal relation between increased arterial stiffness and LVH.

2.5.2 Clinical implications and future work

Our results indicate a significant positive correlation between changes in arterial stiffness and LVM. Only two of the 23 included studies [22, 38] reported changes in LV diastolic function indices (i.e. the outcome variables E/A and E/e', respectively). Those studies found independent statistical associations between on the one hand reductions in PWV and pulse wave reflection magnitude (assessed by means of augmentation index), and on the other hand improvements in LV diastolic function (via LVMI reduction and improvements in E/A and E/e', Table 2.A1). Takami and Saito [38] hypothesised that the mechanism involved could be a delay in arrival of the reflected pulse wave due to decreased PWV, which in turn reduces left ventricular afterload [38]. However, it should be noted that using augmentation index as proxy for wave reflection magnitude is deemed contentious by some researchers in the field [3, 17]. Hashimoto et al. [14] reported a positive correlation between changes in LVM and reflection magnitude, calculated using a 'gold standard' method of assessing pulse wave reflections (i.e. based on solving the physical laws of mass conservation and momentum balance [47]). The authors reported that reducing stiffness of peripheral muscular arteries, which they considered to be the root cause of increased pulse wave reflection, was more important than reducing central arterial stiffness, in the regression of LVM [14]. Tomiyama et al. [41] reported that candesartan leads to significantly greater reductions in stiffness of muscular arteries (i.e. assessed by brachial-ankle PWV), as compared to amlodipine [41], with similar decreases in LVMI of 7 g/m² and 6 g/m², respectively.

In summary, our results suggest that therapeutic agents that aim to lower arterial stiffness may lead to greater reductions in LVM. However, further clinical trials with multiple follow-up measurements, using pressure-independent arterial stiffness indices, are required to establish the causative role of arterial stiffness-lowering in reduction of LVM. To achieve the latter, a stiffness index such as CAVI₀ could be a promising candidate [37]. Additionally, directing more attention to pulse wave reflection indices may further advance insight into LVM reduction [14, 38]. Of particular interest are (lifestyle or surgical) interventions improving physical activity and diet, since these kinds of trials provided promising results in terms of arterial stiffness and LV diastolic function improvements [2, 8, 19, 25, 31], without invoking *per se* the effects of direct actions of antihypertensive drugs on the cardiovascular system.

2.5.3 Limitations

Our review is limited by its reliance on published data causing an inherent risk of publication bias, as neutral studies (without changes in LVMI or PWV) are less likely to be accepted by publishers.

A general conclusion about the effect size of lowering blood pressure and arterial stiffness on LVH is difficult, since the quality of the studies was variable (quality rating between 2 and 8 points out of 10 for RCTs and between 5 and 9 points

for cohort studies, Table A1 and A2). Most studies quantified arterial stiffness using carotid-femoral PWV or brachial-ankle PWV (i.e. calculated using pulse transit time and path length). For studies reporting either a change in compliance or distensibility, we were limited to calculating an estimate of PWV using the Bramwell-Hill equation. Regional (i.e. carotid-femoral and brachial-ankle) PWV values are physically different compared to single-point (i.e. aortic) PWV values, calculated using the Bramwell-Hill equation. However, previous work including patient studies [10, 16] and mechanistic computational studies [48] showed reasonable proportionality between regional PWV and single-point PWV. Also, the study of Chow and Rabkin [7] showed appropriate proportionality between baPWV and cfPWV. Therefore, we believe that pooling of changes in cfPWV, baPWV, and aoPWV can be justified. We, however, cannot exclude that pooling the various methodologies of PWV assessment influenced the associations we found.

Furthermore, considering the heterogeneity in antihypertensive treatment and the limited number of studies included, we have not been able to conduct antihypertensive drug class specific analyses. Lack of correlation between changes in SBP and LVMI could be related to the fact that most studies included in this review performed office BP measurements instead of 24-hour ambulatory BP measurements. Office blood pressure measurements contain more variable SBP readings, e.g. due to inter-individual differences in white-coat effect. Previously, it was reported that in hypertensive children 24-hour SBP relates with LVMI, but not with office SBP [35].

Lastly, minor limitations of this review include our language restriction for only English written articles, and our inclusion of non-RCT studies, which in the hierarchy of evidence are inferior to RCT studies.

2.6 Conclusions

This systematic review demonstrates that there is evidence in well-controlled clinical intervention studies that a decrease in arterial stiffness is associated with reduction of LV mass. To eliminate blood pressure-dependent effects for the correlation between arterial stiffness and LV structure, blood pressure-independent markers should be used in future studies. In that way, better identification of potential targets for antihypertensive drug treatment may be facilitated. In addition, the potential of lifestyle interventions (e.g. physical activity and diet) in the research field remains to be emphasised.

2.A1 Appendix Figures and Tables

Figure A1: Top: Scatter plots displaying the relation between changes in left ventricular mass index (ΔLVMI), and changes in carotid-femoral, brachial-ankle, and aortic pulse wave velocity (ΔcfPWV , ΔbaPWV , ΔaoPWV , respectively). Bottom: Relation between changes in ΔcfPWV , ΔbaPWV , ΔaoPWV and changes in systolic blood pressure (ΔSBP). Symbols: r : Pearson correlation coefficient. p : statistical significance level.

3.1 Abstract

We developed a whole-circulation computational model by integrating a transmission line (TL) model describing vascular wave transmission into the established CircAdapt platform of whole-heart mechanics. In the present paper, we verify the numerical framework of our TL model by benchmark comparison to a previously validated pulse wave propagation (PWP) model. Additionally, we showcase the integrated CircAdapt-TL model, which now includes the heart as well as extensive arterial and venous trees with terminal impedances. We present CircAdapt-TL haemodynamics simulations of 1) a systemic normotensive situation and 2) a systemic hypertensive situation.

In the TL-PWP benchmark comparison we found good agreement regarding pressure and flow waveforms (relative errors $\leq 2.9\%$ for pressure, and $\leq 5.6\%$ for flow). CircAdapt-TL simulations reproduced the typically observed haemodynamic changes with hypertension, expressed by increases in mean and pulsatile blood pressures, and increased arterial pulse wave velocity. We observed a change in the timing of pressure augmentation (defined as a late-systolic boost in aortic pressure) from occurring after time of peak systolic pressure in the normotensive situation, to occurring prior to time of peak pressure in the hypertensive situation. The pressure augmentation could not be observed when the systemic circulation was lumped into a (non-linear) three-element windkessel model, instead of using our TL model. Wave intensity analysis at the proximal aorta indicated earlier arrival and increased intensity of reflected waves with hypertension as compared to normotension, in good qualitative agreement with findings in patients.

In conclusion, we successfully embedded a TL model as a vascular module into the CircAdapt platform. The integrated CircAdapt-TL model allows mechanistic studies on heart-vessel interaction.

3.2 Introduction

THE CircAdapt platform, a zero-dimensional whole-heart model developed in our lab, historically focussed on cardiac mechanics. It has been successfully used for simulating haemodynamics during cardiac conductance disorders, valve pathologies, and changes in afterload [23, 26, 34, 43]. Lacking a distributed model of the vascular system, the current CircAdapt model is yet unable to simulate heart-vessel interaction at the level of arterial wave dynamics.

Arterial pulse waves, constituting a component of ventricular afterload, appear to have implications in age-related changes in left ventricular mass, and left ventricular hypertrophy [12, 29]. So-called wave intensity analysis (WIA) allows characterisation of both pulse wave magnitude and propagation direction, thereby requiring synchronous and co-localised measurements of blood pressure and blood flow velocity signals [35]. WIA applied to patient measurement data is sensitive to synchronisation errors and the signal processing characteristics of the measurement devices [37], which hampers or limits detailed studies on heart-vessel interaction, especially concerning causal relationships.

Computational models of whole-circulation mechanics, such as CircAdapt, allow for well-controlled simulations, facilitating comprehensive study of single- and multi-factorial relationships between arterial system properties and cardiac structure and function. In the present study we introduce and demonstrate the CircAdapt-TL model (Fig. 3.1): a whole-circulation model with an integrated segmental transmission line (TL) module, describing vascular wave propagation, reflection and transmission. We verify the numerical implementation of the TL model by a benchmark comparison of the model to the established pulse wave propagation (PWP) model of Kroon et al. [21]. Additionally, we demonstrate operation and output of the integrated CircAdapt-TL model, by simulating systemic normotensive- and hypertensive conditions. We evaluate the implications of modelling vascular wave transmission on aortic haemodynamics by comparing simulated left ventricular- and aortic pressure tracings of the integrated CircAdapt-TL model with the tracings obtained with the systemic circulation lumped into the existing CircAdapt non-linear three-element windkessel (3WK) model (i.e. neglecting wave transmission effects). Further evaluation includes WIA applied to simulated carotid arterial pressure and flow waveforms in semi-quantitative comparison with WIA applied to patient measurements.

3.3 Models

3.3.1 Overview of complete model

Our vascular module describing wave transmission in vascular networks will be integrated into the existing CircAdapt platform (www.circadapt.org). This model platform has a modular setup, currently consisting of a 0D whole-heart mechanics model, valve haemodynamics model, and non-linear three-element

Figure 3.1: The new vascular module interfaces the existing whole heart-heart mechanics and arterio-venous impedance modules. The CircAdapt-TL model contains the cardiac modules describing whole-heart mechanics, including interventricular interactions, and the systemic and pulmonary circulations [25]. Cardiac valves are modelled as described in Palau-Caballero et al. [34]. The vascular module is described in section ‘Vascular module’. The arterio-venous impedance module, modelling the peripheral circulation using a non-linear three-element windkessel (3WK) was previously developed by Arts et al. [3]. Abbreviations: RA: right atrium, LA: left atrium, TV: tricuspid valve, PV: pulmonary valve, AV: aortic valve, RV: right ventricle, LV: left ventricle, MV: mitral valve, art: arterial, ven: venous, 3WK: non-linear three-element windkessel model. Symbols: R_p : peripheral resistance, Z_{wave} : wave impedance, C : compliance.

windkessel models of the pulmonary and peripheral circulations (Fig. 3.1). In the next section, we introduce the governing equations, modelling assumptions and implementation of our new vascular module in detail.

3.3.2 New vascular TL-module

To model pressure-flow waves within segments of blood vessels, we assume 1) blood vessels to be thick-walled, longitudinally constrained non-linear elastic tubes, 2) blood to be incompressible and Newtonian and 3) that gravity forces can be neglected. Furthermore, we assume 4) no leakage of blood to small side-branches that are not explicitly modelled. Application of the laws of balance of mass and momentum, and subsequent integration over the tube’s cross-sectional area yield the governing equations [16]:

$$C \frac{\partial p}{\partial t} + \frac{\partial q}{\partial z} = 0, \quad (3.1)$$

$$L \left(\frac{\partial q}{\partial t} + \frac{\partial}{\partial z} \int_A v_z^2 dA \right) + \frac{\partial p}{\partial z} = f, \quad (3.2)$$

where $p = p(z, t)$ is the pressure at the axial vessel coordinate z , and $q = q(z, t)$ the flow rate at that coordinate. Furthermore, A denotes cross-sectional lumen area,

and L and C are the tube inertance and compliance per unit length, respectively. Term $L \frac{\partial}{\partial z} \int_A v_z^2 dA$ represents the convective acceleration term, with v_z the axial blood velocity. Term f represents friction force per unit volume caused by viscous properties of the blood, defined $f = 2\pi r_0 \tau_w / A_0$ [6]. Here, symbol τ_w denotes wall shear stress, r_0 reference radius, and A_0 reference cross-sectional lumen area, respectively. After neglecting the convective acceleration term and assuming an approximate velocity profile to estimate τ_w [6], the governing equations can be rewritten to the telegrapher's equations:

$$-\frac{\partial q}{\partial z} = C \frac{\partial p}{\partial t}, \quad (3.3)$$

$$-\frac{\partial p}{\partial z} = L(\alpha_0) \frac{\partial q}{\partial t} + R(\alpha_0)q, \quad (3.4)$$

with $L(\alpha_0)$ and $R(\alpha_0)$ a characteristic Womersley number-dependent inertance and resistance term, defined by

$$L(\alpha_0) = g(\alpha_0) \frac{\rho}{A_0}, \quad (3.5)$$

$$R(\alpha_0) = h(\alpha_0) \frac{8\pi\eta}{A_0^2}, \text{ with} \quad (3.6)$$

$$\alpha_0 = r_0 \sqrt{\rho\omega_0/\eta}. \quad (3.7)$$

The functions $g(\alpha_0)$ and $h(\alpha_0)$ were derived by Bessems et al. [6] and are detailed in Appendix 3.A1.2. The characteristic Womersley number (α_0) describes the ratio of instationary inertia forces and viscous forces, governed by vessel radius (r_0), characteristic angular frequency ($\omega_0 = 2\pi/T$, with T the cardiac cycle duration), blood dynamic viscosity (η) and blood density (ρ), respectively (Table 3.1).

Table 3.1: Parameters relevant for the transmission line model.

Symbol	Value or expression	Unit	Meaning	Reference
A_0, r_0	See Table A2 and A3	m ² or m	Reference lumen area or vessel radius	[30, 39]
α_0	$\alpha_0 = r_0 \sqrt{\rho\omega_0/\eta}$	-	Characteristic Womersley number	[6]
b	0.02	-	Collapsible tube fraction	Assumed
Δt	0.001	s	Time step	Assumed
Δz	0.02	m	Element size	Assumed
l_{AV}	$6q_{AV}^{1/3}$	m	Characteristic vessel bed length	Assumed
k	See Tables A2 and A3	-	Vessel stiffness coefficient	[13], Assumed
l	See Tables A2 and A3	m	Vessel length	[30, 39]
η	0.003	Pa s	Blood dynamic viscosity	[47]
$p_{0,a}$	105 (REF), 135 (HYP)	mmHg	Reference pressure for arteries	Assumed
$p_{0,v}$	1.1 (REF), 1.1 (HYP)	mmHg	Reference pressure for veins	Assumed
q_{AV}	See Table A2	ml s ⁻¹	Mean flow through terminal tube	[11, 14], Assumed
q_0	85	ml s ⁻¹	Mean systemic flow	[43]
ρ	1050	kg m ⁻³	Blood density	[47]
T	0.85	s	Cardiac cycle duration	[43]
ω_0	7.39	rad s ⁻¹	Characteristic angular frequency	[6]

REF: Reference simulation. HYP: Hypertension simulation.

The rationale of this method is to calculate R and L based on an approximated velocity profile for which the viscous boundary layer thickness is approximated for the characteristic frequency [6]. To solve the governing equations, we also need a constitutive law to relate (changes in) transmural pressure (p_{trans}) to (changes in) current cross-sectional area (A). We formulated a non-linear power-law to phenomenologically capture the experimentally observed non-linear pressure-area relation of arteries and veins [4, 13]:

$$p_{\text{trans}}(A) = -p_{\text{ext}} + p_0 \left((1+b) \left(\frac{A}{A_0} \right)^{1+\frac{k/3-2}{1+b}} - \frac{bA_0}{A} \right),$$

and

$$C = \frac{dA}{dp_{\text{trans}}},$$
(3.8)

with p_0 a reference pressure, A_0 a reference cross-sectional area, and k the vessel stiffness coefficient. Furthermore, b is a small fraction to simulate collapse of the tube with negative transmural pressure (Table 3.1) and p_{ext} represents a prescribed external pressure (if present). Now we can solve the resulting governing equations in either the time domain or frequency domain [10]. We explicitly chose a time-domain approach, since this permits using non-linear boundary conditions as already present in the CircAdapt platform [43]. Our solving method uses a TL model. A detailed overview of our solving method is provided in Appendix 3.A1.1.

3.3.3 Arterio-venous impedance module

The terminal end of a tube was coupled to a non-linear three-element windkessel (3WK) element [3]. We assumed the windkessel compliance to be pressure-dependent, and scaled by an estimate of the tissues' vessel bed length [46]. As a consequence, wave impedance also becomes pressure-dependent (Fig. 3.1):

$$C_{AV} = l_{AV} \frac{dA}{dp_{AV}} \text{ and } Z_{\text{wave},AV} = \sqrt{\frac{\rho}{A} \frac{dp_{AV}}{dA}},$$
(3.9)

with AV , the subscript for the arterial and venous contributions, i.e. $AV = [\text{art,ven}]$. Such approach enables simulating large changes in haemodynamic load (e.g. exercise or hypertension) without requiring to manually adjust the 3WK parameter values. The derivatives in the aforementioned equations were calculated at the connection point (i.e. a node) of a tube with a 3WK, using the constitutive relation as given in Eq. 4.2. The parameter l_{AV} represents the characteristic length of a peripheral bed. We estimated the vessel bed length using the relation given by $l_{AV} = 6q_{AV}^{1/3}$, with q_{AV} the mean peripheral flow through any terminal tube. To obtain first-order approximations of l_{AV} among all peripheral beds, we utilised this relation in conjunction with flow distribution estimates as reported in Table A2. Furthermore, using a physiology textbook [11], we estimated that in rest

21% of the cardiac output is directed to the head, 47% to the abdomen, 18% to the pelvis and lower extremities, and 14% to the upper extremities, respectively. The peripheral resistance (R_p) was defined via a flow source, controlled by the instantaneous arterio-venous pressure difference (Fig. 3.1) [3]:

$$R_p = \frac{P_{\text{art}} - P_{\text{ven}}}{q_{\text{AV}}} . \quad (3.10)$$

3.3.4 Cardiac module

The atria and ventricles of the heart were modelled as contractile chambers. The ventricles are surrounded by three cardiac walls: the left ventricle free wall, interventricular septum and right ventricle free wall (Fig. 3.1). Ventricles are mechanically coupled, based on force equilibrium in the junction of the ventricular walls [25]. The atria are surrounded by the left atrial wall and right atrial wall (Fig. 3.1). The cardiac chambers are considered as contractile cavities formed by the one-fibre model, relating myofibre stress to cavity pressure using the assumption that myofibre stress is homogeneously distributed within the myocardial wall [1]. The phenomenological model of myofibre mechanics was previously described [43]. The one-fibre model is used to calculate myofibre stress from myofibre strain. Total Cauchy myofibre stress experienced by cardiac tissue comprises of a summation of active stress, present in the actin filaments and separate microstructural contributions (i.e. titin and the extracellular matrix, assumed to act in parallel). Transmural pressure is calculated from wall tension, derived from total Cauchy stress and wall curvature using Laplace's law [43]. Cavity pressures are calculated by adding the transmural pressures to the pericardial pressure surrounding the myocardial walls. As commonly used in other cardiac models, the pericardium was assumed a compliant bag, modelled using a non-linear relation relating pericardial pressure and volume [19]. The pulmonary circulation was modelled as 3WK (see Section 'Arterio-venous impedance module'), connecting the pulmonary artery with the pulmonary veins [33]. Full details of the cardiac model can be retrieved from Walmsley et al. [43] and Lumens et al. [25].

3.3.5 Valve module

Valve flow (q_{valve}) was generated using the unsteady Bernoulli equation, assuming incompressibility and inviscid, irrotational flow:

$$\frac{\rho l_{\text{valve}}}{A_{\text{valve}}} \frac{\partial q_{\text{valve}}}{\partial t} = \Delta p - \frac{1}{2} \rho q_{\text{valve}} |q_{\text{valve}}| \left(\frac{1}{A_{\text{valve}}^2} - \frac{1}{A_p^2} \right) , \quad (3.11)$$

with the term on the left hand side the unsteady inertia, governed by blood density, effective valve length (l_{valve}) and valve cross-sectional area (A_{valve}) [34]. The first term on the right hand side denotes the pressure difference (Δp) and the second term is the change in kinetic energy, with A_{valve} and A_p cross-sectional areas of

the valve and proximal to the valve, respectively. For A_{valve} , a phenomenological valve opening and closing function depending on the pressure gradient was used [34]. In case $\Delta p > 0$, A_{valve} instantaneously increases towards an effective valve area representing a completely opened valve. In case $\Delta p < 0$, on the other hand, flow gradually decreases due to inertia. Furthermore, A_{valve} gradually decreases towards a quasi-closed state, with small leakage to avoid division by zero [34].

3.3.6 Simulations and analysis

Benchmark comparison

First, we evaluated the TL model's numerical framework in a benchmark comparison, comparing arterial pressure and flow waveforms generated by on the one hand the TL model and those generated by the PWP model, developed by Kroon et al. [21]. The numerical framework of this PWP model was previously validated in Boileau et al. [8] against *in vitro* experiments, whereas Bessems et al. [6] confirmed the validity of the approximate velocity profile against Womersley theory. In the benchmark comparison, we considered large central arteries (vessel diameters between 15 and 30 mm) as well as smaller arteries of the left arm (vessel diameters between 2 and 11 mm, Table A2). Furthermore, the same set of equations (i.e. the balance equations and the constitutive law) was solved for the PWP- as well as for the TL model. We also kept boundary conditions (i.e. constitutive law and 3WK parameters) equal between the PWP- and TL model. At the proximal aorta we prescribed a periodical flow wave (q_{inflow}) with a period of 0.85 s. This flow wave was composed of a half-sinusoidal wave with a duration (t_c) of 0.3 s and a peak flow rate (q_p) of 350 ml s^{-1} , whereas flow was zero in the rest of the period,

$$q_{\text{inflow}}(t) = \begin{cases} q_p \sin\left(\frac{\pi t}{t_c}\right) & \text{if } 0 \leq t \leq t_c \\ 0 & \text{if } t > t_c. \end{cases} \quad (3.12)$$

The PWP model used a simplified trapezoidal scheme for spatial discretisation and a second-order backward difference scheme for time discretisation. For each tube in the domain, agreement between models in terms of pressure and flow, was quantified by calculation of root mean square errors (ϵ) and relative errors

(δ):

$$\begin{aligned}\epsilon_{p,n} &= \sqrt{\frac{\sum_{t=0}^T (p_{TL}(t) - p_{PWP}(t))^2}{N_t}}, & (3.13) \\ \epsilon_{q,n} &= \sqrt{\frac{\sum_{t=0}^T (q_{TL}(t) - q_{PWP}(t))^2}{N_t}}, \\ \delta_{p,n} &= \frac{1}{N_t} \sum_{t=0}^T \left| \frac{p_{TL}(t) - p_{PWP}(t)}{p_{PWP}(t)} \right| \cdot 100\%, \text{ and} \\ \delta_{q,n} &= \frac{1}{N_t} \sum_{t=0}^T \left| \frac{q_{TL}(t) - q_{PWP}(t)}{\max_n(q_{PWP}(t))} \right| \cdot 100\%,\end{aligned}$$

with n the tube reference number, T the cardiac cycle duration and N_t the number of time points for which a comparison is made. A complete overview of the benchmark comparison setup is provided in Appendix 3.A2.

Simulation of arterial and venous haemodynamics using the CircAdapt-TL model

We first show the applicability of the CircAdapt-TL model in terms of simulation of pressure and flow waveforms throughout arteries and veins as well as changes in wave dynamics when simulating systemic hypertension. Furthermore, we compare LV and aortic pressure tracings of the CircAdapt-TL model with those obtained when lumping the systemic arterial and venous blood vessels into a single 3WK. For the first purpose, we implemented an arterial tree (Fig. 3.2 and Table A2), for which the morphological and mechanical properties were based on the work of Reymond et al. [39], and a venous tree (Fig. 3.3 and Table A3), based on the work of Müller and Toro [30]. Since in the present study we were not interested in simulating pressure and flow in cerebral and coronary vessels, we excluded these vessels from our model domain. Vessel stiffness coefficients (k) for the aortic segments as well as arteries of the left and right arm were as used in the benchmark comparison. Furthermore, for the arteries of the leg (i.e. the iliac, femoral and tibial arteries), we chose k equal to 30, based on data of Hayashi et al. [13]. Given the lack of human data on veins, a fixed k -value of 10 was chosen for all veins in the model domain.

We performed the following sets of simulations.

1) Using the CircAdapt-TL model, we performed:

- A reference simulation (REF-TL) in which we model the case of normal arterial stiffness. For this simulation, we kept reference pressure (p_0) at 105 mmHg and vessel stiffness coefficient (k) as given in Tables A2 and A3. According to clinical standards, we characterised arterial stiffness by calculating the carotid-femoral pulse wave velocity (PWV). We obtained

PWV by dividing the fixed path length between the terminal nodes of the tubes that modelled the carotid artery and femoral artery by the pulse transit time between these nodes. The pulse transit time was obtained as the foot-to-foot time difference between the respective pressure waveforms. Foot detection was performed using the maximum of the 2nd-order derivative of the pressure waveform.

- A systemic hypertension simulation (HYP-TL), in which we model a hypertensive situation. For this simulation, we increased p_0 . Such increase in p_0 can physiologically be interpreted as an increase in peripheral resistance. Furthermore, vascular stiffness parameter k of all systemic arterial segments was increased by a factor Δk . The latter increases the non-linearity of the pressure-area relation (Eq. 4.2), and models an increase in material stiffness of the vessel wall. For the HYP simulation, we imposed $[p_0, \Delta k] = [135 \text{ mmHg}, +6]$. This resulted in a blood pressure exceeding 140/90 mmHg, a situation defined as hypertension according to the European Society of Hypertension/European Society of Cardiology guidelines [49].

2) Using the CircAdapt-3WK model, we performed

- A reference and hypertension simulation. Now, the systemic circulation was lumped into a 3WK (REF-3WK and HYP-3WK, see Appendix 3.A3).

For the REF-TL and HYP-TL simulations, we compared pressure and flow waveforms for cardiac chambers, central arteries and veins, as well as trans-valvular flows. Furthermore, haemodynamic indices (i.e. diastolic, systolic blood pressures, pulse wave velocity) were compared between the REF-TL and HYP-TL simulation. Systolic and diastolic aortic blood pressures were calculated from the tube that mimics the ascending aorta (i.e. tube #1, Fig. 3.2). The following analyses were conducted to assess the implications of using the TL model on aortic haemodynamics. First, we compared the morphology of pressure tracings of the LV and aorta obtained using the CircAdapt-TL model with those from the CircAdapt-3WK model. Second, wave intensity analysis was performed in the common carotid artery. Wave intensity analysis provides an approach to determine the characteristics of the primary wave originating from wave reflection, (i.e. termed the backward compression wave (BCW)) [35]. Wave intensity may be defined as the rate of energy transfer per unit area, often given in units of $[\text{W m}^{-2} \text{ s}^{-2}]$ [48]. Wave intensity is positive (dI^+) for a forward running wave, and negative (dI^-) for a backward running wave. Furthermore, net wave intensity (dI) is defined as the sum of backward and forward wave intensity, respectively. Using the derived wave intensity tracings, we qualitatively assessed changes in arrival time and intensity of the BCW between the normotensive- and hypertensive situations. Finally, we compared between simulated wave intensity tracings and those obtained in patients. Details regarding derivation of dI^+ , dI^- , and dI are provided in Appendix 3.A5.

Numerical implementation

All simulations were performed in MATLAB 2015a (The MathWorks, Natick, MA, USA) on a standard personal computer running an Intel® Core i7™ processor and 8.00 GB RAM. Blood viscosity was kept at $3 \cdot 10^{-3}$ Pa s, blood density was kept at 1050 kg m^{-3} , and collapsible tube fraction b was kept at 0.02 (Table 3.1). We chose a time step (Δt) of 1 ms. Furthermore, for the simulations performed using the CircAdapt-TL model, we chose an element size (i.e. Δz , indicating the distance between nodes) of 0.02 m. This value was chosen as a trade-off between on the one hand being able to capture geometric tapering of arterial vessels, and on the other hand to restrain simulation time. For both the benchmark evaluation and the simulations that were performed using the CircAdapt-TL and CircAdapt-3WK models, we ensured that numerical convergence was achieved (i.e. negligible change in pressure and flow waveforms when further decreasing Δt and Δz).

3.4 Results

3.4.1 Benchmark comparison

Agreement between pressure and flow waves of the TL model and PWP model for five tubes in the model domain is graphically depicted in Fig. 3.4. Root mean square errors (Eq. 3.13) for pressures and flows for all tubes are given in Table 3.2.

Table 3.2: Benchmark comparison between pressure and flow waveforms of the new transmission line (TL) model and established pulse wave propagation (PWP) model.

tube #	1+2	4	15	19+27	3	16	20	21	22	23	24	26	25
ϵ_p [mmHg]	1.62	1.65	1.68	1.62	2.36	1.68	1.68	2.14	2.96	3.96	3.68	4.03	4.05
ϵ_q [ml s ⁻¹]	2.53	21.20	4.41	5.71	3.02	0.87	1.63	0.32	0.92	0.22	0.48	0.30	0.27
δ_p [%]	0.8	0.8	0.8	0.9	1.2	0.8	0.8	1.5	1.5	2.7	2.2	2.8	2.9
δ_q [%]	0.6	5.6	1.1	1.9	4.5	2.2	3.3	2.8	3.5	3.2	3.1	3.7	5.3

Root mean square errors for pressure (ϵ_p) and for flow (ϵ_q), as well as their relative errors (δ_p and δ_q) describe agreement between both models. Agreement was calculated for the element located at the centre of the tube.

Between models, we found good agreement in terms of pressure and flow waveforms for proximal arteries (e.g. aorta, carotid, subclavian and vertebral arteries), expressed by relative errors $\delta_p \leq 1.5\%$ and $\delta_q \leq 5.6\%$. At the distally located interosseous artery, the difference between both models slightly increased, expressed by $\delta_{p,25}$ equal to 2.9% and $\delta_{q,25}$ equal to 5.3%. Nevertheless, the shape of the pressure and flow waveforms as well as absolute systolic and diastolic pressure and flow values were highly similar (Fig. 3.4).

Figure 3.2: Overview of the complete arterial model domain. Geometrical and mechanical properties of modelled arteries are given in Table A2. Panels display pressure and flow waveforms for three regions (i.e. central, arm and leg, indicated using symbol and colour coding). Grey curves display left ventricular (LV) pressures and volumes, left atrial (LA) pressures and volumes as well as aortic valve flow. Line type indicates the distance from the heart within a region; proximal: solid line, intermediate: dash-dotted line, distal: dotted line, respectively. Arrows indicate the direction of mean blood flow. Aortic valve closure is indicated by the vertical blue dashed lines.

Figure 3.3: Overview of the complete venous model domain. Geometrical and mechanical properties of modelled veins are given in Table A3. Panels display pressure and flow waveforms for three regions; central, arm and leg, indicated using symbol and colour coding. Line type indicates the distance from the heart within a region; proximal: solid line, intermediate: dash-dotted line, distal: dotted line, respectively. Grey curves display right ventricular (RV) pressures and volumes, right atrial (RA) pressures and volumes. Arrows indicate the direction of mean blood flow. Aortic valve closure is indicated by the vertical blue dashed lines.

Figure 3.4: Results of the benchmark comparison. Pressure (p) and flow (q) waveforms generated by the transmission line (TL) model and 1D pulse wave propagation model (PWP) model are shown for various locations along the arterial domain. Agreement between p and q waveforms is expressed by root mean square errors ϵ_p and ϵ_q , as well as relative errors δ_p and δ_q .

3.4.2 Simulation of normotension and hypertension

In Figs 3.2 and 3.3, pressure and flow waveforms in normotension are displayed for arteries and veins at three regions (i.e. the central-, arm- and leg region). Arterial pressure waveforms at distal locations are characterised by an increase in pressure amplitude, as well as a reduction in peak width. The arterial pressure waveforms at distal locations show a more prominent dicrotic notch compared to the pressure waves at proximal locations. For veins, a biphasic pressure waveform can be distinguished, with venous flow and pressure in anti-phase (Fig. 3.3).

In the REF-TL simulation, pulse wave velocity (PWV) was 5.5 m s^{-1} , representing a PWV value commonly found in subjects aged <30 years [28]. For the HYP simulation, pulse wave velocity (PWV) was 8.0 m s^{-1} , representing a PWV value clinically associated with early aortic stiffening, and commonly found in subjects aged >50 years [28]. The blood pressure values in the REF-TL simulation were within the normal range (Table 3.3). As shown in Fig. 3.5, simulating systemic hypertension (HYP) caused arterial pressure to increase. This resulted in an increase in left ventricular pressure and left atrial pressure, whereas pulmonary

artery pressure and pulmonary venous pressure slightly increased (Fig. 3.5). The HYP-TL simulation showed an increase in systolic blood pressure (p_{sys}) from 128 to 193 mmHg and an increased diastolic blood pressure (p_{dia}) from 75 to 92 mmHg (Table 3.3).

Figure 3.5: CircAdapt-TL model simulated time courses of pressure and flow for the reference (REF-TL) simulation (left), and the hypertension (HYP-TL) simulation (right). Curves display time courses of pressure (solid lines) and flow (dotted lines) of the left ventricle and large arteries; the right ventricle and pulmonary artery; the left atrium and pulmonary vein; and the right atrium and vena cava, respectively. AVC: aortic valve closed, AVO: aortic valve open, MVC: mitral valve closed, MVO: mitral valve open, PVC: pulmonary valve closed, PVO: pulmonary valve open, TVC: tricuspid valve closed, TVO: tricuspid valve open.

Table 3.3: Haemodynamic indices in the reference (REF) and hypertensive (HYP) simulations.

Index	REF	HYP	Unit	Meaning
p_{sys}	128	193	mmHg	Systolic pressure in the aorta
p_{dia}	75	92	mmHg	Diastolic pressure in the aorta
p_{pulse}	53	101	mmHg	Pulse pressure in the aorta
PWV	5.5	8.0	m s^{-1}	Carotid–femoral pulse wave velocity

Fig. 3.6 shows LV and ascending aortic pressure tracings obtained using the CircAdapt-3WK model and the CircAdapt-TL model, respectively. The aortic pressure tracings of the REF-TL and HYP-TL simulation showed pressure augmentation (i.e. a systolic pressure boost) as well as an aortic notch, whereas for CircAdapt-3WK model simulations, these waveform characteristics were absent. In the REF-TL simulation, systolic pressure augmentation occurred after time of peak systolic pressure, whereas in the HYP-TL simulation this occurred prior to the time of peak systolic pressure.

Wave intensity tracings (dI^+ , dI^- , and dI , respectively) of the REF-TL and HYP-TL simulation were calculated for the left common carotid artery (Fig. 3.7A). The carotid arterial wave intensity tracings of the REF-TL simulation indicate a forward compression wave (FCW) followed by a backward compression wave (BCW). At end-systole, there is a forward expansion wave (FEW) associated with the deceleration of the rate of myocardial contraction [36]. In the REF-TL simulation, the onset of the BCW occurred 38 ms after onset of left ventricular ejection, whereas for the HYP-TL simulation the delay was 28 ms (Fig. 3.7A). Peak wave intensity of the BCW was approximately equal for the HYP-TL simulation ($4.19 \cdot 10^5 \text{ W m}^{-2} \text{ s}^{-2}$) as compared to the REF-TL simulation ($4.23 \cdot 10^5 \text{ W m}^{-2} \text{ s}^{-2}$) (Fig. 3.7A). Overall, the pattern of the simulated wave intensity tracings was similar to measured carotid arterial wave intensity tracings as reported by Hughes et al. [15] (Fig. 3.7B).

Figure 3.6: Left ventricular- and aortic blood pressure tracings simulated using, on the one hand, the CircAdapt model with the systemic circulation lumped into a non-linear three-element windkessel model (3WK) and, on the other hand, CircAdapt with the systemic circulation represented by transmission lines (TL). Pressure tracings are given for the normotensive (REF-3WK and REF-TL, respectively) and hypertensive situation (HYP-3WK and HYP-TL, respectively).

Figure 3.7: Wave intensity analysis. **A:** Carotid arterial pressure- and flow velocity waveforms of the reference (REF-TL) and hypertensive (HYP-TL) simulations, and corresponding wave intensity traces. **B:** Normalised carotid arterial wave intensity traces of two patients (adapted from [15], with reference to type C- and A-waveforms). Abbreviations: dI^+ , dI^- and dI denote forward-, backward-, and net wave intensity, respectively. FCW, BCW, FEW: forward compression wave, backward compression wave, and forward expansion wave, respectively.

3.5 Discussion

We integrated a transmission line (TL) model into the existing CircAdapt platform of whole-heart mechanics. The resulting benchmarked CircAdapt-TL model now also describes vascular wave transmission. The presented model and simulation/validation results bring the following innovative steps forward. First, our model platform allows for computationally efficient simulation of cardiac mechanics and vascular haemodynamics. CircAdapt-TL, as implemented in MATLAB, simulates a single cardiac cycle in 6 s, whereas the CircAdapt-3WK model requires 4 s but does not model wave transmission. We consider our TL implementation of a distributed model well-justified based on the acceptable increase in computational time. Second, the modular structure of CircAdapt-TL renders it easy to change the model domain (e.g. through user-defined assembly of network connections of the various modules). This versatility comes at hand when handling the model in a non-engineering environment, for example in a classroom of cardiologists in training. Third, the coupling of the extension of CircAdapt heart [25] with our framework to capture large vessels, in conjunction with modest increase in computational demand, facilitates extensive uncertainty quantification and sensitivity analysis of detailed haemodynamics mechanisms.

The field of distributed modelling of vascular wave transmission considers continuous pulse wave propagation (PWP) models that compute pressure and flow using numerical techniques such as finite differences or the method of characteristics [42], and models that use transmission line (TL) theory based on the telegraph equations [18, 20, 47]. We chose the TL model for its reduced computational cost as compared to models using the method of characteristics, its capability of operating in the time-domain, and its compatibility with the existing CircAdapt model [20, 43].

The validity of our TL model's numerical implementation was assessed by comparing pressure and flow waveforms generated with the TL model with those generated by the validated model of Kroon et al. [21]. For adequate comparison, an exact same model domain ranging from the large central arteries towards the smaller arteries of the left arm was chosen. Moreover, for both models boundary conditions defining proximal inflow, vessel wall mechanics, and outflow conditions were kept identical. Remaining differences in pressure and flow waveforms between both models may be attributed to the fact that in deriving the propagation constant, our TL model neglects the higher order terms to render the attenuation constant frequency-independent (Appendix 3.A1.2). This assumption is justified for high frequencies, but may become questionable for low frequencies. For the PWP model of Kroon et al. [21], such assumption was not made, since the attenuation in that model is incorporated by wall shear stress [21].

For the CircAdapt-TL model, pressure and flow waveforms of the arteries showed physiologically realistic behaviour in both time and position along the modelled domain. The morphology of arterial pressure waveforms of the aorta towards the radial and ulnar arteries resemble pressure waveforms measured during pressure catheter withdrawal from the aorta to the radial artery in man

[38]. Venous pressure and flow waveform morphologies were similar to the ones obtained in the computational model study of Müller and Toro [30]. We found a similar venous pressure pulsatility (i.e. the maximum–minimum difference in venous pressure) as these investigations reported (i.e. between 1.2 and 2.3 mmHg in the central veins and between 0.9 and 3.9 mmHg in veins of the arm, respectively). In the reference (REF-TL) simulation, systolic and diastolic pressure in the aorta as well as pulse wave velocity were within normal ranges. In the hypertension (HYP-TL) simulation, blood pressure clearly increased indicated by the aortic systolic and diastolic pressures of 193 and 92 mmHg. The pulse pressure increase in the systemic hypertension simulation to 101 mmHg is considered high given the moderate increase in pulse wave velocity to 8.0 m s^{-1} [28]. In our model, such large increase in pulse pressure could be caused by the fact that we did not incorporate the dilatation of arteries caused by vascular remodelling in hypertension [17, 28].

For the hypertension simulation, wave intensity analysis revealed earlier arrival of a backward compression wave (Fig. 3.7A), consistent with human measurements [24]. The simulated ascending aortic blood pressure waveform changed from a type C waveform in the REF-TL simulation, most often seen in young adults under 30 years of age, to a type A waveform in the HYP-TL simulation, most often seen in subjects aged 40 to 65 years [31]. Although the classification of pressure waveforms according to systolic pressure augmentation may appear subtle, the clinical-epidemiological field assesses indices derived from systolic pressure augmentation for cardiovascular risk stratification [45, 32]. Simulated carotid arterial wave intensity tracings appeared similar to illustrative examples of measured tracings (Fig. 3.7B). In the HYP-TL simulation, a so-called mid-systolic forward expansion wave was present, similar to patient case 1 (around $t=0.2 \text{ s}$) as described in [15]. Though this illustrates the level of detail possible in model-based haemodynamic studies, the mechanistic interpretation of e.g. a mid-systolic forward expansion wave is beyond the scope of this method paper.

With lumping the systemic vessels into a 3WK, the aortic pressure tracings lost the typical dynamics around the dicrotic notch, which were present in the REF-TL and HYP-TL simulations. Moreover, the (early) systolic pressure augmentation in the LV and aortic pressure tracings was absent for the pressure tracings of the REF-3WK and HYP-3WK simulation (Fig. 3.6). Given the interest in parameters such as systolic pressure augmentation, we believe that using distributed models like ours, for studies on heart-vessel interaction, may be preferable over using 3WK models. However, future experimental studies and clinical comparisons are needed to appraise the added value of distributed models over 3WK models in testing heart-vessel interaction hypotheses.

3.5.1 Limitations

A simplification in the TL model is that convective acceleration is neglected. However, the influence of convective acceleration on arterial pressures and flows is believed to be small [41]. Moreover, it was found that inclusion of convective

acceleration in an arterial model domain, similar to the one used in the present study, changed pressure and flow waveforms in the various arteries only slightly (i.e. a root mean square error of 1.3 mmHg for thoracic aortic pressure waveform and 11.3 ml s^{-1} for thoracic aortic flow waveform, respectively [39]). We expect, however, that the effect of convective acceleration will be more important when simulating exercise conditions. Therefore, in such studies the modelling error related to convective acceleration needs to be properly considered.

By excluding cerebral and coronary vessels from our model domain, we neglect the presumed influence that wave reflections and re-reflections from head and neck vessels or vessels in the myocardium may have on observed ascending aortic and carotid waveforms [39, 44].

Our model neither contains a skeletal-muscle pump model nor does it incorporate venous valves. Hence, the present vascular model will not account for these functional aspects with postural changes. For studies with emphasis on venous haemodynamics, the CircAdapt platform allows for a straightforward implementation of venous valves, using for instance the existing valve module as a starting point.

Like all distributed models of 1D wave transmission, our model cannot capture the complex pressure losses or local wall shear stresses when applied to disease conditions (e.g. stenosis or aneurysm). This requires either use of calibrated loss models or coupling of detailed 3D models of stenoses and aneurysms to 1D models, respectively [5, 7].

Reymond et al. [40] reported for the case of an apparently healthy aorta, that pressure and flow waveforms from a 3D computational fluid dynamics model and from a 1D PWP model are highly similar. The latter finding supports our notion that, in general, distributed models of wave transmission are well suited to examine and quantify heart-vessel interaction at the level of pressure and flow waveform characteristics.

3.5.2 Perspectives

The utility of the CircAdapt-TL model should be further tested by direct comparisons against detailed haemodynamic data from humans. We consider the concurrent use of *in vivo* as well as simulated data as most valuable, because both arms bring complementary assets. The model allows error free assessment of phase relationships between signals and *in vivo* data enables characterisation of biological and pathological variability.

In the future, we aim to further extend the CircAdapt-TL model with the cardiac adaptation module of Arts et al. [2]. This module contains a homeostatic control loop that senses offsets in mechanical load (e.g. as present in chronic hypertension), and in response, imposes geometrical (i.e. cavity volume and wall volume) adaptation of the heart. We believe that modelling cardiac adaptation is vital in assessing candidate haemodynamic indices.

Key clinical studies in this field include that of Hashimoto et al. [12]. They found a positive association between left ventricular mass, and wave reflection

magnitude derived from pressure and flow velocity measurements, following antihypertensive treatment in left ventricular hypertrophy patients. However, a limitation of such clinical studies is that for non-invasive acquisition, pressure signals are obtained at distal measurement sites (e.g. at the radial artery) and therefore require a transfer function to obtain an estimate of the aortic pressure signal. Moreover, for clinically-gathered data, correct synchronisation of pressure and flow velocity signals is crucial, because only a small (e.g. 5 ms) misalignment can cause substantial changes in derived wave (intensity) quantities [35].

3.6 Conclusions

We validated and incorporated a one-dimensional vascular module into the CircAdapt platform. The resulting CircAdapt-TL model enables fast simulation of whole-heart mechanics, pressure and flow waveforms at various locations along the arterial and venous systems, and allows detailed haemodynamics studies. The CircAdapt-TL model provides a valuable tool for testing hypotheses concerning heart-vessel interaction and evaluating existing haemodynamics indices.

3.A1 Appendix: Vascular module

3.A1.1 Solving strategy

Pressure and flow in a tube constitutes of the summation of a backward (bw) and a forward (fw) wave component [9]. Therefore, at any location in the tube, it holds that

$$p(z, t) = p_{fw}(z - ct) + p_{bw}(z + ct), \quad (3.A1)$$

$$q(z, t) = \frac{p_{fw}(z - ct)}{Z} - \frac{p_{bw}(z + ct)}{Z},$$

with Z and c the characteristic Womersley number-dependent wave impedance and wave speed defined $Z = \sqrt{L(\alpha_0)/C}$ and $c = 1/\sqrt{L(\alpha_0)C}$, respectively (Section ‘Derivation of the attenuation constant, wave speed and wave impedance’). Considering the proximal inlet of a tube, we assume a linear relation between pressure $p_{in} = p(0, t)$ and flow $q_{in} = q(0, t)$, characterised by a zero-flow pressure p_s and an input resistance Z_{in} :

$$P_{in} = p_s + Z_{in}q_{in}. \quad (3.A2)$$

We derive in Section ‘Derivation of source pressure’ that quantities p_s and Z_{in} can be calculated from p_{bw} and Z using the expressions given by

$$p_s = 2p_{bw}, \quad (3.A3)$$

$$Z_{in} = Z. \quad (3.A4)$$

The proximal load relates p_{in} to q_{in} . Using Eq. 3.A2, p_{in} and q_{in} are calculated. Then, for further calculations we need to determine the amplitude of reflected wave p_{fw} at the entrance. It holds

$$p_{fw} = \frac{1}{2}p_s + Zq_{in}. \quad (3.A5)$$

A tube, representing a blood vessel with length l , has a proximal and a distal side (Fig. A1).

Figure A1: Overview of wave propagation in a tube segment, directed along the z -axis. See text for description of symbols.

For each side Eqs. 3.A1 to 3.A5 may be applied with the remark, that flow at

the distal side is directed outward, implying that the terms with flow $q_{\text{out}} = q(l, t)$ have to change sign. At each moment in time, the amplitudes of the waves entering on both sides of the tube are calculated according to Eq. 3.A5. This wave will arrive with a delay τ later at the opposite ending. As derived by Boucher and Kitsios [9] and applied by Krus et al. [22], the contribution of wave attenuation due to friction may be lumped at the proximal and distal sides of the transmission line. Thus, for the proximal side it holds

$$p_{\text{bw,prox}} = p_{\text{bw,dist}}(t - \tau) \exp(-\zeta l), \text{ with } \tau = \frac{l}{c}. \quad (3.A6)$$

Symbols ζ and τ represent the attenuation constant and wave delay time, respectively. Attenuation constant ζ is assumed a function of the characteristic Womersley number (see Section Derivation of the attenuation constant, wave speed and wave impedance). Since $p_{\text{bw,dist}}$ is calculated before, and τ is assumed to be known, $p_{\text{bw,prox}}$ can be calculated. Pressure $p_{\text{fw,dist}}$ is to be calculated similarly. When knowing these wave amplitudes, zero-flow pressure p_s and an input resistance Z_{in} can be calculated on both sides of the tube, using Eqs. 3.A3 and 3.A4 and their equivalents at the distal side. Pressures and flows related to wave propagation are superimposed on DC-components of flow q_{DC} and pressure p_{DC} [9]. Furthermore, for small blood vessels, the Poiseuille resistance may become important. For the DC-pressure difference over the tube, related to q_{DC} it holds

$$\Delta p_{\text{DC}} = q_{\text{DC}} \frac{8\pi\eta l}{A^2}. \quad (3.A7)$$

Flow q_{DC} , derived in the online supplement section ‘Derivation of the DC-flow’, may vary slowly, practically not influencing the behaviour of the wave. Thus, besides the wave, a tube may be subject to a (nearly) constant flow q_{DC} , not being subject to wave attenuation. Since wave impedance Z is known, we may describe the zero-flow pressures $\tilde{p}_{s,\text{prox}}$ and $\tilde{p}_{s,\text{dist}}$ by adding a DC-component to the zero-flow wave pressures ($p_{s,\text{prox}}$ and $p_{s,\text{dist}}$, respectively) as calculated using Eq. 3.A3:

$$\begin{aligned} \tilde{p}_{s,\text{prox}} &= p_{s,\text{prox}} - q_{\text{DC}}Z + \frac{\Delta p_{\text{DC}}}{2}, \\ \tilde{p}_{s,\text{dist}} &= p_{s,\text{dist}} + q_{\text{DC}}Z - \frac{\Delta p_{\text{DC}}}{2}. \end{aligned} \quad (3.A8)$$

For solving the differential equations, the solution inside is not needed; between nodes just a phase-delay and damping are imposed. However, if needed, a solution may be computed using the right- and left-ward traveling waves, attenuation constant, wave velocity, and position in the segment. Practically, if pressure and flow waveforms half-way would be required as simulation output, then the tube of interest may be subdivided into two separate tubes.

Around junctions and bifurcations, we assumed continuity of static pressure and balance of mass.

3.A1.2 Derivation of the attenuation constant, wave speed and wave impedance

Previously, Huberts et al. [14] showed that for a time-domain analysis, the momentum balance equation can be represented by a lumped-parameter model consisting of a characteristic Womersley number-dependent inertance per unit length ($L(\alpha_0)$) element in series with a characteristic Womersley number-dependent resistor per unit length ($R(\alpha_0)$) element. We define the characteristic Womersley number (α_0) as $\alpha_0 = r_0 \sqrt{\rho \omega_0 / \eta}$, with ω_0 the characteristic angular frequency, r_0 the reference lumen radius, and constants ρ and η the blood density and blood dynamic viscosity, respectively. For our time-domain approach, we adopted the method of Huberts et al. [14]. Expressions for $R(\alpha_0)$ and $L(\alpha_0)$ are given by

$$L(\alpha_0) = \overbrace{\left(\frac{1}{2 - c_p(\alpha_0)} \right)}^{g(\alpha_0)} L_0, \quad (3.A9)$$

$$R(\alpha_0) = \overbrace{\left(\frac{c_q(\alpha_0)}{2 - c_p(\alpha_0)} \right)}^{h(\alpha_0)} R_0. \quad (3.A10)$$

Here, inertance per unit length (L_0) and Poiseuille resistance per unit length (R_0) are defined $L_0 = \rho / A_0$ and $R_0 = 8\pi\eta / A_0^2$, respectively. The coefficients c_p and c_q were derived by Bessems et al. [6]:

$$c_p(\alpha_0) = \begin{cases} 1 + \frac{\sqrt{2}}{\alpha_0} \left(1 - \frac{\sqrt{2}}{2\alpha_0}\right) & \text{if } \alpha_0 > \sqrt{2} \\ \frac{3}{2} & \text{if } \alpha_0 \leq \sqrt{2}, \end{cases} \quad (3.A11)$$

$$c_q(\alpha_0) = \begin{cases} \frac{\alpha_0}{4\sqrt{2}} \left(1 - \frac{\sqrt{2}}{2\alpha_0}\right)^{-1} & \text{if } \alpha_0 > \sqrt{2} \\ \frac{1}{2} & \text{if } \alpha_0 \leq \sqrt{2}. \end{cases}$$

In Fig. A2, g and h are depicted as a function of α_0 . The ranges chosen for α_0 , i.e. $[0, \sqrt{2}]$ and $[\sqrt{2}, \infty]$ render that for the limiting cases of $\alpha_0 = 0$ and $\alpha_0 \rightarrow \infty$, the friction term coincides with Womersley theory [6].

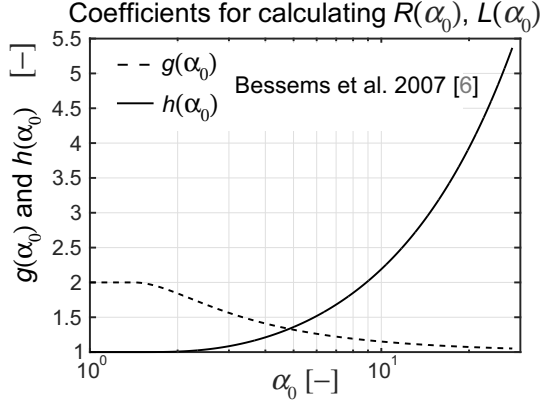

Figure A2: Coefficients g and h as a function of the characteristic Womersley number (α_0), used for calculating the characteristic Womersley number dependent resistance $R(\alpha_0)$ and inertance $L(\alpha_0)$, respectively.

Using the expressions for $R(\alpha_0)$ and $L(\alpha_0)$, attenuation constant ζ is obtained by calculating propagation constant γ , evaluated for characteristic frequency ω_0 . We approximated γ following Matick [27]:

$$\begin{aligned} \gamma &= \zeta + j\beta = j\omega\sqrt{L(\alpha_0)C}\sqrt{1 - \frac{jR(\alpha_0)}{\omega L(\alpha_0)}} & (3.A12) \\ &\approx j\omega\sqrt{L(\alpha_0)C}\left(1 - \frac{jR(\alpha_0)}{2\omega L(\alpha_0)} + \mathcal{O}\left(\frac{1}{\omega^2}\right)\right) \\ &\approx \frac{R(\alpha_0)}{2\sqrt{L(\alpha_0)C}} + j\omega\sqrt{L(\alpha_0)C}, \end{aligned}$$

with ζ the attenuation constant per unit length, β the phase constant per unit length and C the compliance per unit length. The characteristic Womersley number-dependent wave speed c was calculated using

$$c = \frac{\omega}{\beta} = \frac{1}{\sqrt{L(\alpha_0)C}}. \quad (3.A13)$$

Finally, Womersley number-dependent wave impedance was calculated using

$$Z = \sqrt{\frac{L(\alpha_0)}{C}}. \quad (3.A14)$$

3.A1.3 Derivation of source pressure

As previously described, it holds for pressure and flow at any location that

$$\begin{aligned} p(z, t) &= p_{fw}(z - ct) + p_{bw}(z + ct), \\ q(z, t) &= \frac{p_{fw}(z - ct)}{Z} - \frac{p_{bw}(z + ct)}{Z}. \end{aligned} \quad (3.A15)$$

Pressure and flow at the proximal side of the tube are given by

$$\begin{aligned} p_{prox} &= p_{fw,prox} + p_{bw,prox}, \\ q_{prox} &= \frac{p_{fw,prox}}{Z_{prox}} - \frac{p_{bw,prox}}{Z_{prox}}. \end{aligned} \quad (3.A16)$$

If $q_{prox} = 0$ and $p_{bw,prox}$ is known, then for proximal source pressure $p_{s,prox} = p_{prox}$ it follows after substitution of Eq. 3.A16:

$$p_{s,prox} = 2p_{bw,prox}. \quad (3.A17)$$

For short circuit flow $q_{s,prox} = q_{prox}$ with $p_{prox} = 0$, it follows after substitution of Eq. 3.A16:

$$q_{s,prox} = \frac{2p_{bw,prox}}{Z_{prox}}. \quad (3.A18)$$

The source impedance of the proximal side of the tube is calculated using

$$Z_{prox} = \frac{p_{s,prox}}{q_{s,prox}} = Z. \quad (3.A19)$$

Finally, the applied equations for the distal side of the tube are given by

$$\begin{aligned} p_{s,dist} &= 2p_{fw,dist}, \\ q_{s,dist} &= \frac{2p_{fw,dist}}{Z_{dist}}, \\ Z_{dist} &= \frac{p_{s,dist}}{q_{s,dist}} = Z. \end{aligned} \quad (3.A20)$$

3.A1.4 Derivation of the DC-flow

The DC-flow (q_{DC}), averaged over the tube length, changes due to contribution of flow waves entering and leaving from the proximal and distal side. In case no wave enters, the waves inside the tube will disappear completely after wave delay time τ . Using Eq. 3.A8, reaching of the DC-steady state (i.e. term B of Eq. 3.A21 becoming zero) was approximated by a first order differential equation with time

constant equal to τ :

$$\frac{dq_{DC}}{dt} = \left(\overbrace{\frac{p_{s,dist} - p_{s,prox}}{2Z} - q_{DC}}^B \right) \frac{1}{\tau}. \quad (3.A21)$$

3.A2 Benchmark comparison between TL and PWP model

For the benchmark comparison, we implemented a network of tubes describing the central arteries (i.e. the aorta, carotid artery, and vertebral artery), as well as the arteries of the left arm (Fig. A3).

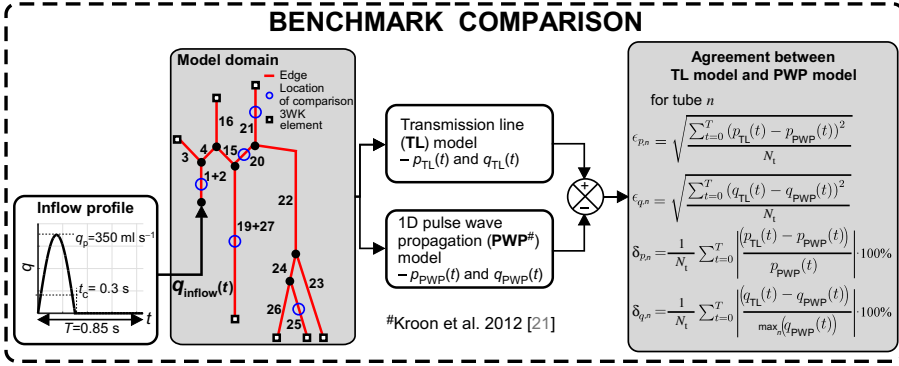

Figure A3: Benchmark comparison of the transmission line (TL) model with the previously validated 1D pulse wave propagation (PWP) model. We implemented a network of 13 tubes representing the large central arteries and the arteries of the left arm. Geometrical and mechanical properties of arterial segments that were used in the benchmark comparison are given in Table A2. A half-sinusoidal inflow profile (q_{inflow}) was prescribed to the ascending aorta. Boundary conditions; proximal inflow, termination of distal vessels using a non-linear three element winkessel model (3WK), vessel geometry and material properties were kept the same for the TL model and PWP model. Evaluated agreement metrics were root mean square errors ϵ_p and ϵ_q , as well as the relative errors δ_p and δ_q . Furthermore, N_t denotes the number of time points for which a comparison was made. A graphical comparison between pressure and flow waveforms is given for five tubes (blue circles).

Geometrical and mechanical properties of all tubes were based on Reymond et al. [39], (Table A2). Vessel stiffness coefficient (k) for the aortic segments, vertebral artery and carotid artery was estimated by fitting the constitutive law to *in vitro* data from Hayashi et al. [13]. For the radial, ulnar and interosseous arteries, stiffness was assumed equal to vertebral artery stiffness. For the subclavian-axillary-brachial arterial segment, stiffness was taken as the mean of aortic and carotid

artery stiffness (Table A2). Flow fractions were based on previously published patient measurements with duplex ultrasound and phase-contrast magnetic resonance imaging [14]. For the benchmark comparison, we defined a half-sinusoidal inflow profile as a proximal inlet boundary condition ($q_{\text{inflow}}(t)$):

$$q_{\text{inflow}}(t) = \begin{cases} q_p \sin\left(\frac{\pi t}{t_c}\right) & \text{if } 0 \leq t \leq t_c \\ 0 & \text{if } t > t_c. \end{cases} \quad (3.A22)$$

Distal tubes were terminated using 3WKs. For these simulations, time step (Δt) was kept at 0.5 ms, duty cycle (t_c) at 0.3 s, cardiac cycle duration (T) at 0.85 s, and peak flow rate (q_p) at 350 ml s^{-1} , resulting in a physiological cardiac output. Boundary conditions were kept equal for the TL model and PWP model. Reference pressure (p_0) was kept at 105 mmHg, external pressure (p_{ext}) at 0 mmHg and outflow pressure at 4 mmHg. We chose an element size of 0.01 m. Convergence of the calculated haemodynamics was evaluated after each simulated cardiac cycle. Hereto, the calculated nodal pressures, $p(t)$, of the current cycle (i_{cyc}) were compared to those of the previous cycle ($i_{\text{cyc}} - 1$). An expression for the haemodynamics convergence norm (ϵ_{norm}) is given as a relative root mean square:

$$\epsilon_{\text{norm}} = \max_n \left(\sqrt{\frac{\sum_{t=0}^T (p_{n,i_{\text{cyc}}}^t - p_{n,i_{\text{cyc}}-1}^t)^2}{\sum_{t=0}^T (p_{n,i_{\text{cyc}}-1}^t)^2}} \right), \quad (3.A23)$$

with n referring to the tube number as given in Table A2. Throughout simulations, the haemodynamics convergence criterion was kept at 10^{-2} . Agreement between p and q waveforms, expressed by root mean square errors ϵ_p and ϵ_q , as well as relative errors δ_p and δ_q , was calculated for the centre element of each tube (Fig. A3).

3.A2.1 Numerical implementation of the pulse wave propagation model of Kroon et al. [21]

For the 1D vessels of the PWP model, we assumed the same constitutive law as used for the TL model. Moreover for the periphery, we implemented the same non-linear three-element windkessel as used for the TL model. Coupling and solving of 1D mass conservation and momentum balance equations (after neglecting the convective acceleration term) and the 0D equation for pressure and flow in the periphery was performed using the method previously published by Kroon et al. [21]. We used a simplified trapezoidal scheme for spatial discretisation. The second-order backward difference scheme was used for time discretisation.

3.A3 Simulations performed using the CircAdapt–3WK model

As described in the main text of this article, we additionally performed reference- and hypertension simulations using the CircAdapt model with the systemic circulation lumped into the non-linear three-element windkessel model (REF–3WK and HYP–3WK, respectively). For the REF–3WK simulation, reference pressure was 105 mmHg and vessel stiffness coefficient (k) was kept equal to 8 for the arterial side and 10 for the venous side, respectively. For the HYP–3WK simulation, reference pressure was increased to 135 mmHg and the k -value of the systemic arterial 3WK was set to 14. For both simulations, characteristic vessel bed length (l_{AV}) was chosen 0.8 m [46].

3.A4 Code availability and calculation loop of the CircAdapt–TL model

The CircAdapt–TL model source code can be retrieved from <https://github.com/Mheu1991/CircAdaptTL/>. Table A1 refers to specific lines of MATLAB-code providing programmatic logic of the aforementioned relations (i.e. Eq A#) that were implemented to solve our TL model. Furthermore, Fig. A4 illustrates the calculation loop in CircAdapt–TL.

Table A1: Index linking mathematical relations of the transmission line model to MATLAB-scripts and underlying lines of code. Previous publications comprising existing CircAdapt modules are indicated.

3.A5 Calculation of wave intensity

The fundamental basis of wave intensity analysis is described in Parker [35]. Briefly, at a fixed measurement location, waves are considered incremental fronts for which the sum of successive forward- or backward travelling wavefronts form the measured pressure- or flow velocity waveform. Wave intensity analysis determines the magnitude and direction of wavefronts from derivatives of local pressure and flow velocity [35]. Wave intensity (dI) is here calculated using the time derivatives of pressure (dp/dt) and flow velocity (dU/dt):

$$dI = \frac{dp}{dt} \frac{dU}{dt} . \quad (3.A24)$$

Wave intensity is positive when forward travelling waves are dominant, whereas it is negative when backward travelling waves are dominant. Wave intensity itself may also be calculated for forward- and backward waves. This requires separation of the simulated pressure and flow velocity waveforms into their respective forward- and backward components. By assuming balance of mass and momentum in elastic tubes and neglecting viscous friction, a simple relation between the time derivatives of pressure and flow velocity is given by [35]

$$\frac{dp}{dt} = \rho c \frac{dU}{dt} , \quad (3.A25)$$

with c the local pulse wave velocity. Parker [35] showed that the relation as given in Eq. 3.A25 may be written for forward- and backward components as

$$\begin{aligned} \frac{dp^+}{dt} &= \rho c \frac{dU^+}{dt} , \text{ and} \\ \frac{dp^-}{dt} &= -\rho c \frac{dU^-}{dt} , \end{aligned} \quad (3.A26)$$

with superscripts "+" and "-" the forward- and backward wave components. Because we assumed that summation of backward- and forward waves yields the

measured pressure and flow velocity waveforms, the aforementioned equation may be expressed as [35]

$$\begin{aligned}\frac{dp^+}{dt} &= \left(\frac{dp}{dt} + \rho c \frac{dU}{dt} \right) / 2, & (3.A27) \\ \frac{dp^-}{dt} &= \left(\frac{dp}{dt} - \rho c \frac{dU}{dt} \right) / 2, \\ \frac{dU^+}{dt} &= \left(\frac{dU}{dt} + \frac{dp}{dt} / \rho c \right) / 2, \text{ and} \\ \frac{dU^-}{dt} &= \left(\frac{dU}{dt} - \frac{dp}{dt} / \rho c \right) / 2,\end{aligned}$$

Using Eq. 3.A24, intensity for forward- and backward waves, and the net pressure wave is expressed by

$$\begin{aligned}dI^+ &= \frac{dp^+}{dt} \frac{dU^+}{dt}, & (3.A28) \\ dI^- &= \frac{dp^-}{dt} \frac{dU^-}{dt}, \text{ and} \\ dI &= dI^+ + dI^-.\end{aligned}$$

For mathematical derivation of Eqs. 3.A27 and 3.A28, we refer to the work of Parker [35]. It should be noted that whereas Parker [35] calculated wave intensity based on *instantaneous differences* in pressure and flow velocity (i.e. dp and dU), we calculated *time derivatives* (i.e. dp/dt and dU/dt). As a result, wave intensity is given in units of $[W \text{ m}^{-2} \text{ s}^{-2}]$, instead of in $[W \text{ m}^{-2}]$.

3.A6 Description of geometrical and mechanical parameters of the implemented network of arteries and veins

Table A2: Geometrical and mechanical properties of arterial segments, based on Reymond et al. [39]. The italic q_{AV} values represent the terminal flow (here expressed as a percentage of cardiac output) as used in the benchmark comparison. The italic tube numbers (e.g. 3) refer to segments that were also used in the benchmark comparison.

4.1 Abstract

The augmentation index (AIx) is deemed to capture the deleterious effect on left ventricular (LV) work of increased wave reflection associated with stiffer arteries. However, its validity as a proxy for wave reflection magnitude has been questioned. We hypothesised that, in addition to increased wave reflection due to increased pulse wave velocity, LV myocardial shortening velocity influences AIx.

Using a computational model of the circulation, we investigated the isolated and combined influences of myocardial shortening velocity $v_{s,LV}$ and arterial stiffness on AIx. Aortic blood pressure waveforms were characterised using AIx and the reflected wave pressure amplitude (\hat{p}_{bw} , obtained using wave separation analysis).

Our reference simulation (normal $v_{s,LV}$ and arterial stiffness) was characterised by an AIx of 21%. A realistic reduction in $v_{s,LV}$ caused AIx to increase from 21 to 42%. An arterial stiffness increase, characterised by a relevant 1.0 m s^{-1} increase in carotid-femoral pulse wave velocity, caused AIx to increase from 21 to 41%. Combining the reduced $v_{s,LV}$ and increased arterial stiffness resulted in an AIx of 54%. In a multi-step parametric analysis, both $v_{s,LV}$ and arterial stiffness were about equal determinants of AIx, whereas \hat{p}_{bw} was only determined by arterial stiffness. Furthermore, the relation between increased AIx and LV stroke work was only for about 50% explained by an increase in arterial stiffness, the other factor being $v_{s,LV}$. The \hat{p}_{bw} , on the other hand, related less ambiguously to LV stroke work.

We conclude that the AIx reflects both cardiac and vascular properties and should not be considered an exclusively vascular parameter.

4.2 Introduction

THE augmentation index (AIx) is defined as the late systolic boost in the aortic pressure waveform divided by pulse pressure, and is often expressed as a percentage [27] (Fig. 4.1). Pressure waveform augmentation is commonly assumed to result from the superposition of a reflected wave originating from a (discrete) reflection site in the periphery onto the incoming pressure wave generated by the heart [27]. With increased arterial stiffness, the reflected wave will propagate with increased velocity, causing the augmentation to occur earlier in systole with a consequent increase in AIx [27]. AIx is considered a *vascular* parameter intended to quantify the deleterious effect of systolic wave reflection on cardiac workload, which is associated with adverse cardiovascular outcomes [12].

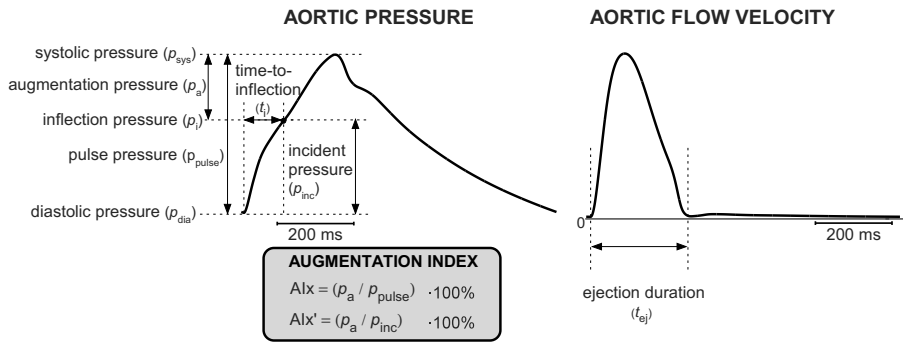

Figure 4.1: Overview of characteristics and indices extracted from the simulated aortic pressure waveform (left pane) and aortic flow waveform (right pane). Left: Augmentation index (AIx), calculated as a percentage-fraction using augmentation pressure (p_a) and pulse pressure (p_{pulse}). AIx' was calculated as the percentage-ratio using augmentation pressure (p_a) and incident pressure (p_{inc}). Time-to-inflection (t_i) is defined as the time interval between foot and the inflection point at inflection pressure p_i . Right pane: Left ventricular ejection duration (t_{ej}), the time interval during which blood is ejected into the aorta.

An advantage of AIx is its non-dimensionality requiring neither calibration of blood pressure nor measurement of blood flow velocity [19]. Blood pressure waveforms can be obtained using noninvasive tonometry at the location of the carotid- or radial arteries, or by oscillometric blood pressure recordings at brachial level [18, 20]. Subsequently, AIx can be estimated from a synthesised central pressure waveform derived from a reconstruction algorithm, applied to the tonometric or oscillometric waveforms. The accuracy of noninvasive AIx estimation by tonometry and oscillometry was evaluated by Chen et al. [8] and Horvath et al. [18], finding a good correlation between catheter- and noninvasive AIx. Furthermore, Wilkinson et al. [45] and Savage et al. [34] reported good inter-observer reproducibility of AIx as measured by tonometry.

The comprehensive meta-analysis of Baksi et al. [5] described AIx to drastically increase with age, despite only a small advance in time of arrival of the reflected wave. Considering the often used paradigm in clinical studies that AIx is a proxy for wave reflection magnitude [12, 19], one would expect similar proportions in the correlation between on the one hand age, and on the other hand AIx and wave arrival time, respectively.

Mechanistically, during systole the blood pressure waveform is the result of the instantaneous interaction between heart and arterial system. This is illustrated by the fact that aortic and left ventricular pressure patterns are in phase and closely related during LV ejection, when assuming normal aortic valve function [9, 43]. Moreover, acute changes in arterial load are directly reflected in the time-course of ventricular and aortic pressures [21]. However, the potential influence of cardiac contractile properties on the AIx is rarely considered in clinical-epidemiological studies. Though a few clinical studies reported an *association* between systolic augmentation and LV diastolic dysfunction [41], the direct *linkage* between AIx and cardiac contractile function is difficult to determine, since AIx is likely to be confounded by other factors such as heart rate, body height and mean arterial pressure [12, 35, 37]. To overcome this issue, physics and physiology-based models of the cardiovascular system may be employed to evaluate the effect of isolated changes of cardiac- and vascular properties on AIx.

The purpose of the present study is to assess the effect of changes in LV contractility and arterial stiffness on AIx utilising the CircAdapt computational model of the circulation (www.circadapt.org) [22, 40]. This closed-loop model was chosen because of its realistic cardiac mechanics model, with sarcomere length coupled to myofibre stress. Furthermore, it contains a vascular model simulating arterial and venous pressure and flow wave haemodynamics. We 1) modulated LV contractile properties by varying sarcomere shortening velocity ($v_{s,LV}$) in the model, and 2) modulated arterial stiffness by varying the vessel stiffness parameter (k). Both $v_{s,LV}$ and k are physiologically relevant parameters, since decreases in $v_{s,LV}$ and increases in k have been associated with ageing [1, 14, 16]. We compared AIx to alternative indices of wave reflection derived using established wave separation (WS) analysis [31, 32]. Finally, we evaluated the relation between AIx and cardiac workload with respect to variations in LV shortening velocity and arterial stiffness.

4.3 Methods

4.3.1 The CircAdapt model

We used the CircAdapt computational model, a closed-loop model of the four-chambered heart and circulation, to simulate cardiac mechanics and haemodynamics [22, 40].

CircAdapt consists of a limited number of modules representing cardiac walls, valves, arteries and veins as well as the systemic and pulmonary vascular beds.

The modules directly relevant for the present study are highlighted in Fig. 4.2. Briefly, CircAdapt's contraction model constitutes of a modified Hill model, de-

Figure 4.2: Overview of the primary relevant modules of the CircAdapt model. We distinguish two modules; the module underlying mechanics of myocardial tissue (CARDIAC) and the module underlying wave propagation in the vascular tree (VASCULAR). The sarcomere model consists of a contractile (si) element with length L_{si} and a series-elastic (se) element with length L_{se} , in parallel with parallel-elastic element (pe) with sarcomere length L_s according to the model of Hill, which assumes a force-velocity relation as shown. Blood vessels are characterised by a stiffness coefficient (k), intraluminal-, external- and transmural pressure (p_{intra} , p_{ext} and p_{trans} , respectively) and cross-sectional area (A). A vessel segment with a given length (l) connects a proximal node to a distal node. Peripheral vascular beds are modeled using an arterio-venous impedance model. Abbreviations: RA: right atrium, RV: right ventricle, LA: left atrium, LV: left ventricle. The model simulation code can be downloaded at <https://github.com/Mheui1991/>.

scribing the sarcomere mechanics (Fig. 4.2). The sarcomere model contains a contractile element with length L_{si} , arranged in series to a series-elastic element with length L_{se} , which in term are arranged parallel to a passive-elastic element with length L_s (Fig. 4.2). The contractile and series-elastic elements describe the additional stress generation due to muscle activation, whereas the passive-elastic element describes passive muscle behaviour (Fig. 4.2). Moreover, the length of the series-elastic element can be interpreted as the elastic deformation of the myosin heads in response to load [22]. Total sarcomere length is defined as the sum of the length of the contractile element and series element, i.e. $L_s = L_{si} + L_{se}$. The rate of shortening of the contractile element (dL_{si}/dt) is given by

$$\frac{dL_{si}}{dt} = v_{s,LV} \left[\frac{(L_{se} - L_{se,iso})}{L_{se,iso}} \right], \quad (4.1)$$

with $v_{s,IV}$ LV sarcomere shortening velocity, assumed $7 \mu\text{m s}^{-1}$ [13] and $L_{se,iso}$ the length of the series elastic element at the onset of isovolumetric contraction [22]. In the model, $v_{s,IV}$ scales dL_{si}/dt . A phenomenological mechanical activation parameter C is calculated as a function of L_s , L_{si} and time [22, 40]. Actively generated myofibre stress is determined using the mechanical activation, multiplied by the sarcomere extension from reference (i.e. $C(L_{si} - L_{si,ref})$) [40]. To obtain cavity pressures and volumes, CircAdapt uses the one-fibre model of Arts et al. [2] that allows for separation of the contribution of cardiac geometry and myofibre stress to cardiac cavity pressure, assuming myofibre stress to be homogeneously distributed within the myocardial wall. Furthermore, the heart is enclosed by the pericardium, modelled as a compliant sac [29] (Fig. 4.2).

CircAdapt enables simulation of pressure and flow waves in arteries and veins. We implemented an arterial and venous tree describing the aorta and vena cava, as well as the subclavian-, carotid-, brachial-, and femoral arteries and veins, respectively. Transmural pressure (p_{trans}) and cross-sectional lumen area (A) are related non-linearly, expressed by the constitutive law based on Arts et al. [4]

$$p_{trans}(A) = -p_{ext} + p_0 \left((1 + b) \left(\frac{A}{A_0} \right)^{1 + \frac{k/3-2}{1+b}} - \frac{bA_0}{A} \right), \quad (4.2)$$

with p_0 a reference pressure, A_0 a reference cross-sectional area, and k represents the vessel stiffness coefficient, governing the non-linearity of the pressure-area relation, and thereby material stiffness (Fig. 4.2) [4]. Additionally, parameter b was incorporated to avoid collapse of the tube with negative transmural pressure. Furthermore, p_{ext} represents a prescribed external pressure. For our reference simulation we chose k -values of 8 for the aorta and vena cava. For both the arteries and veins we chose k -values of 14 for the subclavian, 16 for the carotid, 18 for the brachial, and 20 for the femoral, describing elastic taper (i.e. the increase in vessel wall stiffness towards the periphery [44]). Furthermore, estimations for A_0 and vessel length were based on human data given in Westerhof et al. [44]. Peripheral vascular beds were modeled using an arterio-venous impedance model [3].

4.3.2 Simulation protocols

Departing from our reference (REF) situation as detailed above, we simulated three additional scenarios:

- Reduced shortening velocity ($v_{s,IV}$) of LV sarcomeres from $7 \mu\text{m s}^{-1}$ to $3 \mu\text{m s}^{-1}$ (*reduced shortening velocity*; $v_{s,IV} \downarrow$, Table 4.1). To characterise the imposed change in $v_{s,IV}$, we calculated peak systolic strain rate, because peak systolic strain rate is considered a strong measure of LV contractility [15].
- Increased stiffness of arteries by increasing stiffness parameter k (*arterial stiffening*; $k \uparrow$, Table 4.1). Since the modelled arterial tree contains segments

with different k -values, k -values of all segments were increased by addition of a factor Δk . Here, Δk was set equal to 12 (i.e. $k_{\text{stiffening}} = k_{\text{REF}} + 12$). According to clinical standards, we quantified arterial stiffness using pulse wave velocity. We obtained pulse wave velocity from transit time and travel distance. Transit time was calculated by identification of the foots of the carotid and femoral pressure waveforms. To identify the foot of the pressure wave, we used the maximum of the 2nd-order derivative [10]. Travel distance, on the other hand, was calculated as the path difference between the combined length of the aortic to femoral artery segments and aortic to carotid artery segments.

- The combined effect of a change in cardiac and vascular tissue properties (*combined*; $k \uparrow$, $v_{s,\text{LV}} \downarrow$, Table 4.1).

Additionally, to evaluate the dependence of AIx on LV shortening velocity and arterial stiffness, we also performed parameter sweeps of $v_{s,\text{LV}}$ and Δk , varying LV shortening velocity $v_{s,\text{LV}}$ from 2 to 10 $\mu\text{m s}^{-1}$ with 1 $\mu\text{m s}^{-1}$ increments and Δk from -2 to 14 with increments of 1. All simulations were performed in MATLAB 2015a (The Mathworks, Natick, USA). In all simulations, mean arterial pressure and cardiac output were maintained at 92 mmHg and 5.1 l min⁻¹, respectively, through changes of systemic vascular resistance and circulating blood volume, while heart rate was kept constant at 72 beats min⁻¹. Collapsible tube fraction b was kept at 0.02. Haemodynamics reached steady state prior to analyses. The underlying simulation code and analysis scripts are available under the GNU General Public License v3.0 and can be downloaded from GitHub (<https://github.com/Mheu1991>).

4.3.3 Wave reflection indices extracted from simulations

Wave reflection indices were computed for simulated pressure and flow velocity waveforms of the aorta. To benchmark the relationships between simulated cardiovascular alterations and AIx, we included wave reflection indices obtained using wave separation (WS) analysis ([31], detailed below). While WS analysis yields a wave reflection index expressed as a percentage-ratio, AIx expresses wave reflection as a percentage-fraction using the expression in Fig. 4.1 [12]. Hence, we also introduce the parameter AIx', defined as a percentage-ratio of augmentation pressure to incident pressure (i.e. $p_a/p_{\text{inc}} \cdot 100\%$). Furthermore, we calculated time-to-inflection (t_i , Fig. 4.1, right pane), defined as the time-interval between the foot of the pressure waveform and inflection point [19]. Locations of foot and inflection were identified using the peak and zero-crossing of the 2nd-order derivative of the pressure curve. We extracted LV ejection duration to evaluate whether it was influenced by our simulated changes in LV shortening velocity and arterial stiffness. Using the 2nd-order derivative of the aortic valve flow velocity, LV ejection duration was calculated as the time-difference between the beginning- and end of ejection (Fig. 4.1, right pane, vertical dashed lines).

The concept of WS analysis is based on solving the one-dimensional equations of mass conservation and momentum balance in elastic tubes [31]. In WS analysis,

instantaneous changes in pressure and flow velocity, representing wavefronts, are calculated for the forward and backward directions using the water-hammer equations:

$$\begin{aligned} dp_{fw} &= \rho c dU_{fw}, \text{ and} \\ dp_{bw} &= -\rho c dU_{bw}, \end{aligned} \quad (4.3)$$

where dp_{fw} and dU_{bw} denote forward or backward wavefronts of pressure and flow velocity, respectively, whereas ρ is the blood density (1050 kg m^{-3}), and c is the pulse wave velocity. The variables dp_{fw} , dp_{bw} , dU_{fw} , dU_{bw} and c were determined as described by Parker [31]. Through calculation of forward and backward pressures p_{fw} and p_{bw} , obtained by integration of separated instantaneous pressure components, we derived wave reflection index $\hat{p}_{bw}/\hat{p}_{fw}$, defined as the percentage-ratio between backward pressure wave amplitude (\hat{p}_{bw}) and forward pressure wave amplitude (\hat{p}_{fw}).

4.3.4 Calculation of cardiac workload

To assess whether there is a relation between increased AIx and increased cardiac external work, we assessed cardiac work load by calculation of LV stroke work (W_{stroke}). The variable W_{stroke} was calculated as the numerically integrated area contained by the LV pressure (p_{LV})-volume (V_{LV}) relation:

$$W_{\text{stroke}} = \oint p_{LV} dV_{LV}. \quad (4.4)$$

4.3.5 Statistical analysis

Statistical analyses were performed using IBM SPSS Statistics for Windows, version 24 (IBM Corp., Armonk, NY, USA). Linear regression analysis was performed to examine the relationship between wave characteristics. $P < 0.05$ was considered statistically significant.

4.4 Results

4.4.1 Effects of reduced LV shortening velocity and increased arterial stiffness on augmentation index

Fig. 4.3 and Table 4.1 contain an overview of pressure waveforms and derived characteristics for the four simulated scenarios. Simulating $v_{s,LV} \downarrow$ (red solid curve) did not affect absolute pressure values (Table 4.1).

However, the inflection in the pressure waveform came earlier, (from 96 to 83 ms, Table 4.1) after the foot of the pressure waveform with a marked increase

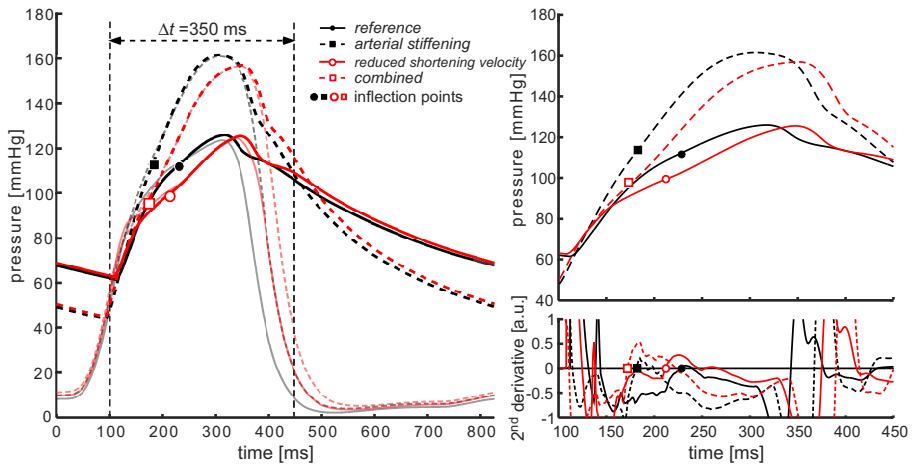

Figure 4.3: Aortic and left ventricular pressure curves for the four simulated scenarios. Left pane: Overview of simulated left ventricular and aortic pressure waveforms for four simulated scenarios. Right pane: Closer look at the systolic segment ($t=100\text{--}450$ ms) of the pressure waveforms (top) and their second order derivatives (bottom). Right pane: Inflection points (black and red symbols, respectively) are located by determining the zero-crossing of the second order derivative of each simulated waveform.

in Alx (from 21 to 42%, Table 4.1). LV ejection duration was prolonged with respect to the reference situation (from 238 to 274 ms, Table 4.1), and peak systolic strain rate (PSSR) magnitude decreased (from -0.91 s^{-1} to -0.69 s^{-1} , Table 4.1). Simulating $k \uparrow$ (Fig. 4.3, dashed black line), increased systolic pressure (127 to 162 mmHg) and decreased diastolic pressure (60 to 42 mmHg, Table 4.1). The inflection occurred significantly earlier during systole (time-to-inflection decreased from 96 to 69 ms) and Alx was markedly increased (21 to 41%, Table 4.1). The PSSR magnitude was only moderately decreased from -0.91 s^{-1} to -0.80 s^{-1} (Table 4.1). The combined effect of $k \uparrow$ and $v_{s,LV} \downarrow$ resulted in a waveform that can be considered an intermediate (Fig. 4.3, red dashed curve) curve of the $k \uparrow$ and $v_{s,LV} \downarrow$ curves, with an Alx increase from 21 to 54%. Ejection duration increased to 309 ms and the inflection point occurred 60 ms after the foot of the pressure waveform. Simulating $k \uparrow$ and $v_{s,LV} \downarrow$ invoked the largest reduction in PSSR magnitude, i.e. reducing from -0.91 s^{-1} to -0.64 s^{-1} (Table 4.1).

4.4.2 Effects on alternative measures of wave reflection

Fig. 4.4 contains a breakdown of simulated pressure waveforms into forward (p_{fw}) and backward (p_{bw}) pressure wave components, using wave separation (WS) analysis. Furthermore, separated pressure wave amplitudes, \hat{p}_{fw} and \hat{p}_{bw} are indicated for the REF (Fig. 4.4, left pane), $v_{s,LV} \downarrow$ (Fig. 4.4, centre pane) and

Table 4.1: Influence of LV shortening velocity and arterial stiffness on blood pressure indices and reflection indices for four distinct simulated scenarios.

Simulation → Metric ↓	Reference (REF)	Reduced shortening velocity ($v_{s,LV}$ ↓)	Arterial stiffening (k ↑)	Combined ($v_{s,LV}$ ↓, k ↑)	Unit
p_{sys}	127	126	162	158	mmHg
p_{dia}	60	63	42	42	mmHg
p_{pulse}	66	63	120	116	mmHg
p_{mean}	92	92	92	92	mmHg
AIx	21	42	41	54	%
AIx'	27	72	70	120	%
$\hat{p}_{bw}/\hat{p}_{fw}$	76	74	76	76	%
\hat{p}_{bw}	28	26	51	48	mmHg
time-to-inflection	96	83	69	60	ms
ejection duration	238	274	285	309	ms
LV stroke work	1.04	0.98	1.18	1.10	J
PSSR	-0.91	-0.69	-0.80	-0.64	s ⁻¹

The indices p_{sys} , p_{dia} , p_{pulse} and p_{mean} are respectively systolic, diastolic, (systolic–diastolic) and mean aortic blood pressure, and PSSR denotes peak systolic strain rate. Note that AIx' and $\hat{p}_{bw}/\hat{p}_{fw}$ are wave reflection indices that consider the ratio of backward and forward pressure wave amplitudes, while AIx considers the fraction of augmentation pressure and pulse pressure, respectively.

k ↑ (Fig. 4.4, right pane) simulations. Reducing LV shortening ($v_{s,LV}$) caused p_{fw} to change in shape but not in amplitude as compared to the reference situation. On the contrary, no clear difference was observed in the p_{bw} waveform. As a result, reflection index $\hat{p}_{bw}/\hat{p}_{fw}$ virtually remained unchanged (76 and 74% respectively, Table 4.1). Increased arterial stiffness (k ↑) resulted in an increase in backward pressure wave amplitude (\hat{p}_{bw}) from 28 to 51 mmHg, whereas $\hat{p}_{bw}/\hat{p}_{fw}$ remained unchanged (76 for both REF and k ↑, Table 4.1). The latter is attributable to a proportional increase in \hat{p}_{fw} and \hat{p}_{bw} (Fig. 4.5).

4.4.3 Parameter sweeps

Parameter sweeps of $v_{s,LV}$ and Δk provide more detailed insight into the relationships between on the one hand the changes in cardiac and vascular properties and on the other hand the indices AIx and $\hat{p}_{bw}/\hat{p}_{fw}$. Combined changes in cardiac and vascular tissue properties seem to relate non-linearly to observed changes in AIx, as is apparent in the contour plot of AIx as a function of $v_{s,LV}$ and Δk (Fig. 4.5, left pane). Our simulation results indicate that AIx is monotonically increasing with both higher arterial stiffness values and lower LV sarcomere shortening velocities. For the simulations corresponding to the white regions (i.e. high $v_{s,LV}$ and low k -values), no inflection point was present in the systolic phase of the aortic blood pressure curve. The relation between AIx' and changes in $v_{s,LV}$ and k was not different, albeit that absolute values, expressing pressure wave augmentation as the ratio between pressure above the inflection point on the curve to pressure below the the inflection, ranged from 30 to 140% for all simulations (Fig. 4.5, centre pane). Using wave separation, we did not find distinctive differences in

Figure 4.4: Wave separation analysis performed using pressure (p) and flow velocity (U) waveforms obtained from 1) the reference simulation, 2) the reduced shortening velocity simulation, and 3) the arterial stiffening simulation. Wave reflection index $\hat{p}_{bw}/\hat{p}_{fw}$ was calculated as percentage-ratio of backward pressure wave amplitude (\hat{p}_{bw}) and forward pressure wave amplitude (\hat{p}_{fw}) using wave separation (WS) analysis. The simulated aortic blood pressure waveform can be reconstructed by addition of separated pressure components (p_{fw} and p_{bw}). The offset is determined by the pressure at $t=0$.

the ratio between backward and forward pressure amplitude $\hat{p}_{bw}/\hat{p}_{fw}$ (range 72 to 76%, Fig. 4.5, right pane). This finding was caused by almost proportional increases in \hat{p}_{fw} and \hat{p}_{bw} .

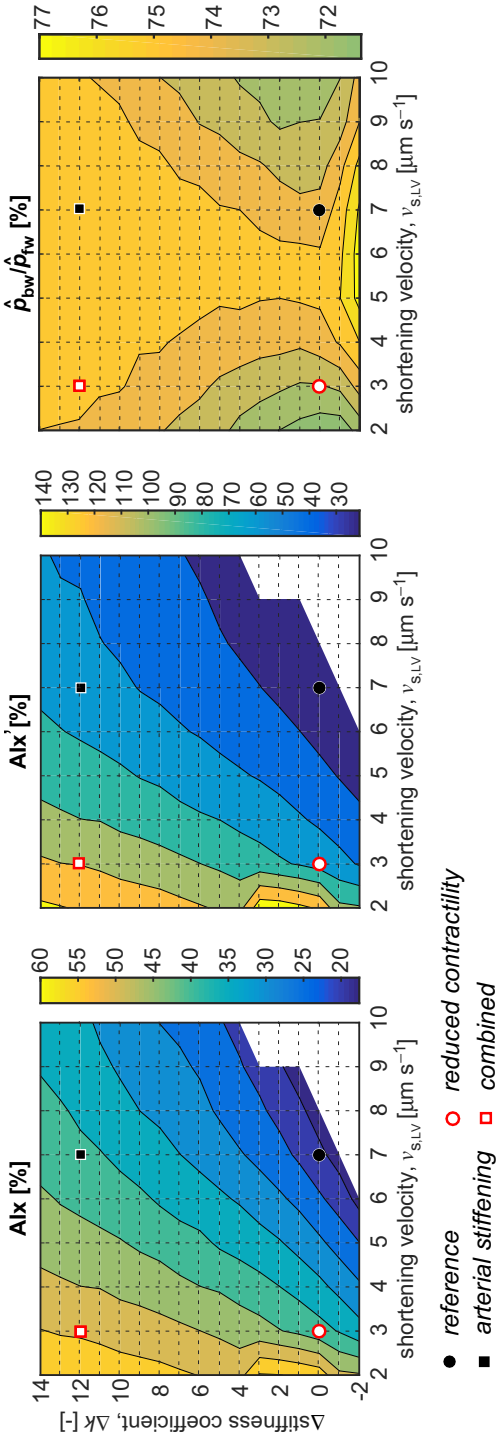

Figure 4.5: Contour plots indicating the relationship between the changes in LV shortening velocity and arterial stiffness and the wave reflection indices considered: Aix (left), Aix' (middle), and $\hat{p}_{bw}/\hat{p}_{fw}$ (right). The distinct simulated scenarios are highlighted by the dots and squares as indicated. Each grid point corresponds to a single simulation. LV shortening velocity parameter $v_{s,LV}$ was varied from $2 \mu\text{m s}^{-1}$ to $10 \mu\text{m s}^{-1}$ with $1 \mu\text{m s}^{-1}$ increments and arterial stiffness parameter Δk was varied between -2 and $+14$ with increments of 1 .

Figure 4.6: Relation between left ventricular stroke work (W_{stroke}) and wave reflection indices, i.e. augmentation index (AIx) and backward pressure amplitude (\hat{p}_{bw}), respectively. Each symbol represents a simulation with a particular left ventricular sarcomere shortening velocity ($v_{s,LV}$; indicated by symbol type) and imposed arterial stiffness (Δk ; indicated using symbol colour saturation). Upper pane: Scatter plot indicating the relation between AIx and W_{stroke} . The dashed line illustrates variation in W_{stroke} values at an AIx value often found in elderly patients (see text). Lower pane: Scatter plot displaying the relation between \hat{p}_{bw} as determined using wave separation and W_{stroke} . Arrows indicate the direction of changes in $v_{s,LV}$ and Δk for the simulations.

4.4.4 Relationship between AIx and left ventricular stroke work

Fig. 4.6 (top panel) shows the relation between AIx and W_{stroke} from simulations with varying arterial stiffness (indicated by colour saturation coding) and LV shortening (indicated by symbol type coding). Parameter sweeps revealed a large scatter in the relation between AIx and W_{stroke} (Fig. 4.6). At a fixed AIx of 40%,

typically found in older subjects [25], W_{stroke} varies by as much as 25% (Fig. 4.6, dashed line). On the other hand, scatter in the relation between \hat{p}_{bw} and W_{stroke} was smaller as compared to that in the relation between AIX and W_{stroke} ($\leq 11\%$ variation in W_{stroke} , for a given value of \hat{p}_{bw}), suggesting an increased cardiac workload with increasing backward pressure wave amplitude (Fig. 4.6).

4.5 Discussion

To our knowledge, this is the first study to mechanistically study and discriminate the influence of LV contractile and arterial stiffness properties on the augmentation index. We compared our findings with alternative measures of wave reflection that were derived using wave separation analysis.

4.5.1 Key findings and interpretation

We found that the AIX is dependent on vascular as well as cardiac properties (Fig. 4.5). Moreover, increased AIX did not necessarily relate to increased LV workload (Fig. 4.6), which goes against the commonly used concept of increased LV workload by increased LV afterload as caused by earlier systolic wave reflections.

We explain the observed cardiac impact on AIX as follows. Given a constant stroke volume, a decreased myocardial shortening velocity will decrease LV volumetric rate ($LV \, dV/dt$) in early systole, causing a greater portion of stroke volume to be expelled during late systole. Therefore, the pressure increase prior to the inflection point will be relatively smaller than the pressure increase after the inflection point, which leads to an increased AIX. This assumes that the timing of the inflection point is primarily determined by the complex arterial impedance, which is in line with current thinking [5].

The AIX is calculated from an aortic blood pressure waveform, whereas wave separation analysis uses, in addition to blood pressure, flow (velocity) information and takes into account aortic impedance [31]. This may explain why backward pressure amplitude in our study is a better correlate of wave reflection, while AIX characterises rather the interactive influence of heart and blood vessels on the blood pressure.

Haemodynamic interaction between blood vessels and heart has been reported in patients as judged from changes in peak systolic strain rate in response to an imposed afterload change [7]. Additionally, previous experimental papers suggest that acute changes in LV myocyte external load (i.e. arterial impedance) impacts myocardial shortening [21, 33], corroborating that cardiac properties by themselves and/or in response to vascular changes influence AIX.

Taken together, the AIX may be an integrative marker of concurrent degenerative processes leading to increased arterial stiffness and reduced myocardial shortening velocity. Clearly, such reinterpretation of AIX requires further corroboration from clinical studies using independent cardiac and vascular measurements. As discussed in the meta-analysis of van der Waaij et al. [39], the number of clinical

studies reporting effects of chronic changes in arterial stiffness on LV function is limited.

4.5.2 Choice of model parameters

Clearly, AIx will likely be determined by multiple factors, especially in humans. For our modelling study, we intentionally selected only one cardiac ($v_{s,IV}$) and one vascular (k) parameter with demonstrated linkages to tissue properties (myocardial shortening velocity and arterial stiffness exponent). The simulated changes in $v_{s,IV}$ and k were by no means intended to model the clinical-epidemiological profiles of heart failure or vascular ageing.

The imposed reduction in LV shortening velocity ($v_{s,IV} \downarrow$) significantly changed the peak systolic strain rate from -0.91 s^{-1} for the reference simulation to -0.69 s^{-1} (i.e. a reduction in magnitude of 24%). This decrease in peak systolic strain rate is physiologically plausible as based on reference data reported in Dalen et al. [11]. In previous work, we conducted a local sensitivity analysis assessing how changes in cardiac CircAdapt model parameters affect aortic augmentation index [17]. In this analysis, testing four candidate cardiac parameters, we found $v_{s,IV}$ to be the most important cardiac determinant of augmentation index which motivated us to select this model parameter in our analysis. We chose to reduce $v_{s,IV}$ based on rat experimental data reporting force-velocity relations in papillary muscle [1]. These data showed a linear decrease in peak muscle shortening velocity of $\approx 50\%$ with increasing age (i.e. 100 to 1000 days). Moreover, in isolated human ventricular myocytes, a reduction in shortening velocity with age was also observed [16]. The arterial stiffening simulation ($k \uparrow$) corresponded to a relevant carotid-to-femoral pulse wave velocity increase from 6.6 m s^{-1} to 7.6 m s^{-1} .

4.5.3 Alternative metrics in relation to wave reflection magnitude

Augmentation index expressed as a percentage-ratio (i.e. the parameter AIx') showed the same dependency on vascular and cardiac properties as was found for the regular AIx. In contrast to AIx and AIx', the ratio of backward and forward pressure wave amplitude calculated by means of wave separation analysis remained relatively unaffected for all simulations (Fig. 4.5). This was caused by a proportional increase in forward pressure wave amplitude with increased arterial stiffness. Such increased forward pressure wave amplitude with age was also observed in men and women in the Framingham Heart Study and was associated with age-related stiffening of central arteries [38]. Our simulations did show a clear pattern between arterial stiffness and backward wave amplitude (\hat{p}_{bw}) as determined using wave separation analysis. Moreover, the pattern was independent of LV sarcomere shortening velocity (Fig. 4.7).

Potential implications of increased backward wave amplitude with respect to cardiovascular risk were reported by Weber et al. [42]. Two key findings of their

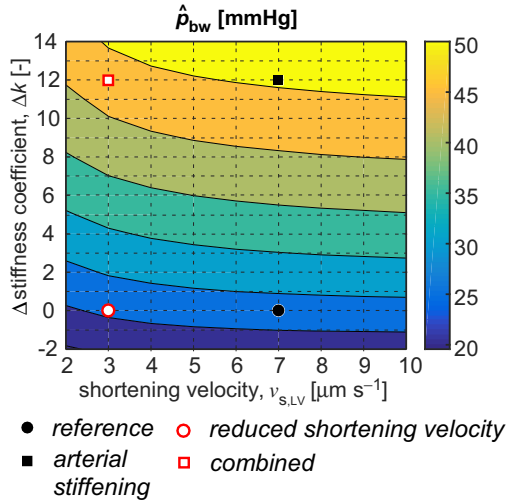

Figure 4.7: Effect of changes in sarcomere shortening velocity $v_{s, LV}$ and vessel stiffness (k) on backward pressure amplitude (\hat{p}_{bw}) assessed using wave separation (WS) analysis. The distinct simulated scenarios are highlighted by the dots and squares as indicated. Each grid point corresponds to a single simulation.

study were that 1) backward wave amplitude was the most consistent predictor of a composite cardiovascular end point, including mortality, in a group of 725 patients undergoing coronary angiography, and 2) the predictive value of AIx and augmentation pressure was inferior to that of backward wave amplitude [42]. The present study supports their findings and extends the explanation towards cardiac influences.

One should take caution when interpreting our simulated scenarios as emulators of human ageing and, hence, to expect an increased reflection magnitude as has been reported by Segers et al. [36] in the ageing population. Several aspects regarding cardio-vascular structure and function (e.g. cardiac mass and vascular segment diameters) that reportedly change with age have been kept constant throughout our simulations. Previously, Maksuti et al. [24] and Pagoulatou and Stergiopoulos [28] performed simulation studies focussing on changes in arterial haemodynamics during physiological ageing, whereas Willemet et al. [46] introduced a method to generate virtual cohorts consisting of arterial haemodynamics models, with varying population characteristics including age. Future studies on the evolution of AIx and other wave reflection indices may consider these methods as a take-off point.

Simulations revealed a linear association between ejection duration and augmentation index. Based on the simulations obtained in our multi-step parametric analysis, an increase in ejection duration of 20 ms caused AIx to increase with 9-percentage points [i.e. indicated by an unstandardised B of 0.43 %/ms, 95% confidence interval=[0.40, 0.45] %/ms, $P < 0.001$]. In the study of Sharman et al.

[37], a similar association between ejection duration and augmentation index of 10 percentage point per 20 ms of increase in ejection duration was found. In our model, this association is explained by a decrease in LV early-systolic volumetric rate with constant stroke volume, causing a significant portion of the LV stroke volume to be expelled after the inflection point (see above).

4.5.4 Cardiac workload

In the present study, we quantified cardiac workload by calculating left ventricular stroke work. Increasing arterial stiffness caused left ventricular stroke work to increase (+13%). Left ventricular stroke work slightly decreased (−6%) for the simulation with reduced left ventricular shortening velocity (Table 4.1). While AIX is derived from arterial measurements, using it to quantify cardiac workload appears to be erroneous, as cardiac contractility plays a role as well. Results imply that backward pressure amplitude —rather than depending solely on arterial stiffness in these simulations— to be more indicative of cardiac workload than AIX.

4.5.5 Previous clinical studies on ventriculo-arterial interaction

Below, two examples of clinical studies investigating aspects of ventriculo-arterial interaction are discussed. Bell et al. [6] reported that during systole the proximal aorta elongates, imposing a higher stretch-related workload on the LV. During diastole, the amount of elastic recoil energy is positively associated with increased early diastolic LV filling, suggesting that elastic recoil of the proximal aorta may benefit LV diastolic function through mechanical ventriculo-arterial coupling. In their analyses on the relations between aortic and LV measures, statistical correction of the (potential) confounding effect of wave reflections was performed using AIX. Given the present results, adjusting for AIX as a proxy of wave reflection may lead to over or undercorrection for the cardiac influence.

Palombo et al. [30] investigated the treatment effects of a calcium-channel blocker on LV structure (e.g. LV mass) and function (e.g. LV stroke work) indices as well as central (aortic) haemodynamics indices. Findings from the study included that the ratio of backward pressure amplitude and forward pressure amplitude was equal between hypertensive patients and normotensive controls, while backward pressure amplitude and LV stroke work were significantly higher for the hypertensive patient group. These findings corroborate our simulation findings that \hat{p}_{bw} best reflects the impact of backward wave reflection with increased arterial stiffness on LV workload.

4.5.6 Limitations

When interpreting our results, one has to realise that the data presented were not based on patient measurements but come from computer simulations. Although

we did not fit our model to patient data, the order of magnitude of the AIx compares well with human studies. In our reference simulation, AIx was found to be equal to 21%, which is in accordance with the range of values reported by Hughes et al. [19] in 65 healthy individuals (44 ± 14 years) and by Savage et al. [34] in 188 patients (56 ± 15 years) with chronic renal failure. Imposing either reduced LV shortening velocity or increased arterial stiffness caused AIx to increase to 41 and 42%, respectively. This is equivalent to the AIx measured in subjects between 70 and 80 years of age [26].

The following aspects regarding model assumptions and choices warrant discussion: The CircAdapt model used in this study describes a highly simplified cardiac geometry, relating myofibre stress and strain by single values. This approach was shown to be valid under the assumption that myofibre stress is homogeneously distributed [2]. A previous study utilising the CircAdapt model obtained physiologically realistic LV strain patterns as compared to global LV strain patterns obtained from MR-tagging [23]. Therefore, we believe CircAdapt's contraction model is appropriate for our study's purpose.

Furthermore, the wave propagation model we used neglects non-linear convective acceleration (i.e. we assume linear wave behaviour), thereby introducing small modelling error in pressure and flow waveforms. However, the implication of such error to derived haemodynamic indices is negligible in our study, since all the wave reflection indices we derived also assume linear wave behaviour.

We simulated arterial stiffening by increasing material stiffness parameter k (Eq. 4.2). Mean arterial pressure (i.e. p_0) was assumed to remain constant. As such, systolic blood pressure increased, whereas diastolic blood pressure decreased, which may not be representative for patients for which diastolic blood pressure is increased as well, e.g. due to increased peripheral resistance. To assess the implication of keeping mean arterial pressure constant on our findings, we repeated the *reference*, *reduced shortening velocity*, *arterial stiffening* and *combined* simulations with p_0 kept at 102 mmHg and 112 mmHg, respectively. With respect to changes (Δ) in augmentation index and backward pressure wave amplitude relative to the reference situation (i.e. the [$v_{s,IV} \downarrow$ -REF], [$k \uparrow$ -REF], and [$v_{s,IV} \downarrow, k \uparrow$ -REF] differences), we found only a minor influence of increasing p_0 (i.e. $\Delta AIx \leq 8\%$ and $\Delta \hat{p}_{bw} \leq 5$ mmHg, respectively).

We believe our model-based findings require further confirmation in clinical studies. Such a study could be a case-control design with isolated systolic hypertension and normotensive patient groups. Measurements in these studies should include speckle-tracking echocardiography to characterise LV contractile function [11], pulse wave analysis to characterise augmentation index [12], wave separation analysis [31] to characterise wave reflection behaviour, as well as stroke volume and blood pressure measurements to estimate cardiac workload.

4.6 Conclusion

We conclude that the AI_x reflects both cardiac and vascular properties, and hence should not be considered a vascular parameter. Furthermore, an increase in AI_x does not necessarily relate to increased stroke work. Hence, we believe AI_x should be abandoned as a proxy for increased wave reflection magnitude due to an arterial stiffness increase.

7.1 Abstract

Quantification of the uncertainty in constitutive model predictions describing arterial wall mechanics is vital towards non-invasive assessment of vascular drug therapies.

Therefore, we perform uncertainty quantification to determine uncertainty in mechanical characteristics describing the vessel wall response upon loading. Furthermore, a global variance-based sensitivity analysis is performed to pinpoint measurements that are most rewarding to be measured more precisely.

We used previously published carotid diameter-pressure and intima-media thickness (IMT) data (measured in triplicate), and Holzapfel-Gasser-Ogden models. A virtual data set containing 5000 diastolic and systolic diameter-pressure points, and IMT values was generated by adding measurement error to the average of the measured data. The model was fitted to single-exponential curves calculated from the data, obtaining distributions of constitutive parameters and constituent load bearing parameters.

Additionally, we 1) simulated vascular drug treatment to assess the relevance of model uncertainty and 2) evaluated how increasing the number of measurement repetitions influences model uncertainty. We found substantial uncertainty in constitutive parameters. Simulating vascular drug treatment predicted a 6-percentage point reduction in collagen load bearing (L_{coll}), approximately 50% of its uncertainty.

Sensitivity analysis indicated that the uncertainty in L_{coll} was primarily caused by noise in distension and IMT measurements. Spread in L_{coll} could be decreased by 50% when increasing the number of measurement repetitions from 3 to 10.

Model uncertainty, notably that in L_{coll} , could conceal effects of vascular drug therapy. However, this uncertainty could be reduced by increasing the number of measurement repetitions of distension and wall thickness measurements used for model parametrisation.

7.2 Introduction

ARTERIAL stiffening is a major determinant of hypertension and vice versa [19]. Treatment options for arterial stiffening can roughly be divided into two categories: 1) prescribing drugs that lower blood pressure and consequently reverse the arterial structural remodelling that occurs with hypertension, or 2) prescribing drugs that directly affect the arterial wall structure [42]. The second category includes cross-link breaking drugs that target the arterial collagen network [20, 48]. These type of drugs aim to break down the advanced glycation end-products (AGE) that form cross-links between collagen molecules [6, 20, 23]. The desired mechanical effect of such drug therapies is to reverse pressure load bearing from a stiff, collagen dominated phenotype to a less stiff, elastin dominated phenotype; resulting in a decrease in material stiffness [27, 48].

In vivo assessment of the performance of vascular drugs has proven to be cumbersome [7]. Arterial stiffness is typically quantified by measuring carotid-femoral pulse wave velocity, or by local assessment of arterial distensibility [20, 48]. A limitation of these indices is their blood pressure dependence, for which an incremental change in these indices could occur solely from a change in blood pressure [38]. In addition, arterial stiffness measurements as such do not yield insight into the effect of a drug at microstructural level, nor do they resolve whether the load-bearing phenotype is collagen or elastin dominated.

A potential solution to this problem lies in the use of computer models that simulate stress-strain behaviour of arteries using physical constitutive relations [15]. In such models, it might be possible to analyse the individual contribution of both elastin and collagen to the overall mechanical response of the vessel wall. *Ex vivo* studies on human carotid arteries, performed in the laboratory, reported good agreement between constitutive model computations and biaxial tensile tests [35, 36]. If such models could be parametrised using non-invasive measurements in patients, they could be used to evaluate the mechanics of the vessel wall patient-specifically. Several studies have attempted to use *in vivo* data to parametrise constitutive models of the arterial wall, as reviewed in Spronck et al. [37]. Typically, diameter, pressure, and intima-media thickness measurements at the carotid artery are used to fit such models [37]. Generally, noise in those measurements will hamper patient-specific evaluation of arterial wall mechanics.

In this study, we aim to 1) assess how measurement uncertainty propagates into uncertainty of mechanical characteristics, estimated using a model of arterial wall mechanics and 2) pinpoint the measurements responsible for the largest spread in mechanical characteristics through sensitivity.

Uncertainty quantification and sensitivity analysis are considered indispensable tools to ensure credibility of computer model-based predictions [26]. We explicitly focus on two types of mechanical characteristics: 1) constitutive parameters, describing the mechanical properties of collagen and elastin; and 2) constituent load-bearing parameters, describing to which extent the blood pressure load is borne per constituent. The latter parameters are considered outcome parameters, obtained by evaluating the model using the best-fit set of constitutive

parameters (Fig. 7.1, left panel). For these purposes, a large set of virtual pressure (P), diameter (D), and intima-media thickness (IMT) measurements will be generated by sampling the measurement distributions of previously published P , D and IMT measurements in healthy volunteers [13].

For each D - P sample, we will obtain continuous D - P curves over the diastolic-systolic pressure range, using the single-exponential function described earlier [24, 11]. Holzapfel-Gasser-Ogden constitutive models will be fitted to these data [15], and uncertainty quantification will be used to quantify the spread in the estimated mechanical characteristics, given the measurement noise (Fig. 7.1, left panel). A sensitivity analysis will be performed to determine how noise in the *individual* measured variables propagates into uncertainty in the model-predicted mechanical characteristics. The relevance of the model output uncertainty magnitude, which results from uncertainty in the model parameters, will be assessed by simulating the effect of AGE-breaker treatment on changes in collagen load bearing behaviour in our model (Fig. 7.1, right panel).

7.3 Methods

7.3.1 Constitutive model definition

To identify mechanical characteristics of the carotid artery wall, we used the Holzapfel-Gasser-Ogden constitutive model describing passive carotid artery wall mechanics [15]. This model was chosen on the one hand for its low number of parameters, and on the other hand for its feasibility in identifying mechanical characteristics when fitted to clinically obtained distensibility data [37]. Here, we will give a brief description of the model. For more details we refer to Appendix 7.A1.

In the model, the carotid artery is considered to be a thick-walled incompressible tubular structure composed of a mixture of two components: 1) elastin, assumed mechanically isotropic, and 2) collagen fibres, assumed mechanically orthotropic. Collagen was modelled by two families of fibres that are helically oriented at an angle of $+\beta_0$ and $-\beta_0$ with respect to the circumferential direction (Fig. 7.2). Elastin and collagen were assumed to operate in parallel. Furthermore, we assumed that there is only deformation along the principal axes, i.e. no shear. The mechanical response of the constituents can be described using a strain energy function (SEF). The SEFs of the constituents combined provide a relationship between stress and strain, and comprise a way of formulating constitutive behaviour of hyperelastic materials [18]. The SEF used for elastin (W_{elast}) is given by

$$W_{\text{elast}} = c_{\text{elast}}(I_1 - 3), \quad (7.1)$$

with I_1 the first invariant of the Green-Lagrange strain tensor, given by $I_1 = \lambda_{rr}^2 + \lambda_{\theta\theta}^2 + \lambda_{zz}^2$, with λ the stretch in the radial (r) direction, circumferential (θ) direction, and axial (z) direction, respectively. The parameter c_{elast} is a constitutive (stiffness) parameter for elastin.

Figure 7.1: Outline of the current study, involving 1) uncertainty quantification (UQ) and sensitivity analysis (SA) of a constitutive model of arterial wall mechanics (methodology, left) and 2) assessment of the relevance of the model output uncertainty when evaluating the effects of vascular drug treatment (clinical application, right). Left: Group-averaged measured variables were obtained from a previous study, measuring twelve healthy subjects. The effect of measurement uncertainty on measured variables was included by perturbing group-averaged variables based on their measurement uncertainty. Within the margins of measurement uncertainty, we generated a data set composed of the 5000 samples containing measured variables. Here, the measured variables are D_d : diastolic diameter; ΔD : distension; P_d and P_p : diastolic and pulse pressure, respectively; IMT: intima-media thickness. Holzapfel-Gasser-Ogden models were fitted to single-exponential diameter-pressure curves, determined for each sample of the generated data set. This yielded initial (INIT) realisations of mechanical characteristics, consisting of constitutive parameters and constituent load-bearing parameters, that were subsequently used for uncertainty quantification and sensitivity analysis. The constitutive parameters are c_{elast} : elastin stiffness parameter; k_1 and k_2 : collagen stress-scaling and stress-curve shape parameters, respectively. The parameter R_1 indicates the unstressed vessel inner radius and is an auxiliary model parameter. The load-bearing parameter L_{coll} indicates the collagen load bearing as a percentage of the blood pressure (BP) load. Right: Assessing the relevance of uncertainty in load-bearing parameters by simulating advanced glycation end-product (AGE) breaker treatment using the model. We simulated AGE-breaker treatment by reducing parameters k_1 and k_2 equally with respect to their INIT best-fit values.

The SEF used for collagen (W_{coll}) is given by

$$W_{coll} = \frac{k_1}{k_2} \left[\exp \left[k_2 \left(\lambda_{fibre}^2 - 1 \right)^2 \right] - 1 \right], \quad (7.2)$$

Figure 7.2: Overview of unstressed (top) and stressed (bottom) configurations of an artery. Top: P : internal pressure, F_z : reduced axial force, R : unstrained radius, R_i : unstrained inner radius, R_o : unstrained outer radius, α : opening angle, L : unstrained vessel length. In the unstressed configuration, we consider two families of helically orientated collagen fibres, with an angle $\pm\beta_0$ with respect to the circumferential direction. Bottom: r : stressed radius, r_i : stressed inner radius, r_o : stressed outer radius, A_w : cross-sectional wall area in the stressed configuration, l : stressed vessel length, λ_{zz} : axial pre-stretch.

where k_1 as well as k_2 are constitutive parameters and λ_{fibre} denotes fibre stretch, given by $\lambda_{\text{fibre}} = \sqrt{\cos^2(\beta_0)\lambda_{\theta\theta}^2 + \sin^2(\beta_0)\lambda_{zz}^2}$. This collagen SEF should only contribute when the fibres are extended (while collagen fibres cannot sustain compression; Holzapfel et al. [15]). The positive luminal arterial pressure used in all our simulations ensures that such condition is always met.

For incompressible materials, the local stress-strain behaviour can be calculated using the derivatives of the SEFs:

$$\sigma_n = -P_h + \lambda_n \frac{\partial W_{\text{elast}}}{\partial \lambda_n} + \lambda_n \frac{\partial W_{\text{coll}}}{\partial \lambda_n}, \quad (7.3)$$

with σ_n the Cauchy stress. The subscript n is rr for the radial direction, $\theta\theta$ for the circumferential direction and zz for the axial direction. The pressure P_h is the local hydrostatic pressure within the wall.

In W_{elast} and W_{coll} , the following parameters thus characterise the constitutive behaviour of elastin and collagen:

- c_{elast} : stiffness parameter of elastin, units of Pa.
- k_1 : stress scaling parameter of collagen, units of Pa.
- k_2 : collagen stress-curve shape parameter, dimensionless.

Elastin acts physiologically as the predominant load bearer for low pressure loads, whereas collagen, which is modelled as an unstressed fibrous material for low pressure, starts bearing load at higher pressures [14, 27, 32, 45]. The fitted parameters should result in a relation that mimics this behaviour. To quantify collagen load bearing, we estimated L_{coll} , being the pressure load borne by collagen as a percentage of the total blood pressure load (see Appendix 7.A1.4).

Based on literature reports on excised human and animal carotid arteries, we assumed that the artery is subjected to an initial axial pre-stretch (λ_{zz} , Fig. 7.2) of 1.20 [37]. The helix angle of the two families of collagen fibres in our model was assumed to be $\pm 35.3^\circ$ in the unstressed configuration (Fig. 7.2) [1]. This angle was chosen from an analytical solution that for a thin-walled, fibre-reinforced tube results in a constant reduced axial force (F_z) over the cardiac cycle ($dF_z/dP = 0 \frac{\text{N}}{\text{Pa}}$) [1, 18, 41, 44, 46]. Here, F_z is defined as the force applied in the axial direction additional to that generated by the pressure on the closed ends of the vessel [14]. Furthermore, in an earlier study fitting a thick-walled two-fibre material model to experimental data from coronary arteries, an optimal fibre angle of 36° was found [43]. Cross-sectional wall area (A_w , Fig. 7.2) was calculated from the diastolic outer diameter of the carotid (D_d) as well as IMT, using the relation given by

$$A_w = \pi \left(\frac{1}{4} D_d^2 - \left(\frac{1}{2} D_d - \text{IMT} \right)^2 \right). \quad (7.4)$$

To map from a cut, stress-free configuration of an artery, to an unloaded intact configuration, to a loaded configuration, we define two additional parameters (Fig. 7.2, [16, 18, 37]): the opening angle (α) and the unstressed inner vessel radius (R_i). The value for α was taken from literature (100° , [37]). The parameter R_i was fitted using the constitutive model fitting routine (see below).

Residual stresses are accounted for by using the parameters λ_{zz} , α and R_i to define the stretches in the loaded configuration with respect to the stress-free configuration, as described in Appendix 7.A1. To obtain D - P and F_z - P relations, the following boundary value problem was considered. Assuming axisymmetry and neglecting torsion, acceleration forces, body forces and axial extension, the relevant components of the radial momentum balance are given by

$$\frac{\partial \sigma_{rr}}{\partial r} + \frac{\sigma_{rr} - \sigma_{\theta\theta}}{r} = 0. \quad (7.5)$$

Applying the boundary conditions $\sigma_{rr}(r_i) = -P$ and $\sigma_{rr}(r_o) = 0$, with r_i the vessel inner radius and r_o the vessel outer radius, the expression for lumen pressure is

given by

$$P = \int_{r_i}^{r_o} \frac{\sigma_{\theta\theta} - \sigma_{rr}}{r} dr . \quad (7.6)$$

Reduced axial force is given by

$$F_z = \pi \int_{r_i}^{r_o} (2\sigma_{zz} - \sigma_{rr} - \sigma_{\theta\theta}) r dr . \quad (7.7)$$

7.3.2 Parametrisation

Clinical measurements

The measurement protocol and data used in the present study are elaborated by Holtackers et al. [13]. Briefly, twelve apparently healthy volunteers (22 ± 3 years, 6 male) were recruited. The study was approved by the medical ethics committee of Maastricht University Medical Centre (Maastricht, The Netherlands) and written consent was obtained from all participants prior to enrolment.

Ultrasound (US) B-mode recordings were performed at the right common carotid artery (CCA) in the anterolateral plane, and obtained in triplicate. Diastolic blood pressure (P_d) and pulse pressure (P_p) were measured three times during the US imaging protocol using an oscillometric device (Omron 705IT; Omron Healthcare Europe, Hoofddorp, The Netherlands).

The US recordings were analysed to determine right CCA cyclic distension (i.e. diastolic-systolic diameter change, ΔD) and diastolic diameter (D_d). Because the echo tracking tool used (RFQAS; Esaote, Maastricht, The Netherlands) utilises the media-adventitia echoes of near and far walls, we assumed the measured diameter signal over time to reflect the CCA *outer* diameter [37]. Furthermore, we obtained IMT at P_d using an automated software tool that reported good agreement with manual IMT methods [47].

Generation of data set for constitutive modelling

For the present analysis, we obtained an initial data set consisting of group-averaged values for P_d , P_p , D_d , ΔD , and IMT (Fig. 7.1, left panel). Subsequently, uncertainties in the measured variables were accounted for by generating multiple samples within the uncertainty ranges of each measured metric. We assumed Gaussian distributed uncertainty domains for each measured variable M_i in \mathbf{M} , given by

$$M_i = \bar{M}_i \pm 1.96 \frac{SD_{\text{intra}, M_i}}{\sqrt{N_{\text{rep}}}} , \quad (7.8)$$

see also Table 7.1.

Each sample consisted of a vector \mathbf{M} containing the following variables: $\mathbf{M} = [P_d, P_p, D_d, \Delta D, \text{IMT}]$. Here, \bar{M}_i represents the average measured value of variable M_i and SD_{intra, M_i} represents the corresponding intra-subject standard deviation

Table 7.1: Overview of average values, intra-subject SDs and uncertainty domains per measured variable.

Parameter	Unit	Data of twelve subjects		
		Mean	Intra-subject SD	Uncertainty domain
P_d	mmHg	72	3 ± 0	[69; 75]
P_p	mmHg	58	3 ± 1	[54; 62]
D_d	mm	6 ± 37	0 ± 22	[6.12; 6.62]
ΔD	mm	0 ± 789	0 ± 035	[0.750; 0.829]
IMT	μm	539	40	[494; 584]

Intima-media thickness (IMT) was obtained at P_d . Intra-subject SD was determined using the method described in Bland and Altman [3]. The uncertainty domains of the measured variables were calculated using their respective mean and intra-subject SD values, see Eq. 7.8.

(i.e. indicating measurement error [3]). In our data set, measurements were performed in triplicate (i.e. $N_{\text{rep}} = 3$) [13]. Samples were generated within the uncertainty domains of the measured variables, using Sobol's low discrepancy series, implemented in the MATLAB Statistics and Machine Learning Toolbox function `sobolset` (MATLAB R2015a; The MathWorks, Natick, MA, USA) [34]. This sampling method samples the uncertainty domains uniformly and was chosen as a "worst case scenario". To ensure adequate convergence of mechanical characteristics distributions, we generated 5000 samples. Systolic blood pressure (P_s) was calculated as $P_s = P_d + P_p$; systolic diameter (D_s) was calculated as $D_s = D_d + \Delta D$. The distributions of D_d , D_s , P_d , and P_s as well as IMT are shown in Fig. 7.3. The greater amount of scattering of systolic D and P data points compared to diastolic data points is caused by the fact that systolic blood pressure is defined as the sum of diastolic and pulse pressure.

As diastolic and pulse pressure were assumed to be independent, their sum (systolic blood pressure) will have a larger spread than diastolic blood pressure alone. The larger spread in systolic diameter than in diastolic diameter has the same origin, as systolic diameter is defined as the sum of diastolic diameter and distension.

For each sample in the data set, the following single-exponential function was parametrised to obtain continuous D - P relations:

$$P(D) = P_d \exp \left[\gamma \left(\frac{D^2}{D_d^2} - 1 \right) \right]. \quad (7.9)$$

Here, D is a continuous variable describing vessel diameter and γ is a dimensionless non-linearity factor, which is calculated from systolic and diastolic blood

Figure 7.3: Density plots displaying the distributions of the 5000 computer-generated samples for diastolic and systolic blood pressure and diameter (left), as well as intima-media thickness (right). Density of diastolic pressure and diameter as well as intima-media thickness samples is high. The greater amount of scattering of systolic diameter and pressure samples arises from the fact that systolic blood pressure is defined as the sum of diastolic and pulse pressure, assumed independent. Similarly systolic diameter is defined as the sum of diastolic diameter and distension, also assumed independent.

pressures and diameters as described by Meinders and Hoeks [24]:

$$\gamma = \frac{\log\left(\frac{P_s}{P_d}\right)}{\frac{D_s^2}{D_d^2} - 1}. \quad (7.10)$$

Model fitting procedure

The constitutive model was fitted to the single-exponential curve, obtained for each sample \mathbf{M} of the data set. Model fitting was performed by variation of model parameters c_{elast} , k_1 , k_2 , and R_i (Fig. 7.1, left panel). Lower and upper bounds of all fitted parameters are given in Table 7.2.

Table 7.2: Complete overview of lower and upper parameter bounds used for fitting the diameter-pressure data.

Parameter	Unit	Lower bound	Upper bound
c_{elast}	kPa	1	400
k_1	kPa	$0.1 \cdot 10^{-3}$	400
k_2	-	0	100
R_i	m	$0.5 \cdot 10^{-3}$	$10 \cdot 10^{-3}$

For each sample in the data set, we assumed the single-exponential curve to be valid within the range $P \in \{P_{d,\text{sample}} - 15 \text{ mmHg}, P_{s,\text{sample}} + 15 \text{ mmHg}\}$

[11, 24]. In Fig. 7.3 (left), the distribution of $P_{d,\text{sample}}$ vs. $P_{s,\text{sample}}$ is displayed.

Fitting was performed using the trust-region reflective algorithm [25], implemented in the MATLAB Optimization Toolbox function `lsqnonlin` and was initiated from 10 random start points in the parameter space using the MATLAB Global Optimization Toolbox function `MultiStart`. The same 10 start points were used for fitting all samples. Throughout model fitting, we aimed to minimise the sum of squared differences between measured pressure from the single-exponential curve P_j and modelled $P_{\text{mod},j}$:

$$\epsilon_P = \frac{1}{n_P} \frac{1}{P_P^2} \sum_{j=1}^{n_P} (P_j - P_{\text{mod},j})^2, \quad (7.11)$$

where, for each sample, n_P is the number of fitting points and P_P is the pulse pressure.

As a physiological constraint, F_z was forced to remain constant at a target value defined $F_{z,\text{target}}$, with varying pressure. This assumption was based on experimental work performed by Van Loon [44] and Weizsäcker et al. [46], observing axial force to be nearly insensitive to changes in pressure for arteries inflated at their *in vivo* axial pre-stretch. We enforced this constraint by minimising the following expression:

$$\epsilon_{F_z} = \frac{1}{n_P} \frac{1}{F_{z,\text{target}}^2} \sum_{j=1}^{n_P} (F_{z,j} - F_{z,\text{target}})^2, \quad (7.12)$$

where $F_{z,\text{target}}$ was assumed to be equal to 0.5 N. This value was based on a study by Patel et al. [28] in excised, vertically suspended canine arteries that were extended by hanging weights from the bottom end of the artery. For the carotid artery to restore its *in vivo* length, a weight of 54 g was required, corresponding to an F_z of 0.5 N. The two weighted errors ϵ_P and ϵ_{F_z} are combined into the weighted total sum of squares (ϵ_T):

$$\epsilon_T = w_P \epsilon_P + w_{F_z} \epsilon_{F_z}, \quad (7.13)$$

where w_P and w_{F_z} are non-dimensional weighting factors. Here, we chose $w_P = 10$ and $w_{F_z} = 1$. The ϵ_P term was given a higher importance than the ϵ_{F_z} term, because of absence of F_z measurements in our study and uncertainty in the assumed target value for F_z . The fitting error describing goodness-of-fit is expressed as a normalised root mean square error ($E_{\text{RMS},P}$ and E_{RMS,F_z}):

$$E_{\text{RMS},P} = 100\% \cdot \sqrt{\epsilon_P}, \quad \text{and} \quad (7.14)$$

$$E_{\text{RMS},F_z} = 100\% \cdot \sqrt{\epsilon_{F_z}}. \quad (7.15)$$

7.3.3 Simulations and analysis

Initial constitutive parameter estimation

The constitutive model was fitted to all 5000 samples of the generated data set using the procedure explained in the previous section. This yielded 5000 initial constitutive model realisations (i.e. termed INIT).

Uncertainty quantification and sensitivity analysis

All constitutive model realisations together yield insight in the distribution of the mechanical characteristics that results from the presence of measurement uncertainty. This distribution of mechanical characteristics was therefore used to quantify the uncertainty in constitutive parameters (i.e. the fitted parameters c_{elast} , k_1 , and k_2), as well as collagen load bearing parameters, (i.e. the outcome parameter L_{coll} at various blood pressure levels, Fig. 7.1, left panel). We used kernel density estimation (KDE) to visualise the distributions of constitutive parameters and load bearing parameters. KDE estimates the probability density function, which in this context implies the probability density of finding a certain value of a constitutive parameter or load bearing value [33]. Furthermore, we quantified spread in parameters using the median and the 25th to 75th percentile confidence interval (PCI_{25→75}). Calculating the PCI_{25→75} comes at hand when assessing spread of skewed distributions.

Sensitivity analysis (SA) was subsequently used to apportion uncertainty in the model-predicted mechanical characteristics to uncertainty in specific measured variables, or their interactions [17]. A global variance-based SA was performed using regression-based adaptive generalised polynomial chaos expansion (agPCE), as detailed in Quicken et al. [29]. The agPCE method captures the relation between mechanical characteristics (X_i) and measured variables (M_i) by means of an adaptively constructed finite polynomial expansion f_{agPCE} :

$$X_i = f^{X_i}(\mathbf{M}) \approx f_{\text{agPCE}}^{X_i}(\mathbf{M}). \quad (7.16)$$

Here, \mathbf{X} contains the mechanical characteristics, i.e. $\mathbf{X} = [c_{\text{elast}}, k_1, k_2, L_{\text{coll}}]$. Furthermore, $\mathbf{M} = [M_1, M_2, \dots, M_{N_{\text{vars}}}] = [P_d, P_p, D_d, \Delta D, \text{IMT}]$, and N_{vars} is the number of measured variables. Such a polynomial expansion provides a meta-model of the mechanical characteristics estimation method. After constructing the meta-model, the value of the leave-one-out cross-validation coefficient (Q^2) was computed. Coefficient Q^2 , ranging between a value of 0 and 1 is a quality measure of the meta-model, indicating its predictive properties [40]. Throughout this study we assumed $Q^2 > 0.99$ to indicate an appropriate meta-model.

From the meta-model, the variance of a mechanical characteristic (a measure of its uncertainty) can be computed. The following sensitivity metrics were computed:

- **Main sensitivity indices.** The main sensitivity index (S_i) of measured vari-

able M_i represents the expected reduction in uncertainty of the mechanical characteristic if M_i were known exactly. Assessment of S_i determines which measured variables are most rewarding to be measured more accurately to reduce model output uncertainty (i.e. parameter prioritisation) [31].

- **Total sensitivity indices.** The total sensitivity index (S_T) of M_i represents the expected uncertainty in the mechanical characteristic that would remain if all other measured variables except M_i were known exactly. Assessment of S_T determines which measured variables could potentially be fixed within their uncertainty domain (i.e. parameter fixing) [31].

The contribution of each measured variable to total uncertainty in estimating mechanical characteristics can be illustrated as the segments of a disc (Fig. 7.1). Total uncertainty may be apportioned to single measured variables but, may also arise from interaction between measured variables (Fig. 7.1). Moreover, significant interaction effects are indicated by large differences between total sensitivity indices and main sensitivity indices [39].

Simulating the effect of AGE-breaker vascular drugs

AGE-breaker treatment was simulated using the INIT realisations as take-off points (Fig. 7.1, right panel). We explicitly assumed that a reduction in cross-link density can be represented in the model by reducing parameters k_1 and k_2 . The rationale of reducing k_1 and k_2 is based on previous work measuring the stress-strain response of collagen tissue at multiple levels of cross-linking [8, 21]. In their work it was observed that a decrease in cross-link density results in 1) a decrease in fibre stiffness at low amounts of strain and 2) a decrease in the non-linearity of the fibre stress-strain response [8, 21]. In our analysis, k_1 and k_2 were equally reduced by 40% of their initial best-fit value yielding the $k_1 \downarrow, k_2 \downarrow$ realisations (Fig. 7.1, right panel). All other constitutive model parameters were assumed to remain unchanged.

7.4 Results

7.4.1 Representative example of a fitted constitutive model

A representative example of a model-based $D-P$ and $F_z - P$ relationship, obtained by model-fitting a sample within the virtual data set is depicted in Fig. 7.4. The best-fit constitutive parameters for this representative sample were $c_{\text{elast}} = 40.1$ kPa, $k_1 = 6.9$ kPa and $k_2 = 8.5$. Collagen load bearing (L_{coll}) increased monotonically with blood pressure from 0.6% at diastolic blood pressure (P_d), to 10.2% at mean arterial pressure (P_m), up to 25.0% at systolic blood pressure (P_s), respectively. The slope of the plotted curves (dD/dP) is a measure of vascular compliance. Low vascular compliance corresponds to high vascular stiffness and vice versa.

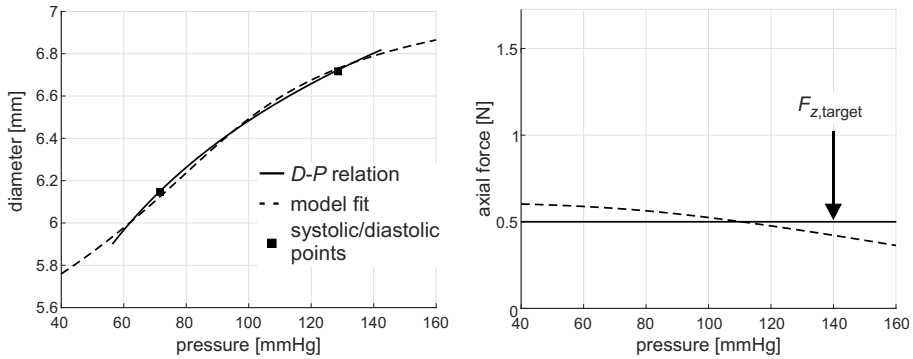

Figure 7.4: Representative example of the model-predicted diameter-pressure (D - P) curve and the reduced axial force-pressure (F_z - P) curve (dashed lines) as well as the group-averaged data fitted upon (solid lines). The difference between measured and model-predicted pressure was minimised over the pressure fitting range (i.e. $P_d - 15$ mmHg to $P_s + 15$ mmHg), whereas reduced axial force was fitted to an assumed target value of 0.5 N ($F_{z,target}$, respectively). Values of fitted parameters were $c_{elast} = 40.1$ kPa, $k_1 = 6.9$ kPa and $k_2 = 8.5$. Fit errors, describing the goodness-of-fit were $E_{RMS,P} = 0.020\%$ and $E_{RMS,F_z} = 16\%$, respectively.

The model fit (dashed lines, Fig. 7.4) shows sigmoidal D - P behaviour over a 40 to 160 mmHg pressure range, suggesting low compliance for the lower part of pressure range followed by higher compliance in the physiological pressure range and again lower compliance for the upper part of the pressure range. Furthermore, there is some deviation between the model-based F_z - P curve and the assumed (pressure-independent) target value of 0.5 N (Fig. 7.4).

7.4.2 Uncertainty quantification and sensitivity analysis

The distributions of the fitted constitutive parameters are shown in Fig. 7.5.

Figure 7.5: Kernel density estimates (KDE) describing the distributions of fitted constitutive parameters (c_{elast} , k_1 , and k_2). Distributions of parameters were quantified using the median and the 25th to 75th percentile confidence interval (PCI_{25→75}), respectively.

Best-fit parameter values for elastin stiffness (c_{elast}) were 47.4 [44.8; 50.0] kPa

(median [PCI_{25→75}]). For collagen parameters, best-fit parameter values were 2.1 [0.8;5.9] kPa for k_1 , and 8.8 [7.9;9.5] for k_2 , respectively.

In Fig. 7.6, distributions of collagen load bearing parameters (L_{coll}) are given at three blood pressure levels (P_d , P_m , and P_s , respectively).

Figure 7.6: Kernel density estimates (KDEs) describing the distribution of collagen load bearing characteristic (L_{coll}). Black line: KDE for initial constitutive model realisations (INIT). Red dashed line: KDEs for model with decreased k_1 and k_2 ($k_1 \downarrow, k_2 \downarrow$). KDEs were calculated at three blood pressure levels; diastolic blood pressure (P_d), mean arterial pressure (P_m) and systolic blood pressure (P_s). Distributions of parameters were quantified using the median and the 25th to 75th percentile confidence interval (PCI_{25→75}), respectively.

Note that $L_{\text{coll}} = 0\%$ indicates that blood pressure load is fully borne by elastin, whereas $L_{\text{coll}} = 100\%$ indicates that blood pressure load is fully borne by collagen. For the initial constitutive model realisations (INIT), we found L_{coll} equal to 1.5% at P_d , 3.1% at P_m , and 16.7% at P_s (medians, respectively). As shown in Fig. 7.6, the 25th to 75th percentile confidence interval for L_{coll} at P_d as well as P_s were large ([0.6;4.5]% and [12.7;24.0]%, respectively), indicating large uncertainty in model predictions of constituent load bearing.

A full overview of main and total sensitivity indices is given in Tables 7.3 and 7.4.

Table 7.3: Main (S_i) and total (S_T) sensitivity indices for constitutive parameters c_{elast} , k_1 and k_2 .

Measured variable	Symbol	Constitutive parameter:					
		c_{elast}		k_1		k_2	
		S_i	S_T	S_i	S_T	S_i	S_T
Diastolic blood pressure	P_d	0.012	0.014	0.00060	0.0011	0.052	0.056
Pulse pressure	P_p	0.0018	0.021	0.027	0.041	0.10	0.12
Diastolic diameter	D_d	0.0060	0.036	0.033	0.047	0.29	0.32
Distension	ΔD	0.62	0.67	0.90	0.93	0.50	0.54
Intima-media thickness	IMT	0.31	0.31	0.0083	0.015	0.00083	0.00083

Sensitivity indices larger than 0.10 are indicated in bold. The coefficient Q^2 , indicating the accuracy of the meta-model, was 0.997, 0.998 and 0.998 for c_{elast} , k_1 and k_2 , respectively

In general, distension and IMT were most rewarding to be measured more reliably. For the constitutive parameters c_{elast} and k_1 , this is illustrated by main

Table 7.4: Main (S_i) and total (S_T) sensitivity indices for collagen load bearing parameters (L_{coll}) at three blood pressure levels; diastolic- mean- and systolic blood pressure (i.e. P_d , P_m and P_s , respectively.)

Measured variable	Symbol	Load bearing parameter:					
		L_{coll} at P_d		L_{coll} at P_m		L_{coll} at P_s	
		S_i	S_T	S_i	S_T	S_i	S_T
Diastolic blood pressure	P_d	0.00043	0.00098	0.00073	0.0016	0.0019	0.0027
Pulse pressure	P_p	0.021	0.035	0.023	0.035	0.052	0.054
Diastolic diameter	D_d	0.036	0.058	0.041	0.059	0.064	0.067
Distension	ΔD	0.90	0.94	0.90	0.93	0.87	0.88
Intima-media thickness	IMT	0.0028	0.0049	0.0031	0.0046	0.0031	0.0048

Sensitivity indices larger than 0.10 are indicated in bold. The coefficient Q^2 , indicating the accuracy of the meta-model, was 0.993, 0.995 and 0.999 for diastolic (P_d), mean (P_m) and systolic blood pressure (P_s), respectively

sensitivity indices (S_i) between 0.62 and 0.90 for distension and 0.31 for IMT (Table 7.3).

For collagen parameter k_2 , distension and diastolic diameter are most influential (Table 7.3). Moreover, pulse pressure has some influence, indicated by an S_i of 0.10 (Table 7.3). For collagen load bearing (L_{coll}), distension was the most important measured variable, indicated by S_i between 0.87 and 0.90 (Table 7.4). The main sensitivity indices of the other measured variables were smaller than 0.06, indicating low influence (Table 7.4).

Reducing uncertainty of blood pressure measurements appears of negligible importance in reducing uncertainty in estimating c_{elast} , k_1 , and L_{coll} , indicated by an $S_i < 0.06$ (Table 7.3). Moreover, total sensitivity indices (S_T) for diastolic blood pressure and pulse pressure were smaller than 0.12, suggesting these variables could be fixed in their uncertainty domain.

For all measured variables, differences between main and total sensitivity indices were minor, i.e. $S_T - S_i$ was smaller than 0.10 (Tables 7.3 and 7.4). This indicates that the contribution of interaction terms between measured variables to the total variance was negligible [31].

7.4.3 Model-based assessment of vascular drug therapies

Fig. 7.7 shows the effect of AGE-breaker treatment (simulated by $k_1 \downarrow, k_2 \downarrow$) on the model-predicted D - P curve, as well as on area compliance (C_A).

Here, the average D - P curves, originating on the one hand from the initial best-fit constitutive parameters (INIT, black line), and on the other hand following reduction of k_1 and k_2 ($k_1 \downarrow, k_2 \downarrow$, red dashed line) are shown. Moreover, C_A is shown in the right panel for all INIT realisations (black circles), and the $k_1 \downarrow, k_2 \downarrow$ realisations (red circles). Area compliance was calculated using $C_A = (A_s - A_d)/(P_s - P_d)$, with $A_s = \pi(D_d + \Delta D)^2/4$ and $A_d = \pi D_d^2/4$, respectively. Simulating $k_1 \downarrow, k_2 \downarrow$ caused a left-upward shift of the group-averaged D - P curve, as well as a 40% in-

Figure 7.7: Left panel: Reducing collagen parameters k_1 and k_2 with 40% (i.e. $k_1 \downarrow, k_2 \downarrow$), caused a left-upward shift in the average diameter-pressure (D - P) relation. Tangent lines (dotted lines) from the diastolic D - P point to the systolic D - P point indicate area compliance. Right panel: Simulating $k_1 \downarrow, k_2 \downarrow$ caused area compliance (C_A) to increase from $0.15 \text{ mm}^2 \text{ mmHg}^{-1}$ to $0.21 \text{ mm}^2 \text{ mmHg}^{-1}$, respectively. For each INIT and $k_1 \downarrow, k_2 \downarrow$ realisation, area compliance was calculated using $C_A = (A_s - A_d) / (P_s - P_d)$, with $A_s = \pi(D_d + \Delta D)^2 / 4$ and $A_d = \pi D_d^2 / 4$, respectively.

crease in C_A (Fig. 7.7). In Fig. 7.6, distributions of L_{coll} for the $k_1 \downarrow, k_2 \downarrow$ realisations (red dashed curves) are shown. We found L_{coll} to equal $0.8 [0.3; 2.5]\%$ at P_d , $1.7 [0.6; 5.0]\%$ at P_m , and $10.8 [7.2; 17.6]\%$ at P_s (median $[PCI_{25 \rightarrow 75}]$). As compared to the INIT realisations, spread in L_{coll} was lower for $k_1 \downarrow, k_2 \downarrow$ realisations (Fig. 7.6).

7.5 Discussion

Computational models of arterial wall mechanics could be valuable for predicting effects of vascular drug therapies on individual arterial wall constituents. The aim of this study was 1) to quantify how measurement noise propagates into uncertainty of the model predictions, and 2) to pinpoint the measurements responsible for the largest spread in mechanical characteristics. The relevance of the model output uncertainty was assessed by simulating the effects of vascular drug treatment on constituent load bearing. To our knowledge, this is the first study to perform rigorous uncertainty quantification and sensitivity analysis, assessing the influence of measurement noise in clinical arterial pressure and diameter measurements on constitutive model predictions.

The present study demonstrates that the clinically usefulness of estimating mechanical characteristics of the carotid artery using a constitutive model is hampered by measurement uncertainty. Using sensitivity analysis, we pinpointed that the majority of uncertainty in mechanical characteristics is caused by uncertainty in measurements of distension and IMT.

7.5.1 Model fitting and parameter estimation

Model fitting was performed on single-exponential diameter-pressure curves calculated from diastolic and systolic diameters and pressures. The assumption of a markedly exponential diameter-pressure curve in the physiological (i.e. diastolic to systolic) pressure range was reported in earlier works by Hayashi et al. [11] and Meinders and Hoeks [24]. At a wider pressure range (i.e. 40 to 160 mmHg), a representative constitutive model realisation suggested sigmoidal diameter-pressure behaviour (Fig. 7.4). Such sigmoidal behaviour was also observed in *in vitro* studies, performing inflation tests on human aortic segments and rat carotid arteries [9, 22].

In the present study, best-fit constitutive parameter values for elastin stiffness (i.e. 47.4 [44.8;50.0] kPa) were in agreement to those found for cadaveric carotid arteries, reporting values between 20 and 60 kPa [30, 35]. Moreover, values for collagen parameter k_2 were well within ranges found in earlier studies [30, 35]. We found a large spread for constitutive parameter k_1 , governing collagen stiffness, i.e. median [PCI_{25→75}] of 2.1 [0.8;5.9] kPa. Previous *in vitro* studies found k_1 values ranging from 2.9 kPa to 99.9 kPa, respectively [35]. Therefore, our findings for k_1 are on the low end to those found in the aforementioned studies. It has been pointed out that appropriate choices of both k_1 and k_2 ensure collagen to virtually not bear load at very low amounts of stretch (i.e. at sub-physiological pressure loads), whereas it will become the dominant load bearer at high amounts of stretch [15]. In the present study, and in *in vivo* studies *per se*, diameter and pressure measurements at these very low pressures are unavailable, making robust estimation of model parameters (particularly k_1) cumbersome, as illustrated by our findings.

7.5.2 Sensitivity analysis

Sensitivity analysis indicated that the most important contributors to uncertainty in c_{elast} are both the variables measured by ultrasound (i.e. distension and IMT), whereas uncertainty in collagen parameter k_1 was primarily caused by measurement uncertainty of distension. Although our model-based approach still requires blood pressure to be measured, improving the precision of distension and wall thickness measurements clearly appears to be most rewarding.

Recent technological advances in vascular imaging, including plane wave ultrasound and image-reconstruction algorithms, could reduce the measurement noise of a single ultrasound measurement [2]. More practically, uncertainty in mechanical characteristics could be reduced by increasing the number of repeated measurements (N_{rep} , Eq. 7.8).

7.5.3 Decreasing measurement uncertainty by increasing the number of repeated measurements

We evaluated to which extent increasing N_{rep} , for all measured variables displayed in Table 7.1, influenced uncertainty in collagen load bearing parameters. Results indicate that increasing the number of repeated measurements from 3 to 10 decreases the spread in L_{coll} by $\approx 50\%$ (i.e. reducing the 25th to 75th percentile confidence interval at systolic blood pressure from [12.7;24.0]% to [14.0;19.9]%, Table 7.5).

Table 7.5: The effect of increasing the number of repeated clinical measurements (N_{rep}) on collagen load bearing parameters (L_{coll}) as predicted using the initial constitutive model realisations

N_{rep}	L_{coll} at P_d		L_{coll} at P_m		L_{coll} at P_s	
	median [%]	PCI _{25→75} [%]	median [%]	PCI _{25→75} [%]	median [%]	PCI _{25→75} [%]
3	1.5	[0.6;4.5]	3.1	[1.2;8.2]	16.7	[12.7;24.0]
5	1.5	[0.7;3.5]	3.0	[1.4;6.7]	16.5	[13.2;21.8]
10	1.5	[0.9;2.7]	3.0	[1.8;5.3]	16.5	[14.0;19.9]

PCI_{25→75}: 25th to 75th percentile confidence interval, P_d : diastolic blood pressure, P_m : mean blood pressure, and P_s : systolic blood pressure.

Based on the results of our sensitivity analysis, increasing the number repetitions of ultrasound measurements appears most rewarding in reducing uncertainty in collagen load bearing parameters.

7.5.4 Model-based assessment of vascular drug therapies

AGE-breaking vascular drug therapy was simulated by changing constitutive model parameters governing collagen behaviour (i.e. parameters k_1 and k_2). We chose to reduce collagen stress scaling parameter k_1 , as well as collagen stress-curve shape parameter k_2 by 40% of their initial best-fit values. Consequently, the modelled collagen becomes incrementally less stiff at low amounts of strain, but will also stiffen 'later' (i.e. at higher amounts of strain), compared to when the initial parameters would be used (Fig. 7.6). This shift in stress-strain behaviour with decreasing cross-link densities was measured also in collagenous tissue such as the pericardium [8, 21]. Reducing constitutive parameters k_1 and k_2 by 40%, resulted in a model-predicted area compliance increase from 0.15 mm² mmHg⁻¹ to 0.21 mm² mmHg⁻¹ (Fig. 7.7). This observed 40% increase in area compliance is in agreement with *in vitro* measurements performed in rat carotid arteries, following AGE-breaker treatment [48]. Furthermore, collagen load bearing is reduced, with the load transferred to elastin instead (Fig. 7.7). The median reduction of collagen load bearing was 1%, 2%, and 6% at diastolic, mean and systolic blood pressures (Fig. 7.5 and 7.6). However, the reduction in collagen load bearing was exceeded by the initial spread in collagen load bearing (Fig. 7.5). This is illustrated by the reduction in collagen load bearing at systolic blood pressure (6%, respectively, Fig.

7.6), which is much smaller compared to the 25th to 75th percentile confidence interval ranging between 12.7% and 24.0%, respectively (Fig. 7.6). In other words, measurement of the benefit of a cross-link breaker on arterial compliance may be easily concealed by uncertainties in the estimation of the effects, given the impact of noise on model output.

7.5.5 Limitations

Unfortunately, no actual distensibility measurements, acquired before and during AGE-breaker treatment were available in this study. Consequently, we had to resort to simulating AGE-breaker treatment using our constitutive model. This was achieved by changing constitutive parameters governing collagen behaviour, reproducing results from an earlier AGE-breaker intervention study [48].

The one-layered Holzapfel-Gasser-Ogden model we used – neglecting active smooth muscle response and containing only three parameters to characterise elastin and collagen behaviour – was chosen as a pragmatic simplification of the actual arterial biomechanical behaviour. Furthermore, our model neglects the dispersion of collagen fibre orientation in the adventitia [10]. We are aware that more elaborate models exist describing the influence of collagen cross-links on the stress-strain behaviour of an artery more directly. For example, in the work of Sáez et al. [30], a cross-linking degree parameter was introduced which includes cross-links behaviour between the main collagen fibres. However, using such a model requires estimating one extra model parameter. To ensure unique parameter values, this would require more clinical data to be measured, which might not be possible in *in vivo* situations. Of note, parameter values in the current study were highly similar, indicated by the fact that the best-fit constitutive parameter values – for each of the 10 random starting points – were highly similar.

In our model, not all combinations of c_{elast} , k_1 , and k_2 yield physiological behaviour. However, the adjustment (fitting) of these parameters ensures that eventually their combination does yield physiological behaviour. The parameter c_{elast} can be physiologically interpreted as the stiffness of the arterial elastin. All fitted values for this parameter ranged from 35 to 55 kPa, which corresponds to previous literature [35]. For k_1 and k_2 , no separate interpretation can be made in terms of physiology. Nevertheless, the fitted combinations of k_1 and k_2 yielded physiologically realistic mechanical behaviour which, given that the elastin model was plausibly parametrised, corresponds to realistic collagen behaviour.

The global variance-based sensitivity analysis method used, distinguishes from more commonly used local methods by taking into account the entire distribution of measured variables, being model free, and assessing interaction between measured variables [5, 29, 40]. However, it assumes on the one hand statistical independence between measured variables and on the other hand that variance is an adequate metric for model uncertainty. The latter assumption becomes questionable for skewed distributions of parameters, i.e. as present in the distributions of parameters k_1 and L_{coll} at P_d and P_m , respectively (Fig. 7.5 and 7.6). A solution to this problem could be to use moment-independent sensitivity methods instead

[5]. To this end, Borgonovo [4] evaluated an alternative sensitivity metric that, instead of being computed using the variance of the model uncertainty distribution, considers this distribution as a whole. In their paper, it was concluded that sensitivity indices of both methods 1) show discrepancies between influential measured variables, but 2) agree in distinguishing non-influential from influential measured variables [4]. Based on these findings, we believe that utilising the variance-based sensitivity analysis as proposed by Quicken et al. [29] in this study is justified.

7.5.6 Conclusion

This study shows that *in vivo* assessment of arterial wall mechanics using a constitutive model is hampered by large model uncertainty. We quantified model uncertainty in constitutive parameters (i.e. c_{elast} , k_1 , and k_2 , respectively), and collagen load bearing parameters, at various blood pressures (L_{coll}). Our simulation of vascular drug therapy suggested a reduction of collagen load bearing of 6-percentage points, at systolic blood pressure. This reduction is 3 to 4 times lower compared to its uncertainty. Therefore, model output uncertainty could conceal potential effects of vascular drugs. Sensitivity analysis revealed that estimation of mechanical characteristics would benefit most from increasing the precision of measurements of arterial diameter, distension, and wall thickness. Whereas the potential for improving the precision of e.g. a single ultrasound measure is practically limited, the effective precision of ultrasound measurements could be improved by increasing the number of repeated measurements.

7.A1 Appendix: Constitutive model

7.A1.1 Constitutive relations

Under the assumption that 1) elastin and collagen act in parallel in terms of mechanical load-bearing; 2) the vessel wall is incompressible, and 3) deformation occurs only along the principal axes, the constituent-specific strain energy functions (Eq. 7.1 and 7.2) were cast into a relation describing local Cauchy stress:

$$\sigma_n = -P_h + \lambda_n \frac{\partial W_{\text{elast}}}{\partial \lambda_n} + \lambda_n \frac{\partial W_{\text{coll}}}{\partial \lambda_n}, \quad (7.A1)$$

The subscript n is rr for the radial direction, $\theta\theta$ for the circumferential direction and zz for the axial direction. This results in the following expressions for σ_{rr} , $\sigma_{\theta\theta}$ and σ_{zz} :

$$\sigma_{rr} = -P_h + 2\lambda_{rr}^2 c_{\text{elast}}, \quad (7.A2)$$

$$\sigma_{\theta\theta} = -P_h + 2\lambda_{\theta\theta}^2 c_{\text{elast}} + 4k_1 \lambda_{\theta\theta}^2 (\lambda_{\text{fibre}}^2 - 1) \cos^2(\beta_0) \left(\exp \left[k_2 (\lambda_{\text{fibre}}^2 - 1)^2 \right] \right), \text{ and} \quad (7.A3)$$

$$\sigma_{zz} = -P_h + 2\lambda_{zz}^2 c_{\text{elast}} + 4k_1 \lambda_{zz}^2 (\lambda_{\text{fibre}}^2 - 1) \sin^2(\beta_0) \left(\exp \left[k_2 (\lambda_{\text{fibre}}^2 - 1)^2 \right] \right), \quad (7.A4)$$

with P_h the local hydrostatic pressure within the wall, λ_{fibre} the fibre stretch given by $\lambda_{\text{fibre}} = \sqrt{\cos^2(\beta_0) \lambda_{\theta\theta}^2 + \sin^2(\beta_0) \lambda_{zz}^2}$, β_0 the fibre helix angle, c_{elast} the constitutive (stiffness) parameter of elastin, and k_1 and k_2 stiffness parameters of collagen, respectively.

7.A1.2 Constitutive framework

We distinguished between the unstressed and stressed states of an artery (Fig. 7.2). Under the assumption of an incompressible wall tissue, a mapping of coordinates (r, θ, z) of the deformed, stressed configuration to coordinates (R, Θ, Z) of the unstressed configuration is given by:

$$r(R) = \sqrt{r_o^2 - \frac{R_o^2 - R^2}{\lambda_{zz} k_\alpha}}, \quad \theta = k_\alpha \Theta, \quad \text{and} \quad z = \frac{l}{L} Z, \quad (7.A5)$$

where R_o and r_o are the outer radii of respectively the unstressed and stressed configuration. The parameter k_α is defined as $k_\alpha = \frac{2\pi}{2\pi - \alpha}$, with α the opening angle (Fig. 7.2). L and l are vessel length of the unstressed and stressed configuration defining the initial pre-stretch of an artery λ_{zz} . The principal stretch ratios

$(\lambda_{rr}, \lambda_{\theta\theta}, \lambda_{zz})$ with respect to the unstressed configuration are:

$$\lambda_{rr} = \frac{R}{rk_\alpha\lambda_{zz}}, \quad \lambda_{\theta\theta} = \frac{k_\alpha r}{R}, \quad \text{and} \quad \lambda_{zz} = \frac{l}{L}. \quad (7.A6)$$

Inner and outer radii (r_i and r_o , respectively) in the stressed configuration can be written as follows:

$$r_i = \frac{\lambda_{\theta\theta} R_i}{k_\alpha} \quad \text{and} \quad r_o = \sqrt{\frac{A_w}{\pi} + r_i^2}, \quad (7.A7)$$

where A_w is the cross-sectional wall area in the stressed configuration (Fig. 7.2). In practice, A_w can be determined by measuring IMT and vessel diameter using ultrasonography [12]. We furthermore assumed $\lambda_{zz} = 1.20$, $\alpha = 100^\circ$, and $\beta_0 = 35.3^\circ$.

7.A1.3 Balance equations

Conservation of momentum is given by

$$\nabla \cdot \boldsymbol{\sigma} = \mathbf{0}, \quad (7.A8)$$

with ∇ the spatial gradient operator. Assuming axisymmetry and neglecting torsion, acceleration forces, body forces and axial extension, Eq. 7.A8 reduces to

$$\frac{\partial \sigma_{rr}}{\partial r} + \frac{\sigma_{rr} - \sigma_{\theta\theta}}{r} = 0. \quad (7.A9)$$

Applying the boundary conditions $\sigma_{rr}(r_i) = -P$ and $\sigma_{rr}(r_o) = 0$, the expression for lumen pressure (P) is given by

$$P = \int_{r_i}^{r_o} \frac{\sigma_{\theta\theta} - \sigma_{rr}}{r} dr. \quad (7.A10)$$

Reduced axial force is given by

$$F_z = \pi \int_{r_i}^{r_o} (2\sigma_{zz} - \sigma_{rr} - \sigma_{\theta\theta}) r dr. \quad (7.A11)$$

7.A1.4 Calculating collagen load bearing parameters

We calculated collagen load bearing (L_{coll}) at three blood pressure levels; diastolic, mean and systolic blood pressure (i.e. P_d , P_m , and P_s , respectively). Mean blood pressure (P_m) was calculated as $\frac{1}{3}P_s + \frac{2}{3}P_d$. Using Eq. 7.A2, the expression for L_{coll} is given by

$$L_{\text{coll}} = \int_{r_i}^{r_o} \frac{\tau_{\theta\theta,\text{coll}}}{\sigma_{\theta\theta} - \sigma_{rr}} dr \Big|_{P \in \{P_d, P_m, P_s\}} \cdot 100\%, \quad (7.A12)$$

with $\tau_{\theta\theta,\text{coll}}$ the circumferential stress borne by collagen, given by

$$\tau_{\theta\theta,\text{coll}} = \lambda_{\theta\theta} \frac{\partial W_{\text{coll}}}{\partial \lambda_{\theta\theta}}. \quad (7.A13)$$

8 General discussion

8.1 Executive summary

IN this thesis, we focussed on developing a computational modelling platform to assess heart-vessel interaction in humans.

We first performed a meta-analysis of clinical studies to explore a conceptual chain-of-events describing how increases in arterial stiffness lead to increases in systolic blood pressure with consequent left ventricular mass increases. Based on the findings as well as the limitations drawn from our meta-analysis, we then turned our attention to developing computational models and applying them to specific research questions. We developed a computational modelling platform describing the heart and vasculature, consisting on the one hand of a well characterised and validated whole-heart model, and on the other hand a newly developed vascular module describing wave transmission in blood vessels. This platform was subsequently used to assess the validity of *augmentation index*, a metric that is hypothesised to capture the deleterious effect of increased wave reflection, and earlier arrival of wave reflections on left ventricular (LV) work.

Parallel to using computational models for hypothesis-testing, we were interested in using our platforms for patient-specific applications. A caveat of patient-specific modelling is missing data. To benefit patient-specific modelling, we evaluated the role of incorporating physical-physiological adaptation rules into models to reduce the amount of clinical data needed to render these models patient-specific.

Following model development and assessment steps, we employed models in two use-cases concerning patient-specific modelling: i) characterising LV (diastolic-) function, which is highly relevant in heart failure with preserved ejection fraction (HFpEF) and ii) constitutive interpretation of arterial stiffness measurement, which is key to treatment monitoring.

8.2 Left ventricular mass, arterial stiffness and systolic blood pressure: Exploring the ‘Bermuda Triangle’

As a first step, we performed a meta-analysis to assess clinical evidence describing changes in indices of cardiac- and vascular structure and function following intervention, i.e. conventional antihypertensive treatment, bariatric surgery or lifestyle interventions. Pooled analysis of clinical data suggested a significant association between treatment-induced changes in arterial stiffness (assessed by pulse wave velocity (PWV)) on changes in LV mass (assessed by LV mass index (LVMI)). This association was characterised by a 6.9 g m^{-2} decrease in LVMI per 1 m s^{-1} decrease in PWV (**Chapter 2**).

Haider et al. [23] established that in subjects with LV hypertrophy (LVH) an LV mass increase of 50 g m^{-1} (i.e. LV mass indexed by body height) increases the relative risk of cardiovascular disease by approximately two-fold. Studies included

in our review reported PWV changes of approximately 1 to 3 m s^{-1} , whereas LVMI changes were approximately to 2 to 35 g m^{-2} (**Chapter 2**). Our findings thus corroborate that arterial stiffness may be a major player in the above described chain-of-events leading to LV hypertrophy.

In the proposed chain-of-events, it is expected that systolic blood pressure is important as well, because increased arterial stiffness has been described as a cause and consequence of increased systolic blood pressure [12, 30, 56]. Furthermore, increased LV mass may result from independent mechanisms including increased arterial stiffness (e.g. through earlier arrival of pulse wave reflections) as well as increased systolic blood pressure (e.g. through decreased aortic compliance) [8, 24, 42].

Unfortunately, we were unable to uncover sequential relations in this chain using our data extracted from clinical intervention studies. The editorial commentary on our review article used the term ‘Bermuda Triangle’ [59] as analogy to express the obscure mutual relations between arterial stiffness, systolic blood pressure, and LV mass. Interestingly, the authors [59] do justice to their analogy by glossing over the essential difference between diastolic blood pressure and systolic blood pressure. Mechanistically, systolic (i.e. ‘peak’) blood pressure determines peak wall stress and, therefore, is a known trigger for LV hypertrophy [19, 22, 51].

Based on our findings from **Chapter 2**, four key issues related to the interpretation of corresponding clinical data and studies may be identified:

- First, the number of follow-up visits throughout intervention was insufficient to infer sequential relations between LV mass and the various haemodynamic indices reported. Meta-analyses of clinical studies appear unsuited to establish causality [1].
- Second, not all data we hoped to find was reported: studies that related left ventricular diastolic function to (changes) in arterial stiffness were scarce.
- Third, data on arterial stiffness changes were limited to reporting functional indices, (e.g. distensibility or pulse wave velocity), and did not consider constitutive/structural properties.
- Fourth, the clinical characterisation of e.g. LV mass and PWV contains measurement noise, which influences the associations found.

8.3 Applications

In this section, we place the findings from our model application studies in a broader perspective. We structure this discussion on the applications as follows: 1) cardiac, 2) vascular, and 3) heart-vessel interaction applications. Future research directions are discussed for each category separately.

8.3.1 Model-based estimation of left ventricular diastolic function indices: Towards non-invasive cardiac catheterisation

We developed a non-invasive computational approach to obtain markers of LV diastolic abnormalities consisting of the metrics LV end-diastolic pressure (p_{ed}) and compliance (C_{ed}) (**Chapter 6**). We tested our model-estimations against data obtained by means of LV pressure-conductance catheterisation, and found reasonable agreement between model and measurement.

The patient population studied in **Chapter 6** ($n=39$) was homogeneous, containing too few patients with HFpEF according to current guidelines [43]. Therefore, it was not possible to examine whether and how p_{ed} and C_{ed} differ between HFpEF and control subjects, nor could we compare our model estimates against common echocardiographic indices, such as E/e' , that are currently being used to distinguish between normal and elevated p_{ed} [43]. Exploitation of an existing case-control study including echocardiography and blood pressure measurements, such as the Queen of Hearts study [11], would help in judging the 'face value' of model-based p_{ed} and C_{ed} .

As a next step, a randomised controlled trial (RCT) is needed to prove the added value of p_{ed} and C_{ed} in classifying HFpEF or diastolic dysfunction. Previously, Zonnebeld et al. [64] proposed an RCT design to assess the added value of computational model predictions to optimise vascular access surgery in haemodialysis patients. Their study design consisted of routine, and routine complemented with model-prediction arms. Such a design would be realistic to test our approach.

Further development may include considering measurements of both baseline and Valsalva in our model-fitting scheme. Such approach, effectively doubling the amount of data available for model-fitting could improve model-estimations. Regarding modelling aspects herein, integration of this data requires mimicking Valsalva circumstances in CircAdapt. Unpublished numerical work, in which we were engaged previously, indicated feasibility of simulating Valsalva using our CircAdapt model. Simulated LV pressure and volume signals during Valsalva showed typical responses as compared to measured ones. Integration of haemodynamic measurements acquired during Valsalva in our model-based approach, demands strict adherence to a standardised Valsalva protocol (e.g. in terms of intra-oral pressure and straining duration, **Chapter 6**).

8.3.2 Expanded view of vascular haemodynamics and wall mechanics: Towards *in silico* assessment of the performance of novel drug therapies

Vascular haemodynamics and wall mechanics were studied using models with varying levels of (anatomical) detail. Our vascular module (**Chapter 3**) describes pressure-flow wave transmission in extensive arterial and venous networks. Although our model's numerical implementation differs from those used in the

existing wave propagation modelling literature [6, 34, 41, 50], we found good agreement between our model's pressure and flow waveforms and those of a previously validated pulse wave propagation model [6, 34], i.e. relative errors in pressure and flow waveforms $\leq 5.6\%$.

The constitutive model we used (**Chapter 7**), assuming a single-layered mixture of elastin and collagen, provides three-dimensional stresses and strains of these microstructural wall components. Constitutive parameter estimation using our model was feasible, and estimated constitutive parameters were in agreement with those reported in literature [53].

We introduced a vascular adaptation model (**Chapter 5**) to facilitate personalisation of vascular networks for use in patient-specific modelling applications. Our vascular adaptation model adequately predicted arterial radius and wall thickness as concluded from our test-case in which we compared model-estimated arterial geometries with those measured using ultrasound and MRI in healthy young volunteers (bias \pm 2SD of difference equal to 0.2 ± 2.6 mm, and -140 ± 557 μ m, respectively).

Observed changes in aortic (systolic) blood pressure with ageing are attributed to changes in aortic compliance or wave reflections [5, 40, 44]. Models describing vascular wave transmission could be used to apportion LV mass changes to changes in compliance or wave reflections. Previous studies simulated arterial haemodynamics in virtual patient cohorts, e.g. to study changes in the aortic pressure pulse during ageing, or to assess the validity of metrics deemed a proxy for arterial stiffness [46, 60, 61]. To create large numbers of virtual haemodynamic models that represent virtual patients, perturbations of vascular segment geometries were imposed based on population-average values [60, 61]. To facilitate research using virtual patient cohorts, the basic concept of our vascular adaptation model may aid physiological parametrisation of subject-specific vascular trees.

In our analysis testing the applicability of incorporating vascular adaptation in haemodynamic models (**Chapter 3**), discrepancies between model-estimated geometries and measured data may result from limitations in the model of vascular adaptation. Our model is formulated based on the hypothesis of a homeostatic feedback mechanism that triggers changes in vascular geometry [31, 37, 39, 63]. Based on experimental data, we proposed a vascular adaptation model in which we assumed complete normalisation of wall (shear) stresses to homeostatic values. It has been suggested that the assumption of wall shear stress normalisation may become invalid for specific patients or patient groups in which the adaptive capacity of blood vessels is compromised (e.g. in diabetes or end-stage renal disease [7, 10, 15]). As consequence, applying the concept of adaptation may be inapplicable in some cases. One way to deal with issues of applicability is to estimate the adaptive capacity of blood vessels on beforehand, for instance using existing non-invasive tests such as flow-mediated dilation (FMD), because FMD-scores have been shown in arterio-venous fistula creation studies to correlate with blood vessels' ability to remodel [3, 45].

In our vascular module, we used a mathematical relation (i.e. referred to as

‘tube law’) for solving for pressures and flows, that relates blood pressure and vessel area. This tube law mimics the elastic behaviour of the vascular wall as observed in experiments by modelling an incremental increase in vessel stiffness for an incremental increase in pressure (Fig. 8.1). For the physiological pressure range (approximately 50 to 180 mmHg, Fig. 8.1), choosing appropriate stiffness values (i.e. k -values, Fig. 8.1) for the tube law resulted in excellent agreement with pressure-radius experiments of human arteries. For pressure loads below 50 mmHg or above 180 mmHg, deviations between tube law (coloured curves) and experiment (black curves) are observed, which limits our tube law’s application to (sub-)physiological pressure ranges.

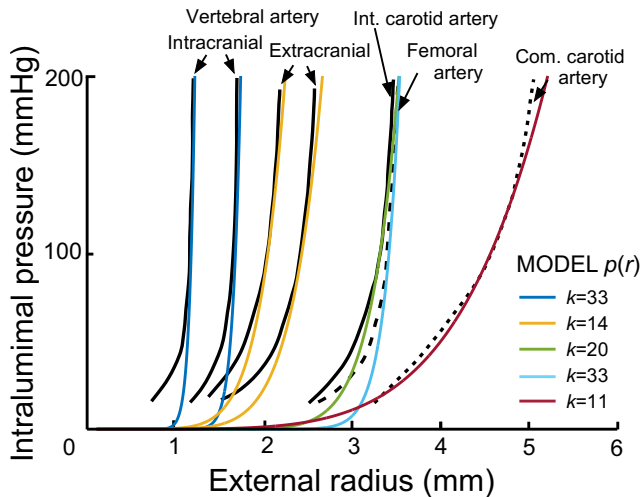

Figure 8.1: Estimated pressure-radius curves using tube law (coloured curves) drawn over previously measured data of human arteries (black solid, dashed and dotted curves, respectively). Measured data were taken from *ex vivo* inflation experiments on human arteries [25].

Ex vivo inflation experiments of human and animal arteries over a wide pressure range (e.g. 0 to 200 mmHg) clearly indicated S-shaped (‘sigmoidal’) pressure-area relations [18, 36]. Such behaviour cannot be captured using our tube law (Fig. 8.1), but requires more elaborate mathematical functions [36], or a constitutive model description of a blood vessel’s behaviour [27].

For some applications, consideration of microstructural properties of the arterial wall in wave transmission models may be necessary, because the vessel wall microstructure influences pressure-flow waves propagation [2].

For example, much research has been conducted in the field of drug development to reverse ageing-related stiffening of arteries [16, 33, 58]. Drugs that were developed include arterial wall collagen cross-link breakers (e.g. alagebrium chloride) that aim to reduce arterial stiffness by cleaving cross-links, thereby reducing

vessel wall material stiffness. These drugs showed beneficial effects on compliance in rats [62]. Since cross-link breakers reportedly affect large artery stiffness, that of small arteries, but also cardiac mass [17, 55, 62] the question, yet again, arises which local compliance or distributed effects of wave propagation play in their reported beneficial effect.

Based on the work performed in the thesis (**Chapters 3, 5 and 7**), creating an interface of on the one hand personalised constituent-based models of arterial wall mechanics and on the other hand our vascular module may serve as starting point for studies assessing effectivity of such novel vascular drugs.

Because significant uncertainty in model-estimates of collagen load-bearing was found, primarily due to measurement error in ultrasound data (**Chapter 7**), we speculated on methods to improve estimation of model predictions [54]. Holtackers et al. [28], demonstrated that local carotid artery distensibility significantly changed when young healthy volunteers were measured under two different (standardised) head positions. This finding may be exploited to effectively double the amount of mechanical information that can be employed for model fitting, by performing measurements at two head positions. Incorporating measurements, acquired at two axial stretch levels (*in vivo* biaxial testing), could thus in future serve as a utility to reduce the uncertainty in constitutive property estimation [49].

8.3.3 Simulating heart-vessel interaction: Blood pressure characteristics, left ventricular hypertrophy, and left ventricular diastolic function

We extended the existing CircAdapt whole-heart model [57] with a vascular module and investigated heart-vessel interaction by calculating on the one hand wave intensity tracings, and on the other hand augmentation index (Aix) (**Chapters 3 and 4**). We found that wave intensity tracings, as derived from our model simulations of local pressure and flow velocity corresponded to clinical measurements [29]. As such, we concluded that our model is suited for studying mechanical linkage between cardiac mechanics and vascular haemodynamics at the level of wave reflections. The advantage of a model of heart-vessel interaction is that it can provide noise-free and controllable study conditions. These characteristics are desirable when performing mechanistic studies, because measurement noise limits determination of wave transit delays, which are about 1 to 20 milliseconds [26, 48].

Patient-studies showed that concentric left ventricular remodelling and LVH are common findings in hypertension [13, 20]. Therefore, consideration of LV afterload in relation to LV structure and function (i.e. heart-vessel interaction) appears to be important for research on treating LVH. Whereas findings from **Chapter 2** offer insight in correlates of left ventricular hypertrophy, it does not elucidate the mechanism leading to left ventricular hypertrophy.

We justified using our circulatory model for heart-vessel interaction hypothesis

testing, based on successful model validation and illustration of its applicability in clinically relevant use-cases (**Chapters 3 and 4**). In a preliminary study, we expanded the circulatory model with a model describing cardiac adaptation [4]. We then simulated the effect of stiffer arteries in our model. Computer simulations of haemodynamics were obtained under a reference normotensive (REF) state and a chronic hypertensive (HYP). Comparing left ventricular mass and pulse wave velocity before and after adaptation to a systemic hypertensive situation, we found a REF–HYP change (Δ) in LVMI of -23 g m^{-2} , as well as a difference in PWV of -2.2 m s^{-1} . Interestingly, the model-predicted increase of LV mass in hypertension finding fits well with the association between Δ LVMI and Δ PWV as extracted from clinical intervention studies (Fig. 8.2).

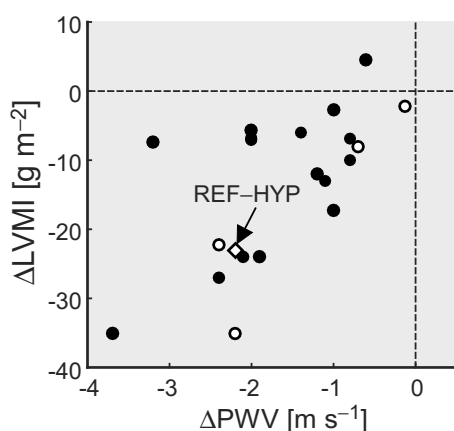

Figure 8.2: Change in pulse wave velocity (Δ PWV) and left ventricular mass index (Δ LVMI) values in clinical studies (circles) and simulation (diamond). Closed circles: antihypertensive drug therapy studies. Open circles: other types of intervention studies, e.g. bariatric surgery. Diamond: Simulated relation between Δ PWV and Δ LVMI obtained by subtraction of systemic hypertension simulation (HYP) values from the reference simulation (REF) values.

Future modelling work should aim for mechanistic hypothesis-testing of the effect of earlier arrival of pulse wave reflections (e.g. using wave intensity analysis) or evaluation of interactive metrics (e.g. A1x) on LV relaxation. Directly related to this aim is the role of wave reflections in diastolic dysfunction [9, 21, 47, 52]. Studies suggested that earlier arrival of wave reflection during the ejection phase would require the cardiac tissue to generate more tension to overcome the increased afterload [8, 21]. Increased tension in the LV sarcomeres is known to affect muscle relaxation, which will impair LV filling (i.e. diastolic function). Research on the role of arterial load aspects in the development of LV diastolic dysfunction is clinically relevant, because LV diastolic dysfunction is a precursor of heart failure, specifically HFpEF [32, 35, 38].

Before we can *in silico* investigate LV relaxation and the role of arterial load

aspects, as described above, we first need to address a limitation of our current model. The physiological validity of the whole-heart model [57] that was used in our full circulatory model was limited by the sarcomere contraction model, containing only a phenomenological description of cardiac muscle contraction and relaxation [57]. Recently, the MechChem sarcomere model was proposed, describing mechanical-chemical interactions in cardiac sarcomeres [14]. The MechChem model does take into consideration tension-dependent relaxation, as governed by intracellular calcium concentration [14]. The MechChem model is currently being interfaced to the existing CircAdapt heart modules, which paves the way for studies investigating e.g. the influence of arterial wave reflections on LV relaxation.

8.4 Multi-scale modelling perspective and clinical relevance

In Section 8.3, we have discussed the model developments and applications that have been presented, distinguishing between cardiac, vascular and interaction aspects. Together, the model-based approaches may be combined into a multi-scale modelling platform, to study cardiovascular (patho-)physiology from e.g. changes in wall-constituent properties of blood vessels to their impact on the contractile function of cardiac muscle (Fig. 8.3).

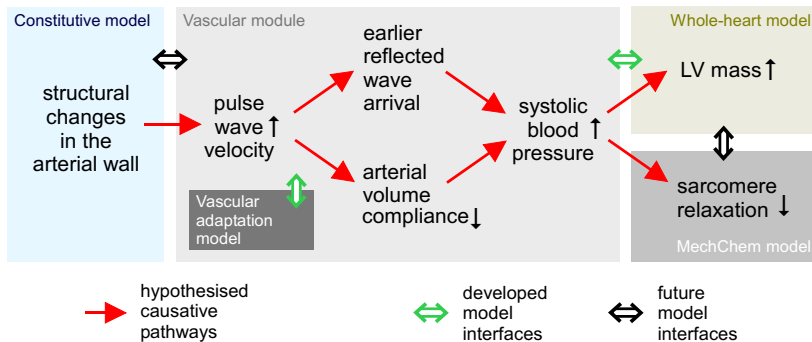

Figure 8.3: Status of development of a multi-scale modelling platform, suited to investigate *in silico* the indicated hypothesised causative pathways.

The hypothesised causative pathways as indicated in Fig. 8.3 are clinically relevant, because the general population becomes increasingly older. As a result, more patients will likely present with age-related arteriosclerosis (i.e. stiffened arteries) and LV remodelling and/or diastolic dysfunction, affecting medical treatment decisions. Therefore, increased mechanistic insight into cardio-vascular ageing, including well-tested indices that capture functional impairment beyond that expected to come with age, is needed to achieve personalised and sustainable health management.

8.5 General conclusions

In this thesis, we developed, characterised and assessed computational models consisting of networks of applied physical-physiological relations. The models have shown to be helpful in understanding measurable haemodynamic measures as well as enabling estimation of non-measurable properties. As such we have contributed to the integrative interpretation of data which nowadays is at the clinician's disposal. Furthermore, the presented model-components may be combined to form a multi-scale platform to further investigate and characterise pathological heart-vessel interaction in the context of an ageing general population. Ultimately, the developing model platform may serve as a 'digital twin' of the cardiovascular system of a human, for example to assess cardiac effects of vascular drugs.

Summary

OUR cardiovascular system enables transportation of dissolved gases, hormones and other substances to support metabolism, growth, and repair. The system consists of an actively contracting heart, which ejects blood into conducting pulmonary and systemic blood vessels. Usually, the heart's left ventricle and the large arteries are coupled in such a way that the volume and rate of the ejected blood match the impedance of the receiving arteries. This coupling is influenced by changes in cardiac and arterial structure and function, which are interrelated through haemodynamic interactions. Therefore, measurable haemodynamic features are of (clinical-epidemiological) interest as markers of cardiovascular health. However, because such markers reflect changes 'in-between' the interacting heart and arteries, their interpretation may be tricky.

We hypothesised that an integrative description of cardiac and vascular physiology may be better suited to mechanistically explain the interrelationships between cardiac and vascular structure and function. The development and application of a computational modelling platform to assess heart-vessel interaction is the subject of this thesis.

As a first step in the development of our computational modelling platform, we performed a meta-analysis of clinical literature on heart-vessel interaction through treatment-induced changes in arterial properties on the one hand and left ventricular (LV) structure on the other hand (**Chapter 2**). Through meta-analysis, we found that a decrease in arterial stiffness is associated with a reduction in LV mass. Unfortunately, it was not possible to infer any causal relationships between arterial stiffness, blood pressure and LV structure.

To infer causality in heart-vessel interaction, we turned our attention to computational models describing circulatory physiology (**Chapter 3**) and extended the existing CircAdapt model, a well-characterised whole-heart model, with a new transmission line (TL) model that also allows for an accurate examination of wave transmission and reflections in blood vessels. The governing equations of the TL model originate from those derived in the 1880s, describing signal transduction along telegraph wires. We first verified the numerical framework of the TL model by benchmarking against a previously validated pulse wave propagation model. The results showed good agreement regarding pressure and flow waveforms (i.e. relative errors $\leq 2.9\%$ for pressure, and $\leq 5.6\%$ for flow). Subsequently, the performance of the combined CircAdapt-TL model was tested in a use-case, simulating carotid artery wave intensity profiles during normotensive as well as hypertensive conditions. The results of this use-case indicate that the domain of applicability of CircAdapt is extended for detailed studies on heart-vessel interaction if the TL model is included.

In **Chapter 4**, we applied the CircAdapt-TL model to scrutinise the validity of the augmentation index (AIx) as a vascular index of increased pulse wave reflections in a stiffer arterial tree. The AIx quantifies a deemed augmentation (i.e. as signalled by an inflection point) of a pressure waveform relative to its peak-to-peak amplitude. In population studies, the AIx increased with age, which is usually interpreted to result from an increase in pulse wave reflections with the age-related stiffening of arteries. We hypothesised that cardiac properties are likely to influence pressure augmentation as well because they too determine the time-course of the arterial pressure waveform. We simulated the isolated and combined influences of myocardial shortening velocity and arterial stiffness on AIx and indeed found that the AIx may depend as much on cardiac as on vascular properties, which goes against the common interpretation of the index.

In the above, our use of models focussed on evaluating hypotheses. A more advanced application would be to predict patient-specific haemodynamic changes and features, which adds the challenge of model personalisation.

Chapter 5 is the first chapter concerning personalisation of computational models. In our previous simulation studies, we prescribed generic vessel geometries for the modelled arterial and veins. Source data describing these geometries came from a collection of independent literature sources. As such, different parts of the modelled vascular tree are based on data from different subjects, differing in age, sex, BMI and other characteristics. Models containing generic descriptions of the human vasculature often appear insufficient for patient-specific predictions. Unfortunately, complete characterisations of blood vessel geometries and properties are usually not available or even attainable in practice. **Chapter 5** presents an adaptation model to complement sparse data on arterial radius and wall thickness, utilising rules for the response to wall stress and shear stress. To test our approach, we acquired vascular MRI and ultrasound data sets of arterial wall thicknesses and radii of central and arm segments in ten healthy subjects. Comparison between adaptation model-predicted and measured geometries demonstrated small differences (bias \pm 2SD of difference equal to 0.2 \pm 2.6 mm for arterial radius, and -140 \pm 557 μ m for wall thickness, respectively). We believe that our methodology is suitable to complete sparse data sets in patient-specific applications.

The subsequent two chapters employed model-based approaches for the patient-specific characterisation of LV or arterial properties, respectively. In **Chapter 6**, we used the CircAdapt-TL model to non-invasively estimate LV end-diastolic pressure (p_{ed}) and compliance (C_{ed}) from routine measurements of brachial artery blood pressure and echocardiographic recordings. We found reasonable agreement between our non-invasive estimates of p_{ed} and C_{ed} and those measured by an invasive catheter.

To improve mechanistic interpretation of clinical arterial stiffness data, inverse modelling approaches may be used to estimate tissue properties from measured vessel geometric and dynamic elastic properties. In **Chapter 7**, we utilised a constitutive model of carotid artery mechanics, describing the stress-strain behaviours of arterial collagen and elastin. As a prerequisite, we performed extensive uncertainty quantification and sensitivity analysis to investigate how measurement

errors propagate into estimation errors. We were able to substantiate that the significant uncertainty with a single set of carotid artery ultrasound and pressure data points can be reduced by increasing the number of repeated acquisitions of cyclic diameter (i.e. distension) and of wall thickness (i.e. intima-media thickness).

This thesis concludes with a general discussion (**Chapter 8**), in which we provide an overall perspective of how the above model developments and personalisation approaches may be further integrated. We envision the role of our developing computational models to facilitate 1) detailed haemodynamic studies, 2) patient-specific estimation of non-measurable characteristics, and 3) *in silico* evaluation of disease progression and treatment scenarios.

Valorisation addendum

TO combat cardiovascular disease and enable patients at risk to age in a healthier way, roughly two strategies can be distinguished. The first strategy consists of the identification of the cellular mechanisms responsible for cardiovascular disease followed by the development of new drugs acting on these cellular mechanisms to halt or even regress the disease ('the biologist's approach'). The second strategy consists of the earlier detection of cardiac and vascular problems by developing diagnostic technologies that characterise the mechanical performance of the heart and vessels ('the engineer's approach').

This thesis advocates the use of computational models that embody human cardiovascular physiology to achieve better characterisation of heart failure and arterial stiffness mechanisms. Ideally, computational models are so realistic that they can be regarded as '**digital twins**' of actual patients. The path towards such a digital twin comprises of both model development steps (**Chapters 3 and 5**) as well as model corroboration steps (**Chapters 4, 6, and 7**), in which the utility of the model is put to the test. Although an ultra-realistic digital twin of human cardiovascular physiology is not available yet, we contribute substantially to the development of a digital twin. It is therefore of no surprise that the present thesis readily contains significant valorisation potential: First, valorisation of the knowledge obtained in this research may advance society and the academic field as primary target groups. The second valorisation aspect represents economic exploration by transferring knowledge into new products or services through business development.

Below, I provide a discussion on both valorisation aspects.

Target groups

Pathological changes to the heart and blood vessels impact local cardiac and vascular tissue properties and influence their function. In patients, this harmful process can progress silently for years but will eventually become apparent. Therefore, assessment of tissue properties can benefit timely diagnosis of pathologies precluding cardiovascular disease. However, clinically applicable measurements alone are often insufficient to assess tissue properties. The combination of mechanistic computational models with a well-selected set of clinical measurements may allow for estimation of tissue properties, using an inverse approach, in which the model is 'tuned' to the measurements. In this thesis, we showed that an inverse approach to routine data has real potential in detecting diastolic dysfunction, a precursor of heart failure (**Chapter 6**).

Currently, assessment of left ventricular filling pressure in patients relies on a clinical algorithm that is based on three echocardiographic indices. Such an algorithm can discriminate between (four) grades of diastolic dysfunction (i.e. with increasing severity; no-, grade I-, grade II- and grade III diastolic dysfunction) [1], each of them reflecting a category of filling pressure, ranging from low to elevated [2]. However, in the absence of one echocardiographic index and conflicting results of the remaining two indices, the clinical algorithm contains a grey zone in which filling pressure is classified as indeterminate. The model-based method introduced in **Chapter 6**, –providing actual estimations of filling pressure and diastolic compliance– could be used alongside or concurrently with the existing clinical algorithm. Such methodology comes at hand when confronted with patients in which the clinical algorithm cannot determine filling pressure.

An inverse method may also be used for characterisation of vascular wall tissue. For this purpose, we did not use the circulatory computational model, but rather a more detailed model describing local arterial wall mechanics that incorporated distinct features of collagen and elastin. The method allows identification of the wall constituent that contributes the most to the increase in stiffness of a patient's arteries. As such, these models may be of use in the design of new vascular drugs (**Chapter 7**).

Parallel to providing personalised estimates, the developed computational models are useful for hypothesis testing. In **Chapter 4**, our model study challenges a widespread interpretive model in which augmentation index is deemed and promoted as an index for arterial properties. Already, an increasing number of human studies show that augmentation index might also be influenced by ventricular function and thus cannot serve as a distinct marker of arterial stiffness or wave reflection magnitude. Our study provided yet another important piece of evidence that the augmentation index does not solely reflect arterial stiffness.

While the research version of the circulatory computational model we used is implemented in a scientific programming environment (MATLAB, The Mathworks, Natick, USA), a stripped-down version of the model is also available on-line as a user-friendly 'CircAdapt simulator'. This simulator is actively used for teaching cardiovascular physiology in the (bio-)medical curricula at Maastricht University and many other universities. Currently, the simulator is capable of describing a catalogue of cardiac pathologies, including cardiogenic shock, pulmonary arterial hypertension, and valvular defects. Integration of the vascular module (**Chapter 3**) that models pressure and flow phenomena in the systemic arterial and venous circulations, further extends this catalogue. The present work paves the way for simulation-based education with even more (vascular) types of pathology. Examples of pathologies as well as their recommended clinical assessment methods include, e.g. 1) arterial stiffening; quantifiable using carotid-to-femoral pulse wave velocity, and 2) peripheral arterial disease; assessable using the brachial-ankle index, respectively.

Utilisation of knowledge for the development of products or businesses

First, the circulatory computational model is of interest to medical device and (health) technology companies. For example, Samsung and Apple have shown interest in developing wearables (e.g. smartwatches) to be used for continuous measurement of the arterial pulse waveform. Samsung's approach uses a smartwatch to measure the photoplethysmogram (PPG) at the location of the radial artery [3]. Specific features of the wrist-measured PPG waveform are hypothesised to be indicative of vascular conditions such as arteriosclerosis, but also of psychological conditions, including mental stress. Both arteriosclerosis and mental stress are known risk factors of cardiovascular disease [4]. Information from continuous monitoring of arteriosclerosis and mental stress could thus be used to identify patients at risk of cardiovascular disease. Computational models like ours are very well suited to (pre-)test and select sets of PPG features that are sensitive for (changes in) arterial and mental health.

Second, the developed methodologies for determining on the one hand left ventricular diastolic indices and on the other hand, arterial wall constituent properties are already well-suited to be integrated as separate cardiac- or vascular workflows in ultrasound machines. When selecting either of the workflows, the corresponding computational model should be initiated, for example as a third-party application, and the user should be guided to perform the measurements that are required to complete or augment the analysis. These computational model approaches to the interpretation of echocardiographic-, and blood pressure data are of interest to companies, such as Microlife Corporation, IMEC, Pie Medical Imaging, and Philips Medical Systems. Partnerships with these companies can be beneficial in two ways. First, third-party integration projects will generate revenue for the Department of Biomedical Engineering, which can be allocated to the hiring of staff or investments in computational resources. Second, partnerships could also include setting up new research and development projects, thereby providing opportunities to further develop our algorithms (e.g. using machine learning methods based on large clinical data sets).

Acknowledgments (Dankwoord)

Bon... U leest hier toch echt in mijn voltooide proefschrift. Het is een behoorlijke reis geweest. Een weg die ik zeker niet alleen heb afgelegd. Ik ben iedereen dankbaar die op de een of andere manier heeft bijgedragen aan het voltooien van dit boekje. Maar nu terzake, want zonder deze tegeltjeswijsheid redden we het ook wel.

Allereerst wil ik mijn promotor en copromotors bedanken.

Beste **Tammo**, je bent een voortreffelijke leermeester geweest. Jouw aantekelijk enthousiasme en je directheid hebben ervoor gezorgd dat ik op de momenten waar het nodig was nog een versnelling hoger schakelde. Je oog voor detail (inclusief *lessons in vigilance*) en je snelle manier van commentaar geven zijn zowel het behalen van deadlines alsmede de kwaliteit van dit proefschrift ten goede gekomen. Tammo, bedankt voor het zijn van mijn promotor.

Beste **Koen**, je wekte mijn interesse voor het onderzoek rondom hart-vaat interactie en vaatwandmechanica. Ik wil je bedanken voor alle tijd die je in het voltooien van dit PhD-traject hebt gestoken en de kansen die je me hebt gegeven om me verder te kunnen ontwikkelen, bijvoorbeeld in het uitvoeren van onderwijstaken. Met plezier kijk ik nu terug op de momenten waarop je met relativerende, vaak filosofische woorden, een vastgelopen “ik” wist vlot te trekken. Mocht dat laatste met woorden niet lukken, dan lukte dat middels een partijtje squash wel.

Wouter, je kwam halverwege de rit mijn promotieteam versterken. Al ruim daarvoor konden we lange discussies voeren over Womersley profielen en gevoeligheidsanalyse. Jouw expertise op het gebied van patiënt-specifiek modelleren komt zeker terug in dit proefschrift. Wouter, bedankt!

Beste **prof. Brunner-La Rocca**, **prof. Dekker**, **prof. Duncker**, **prof. Mischi** en **dr. Rennenberg**, dank jullie wel voor jullie tijd om mijn proefschrift door te nemen en plaats te nemen in de beoordelingscie.

Bart, toen ik als stagiair in het BMT-lab kwam te zitten ben ik bij je in de leer mogen gaan. Wat mooi dat dit boekje twee gezamenlijke publicaties van ons bevat!

Beste **Theo**, ontzettend bedankt voor je wijze lessen en je scherpe pen. Zonder jouw werk aan het golfvoortplantingsmodel had dit boekje er heel anders uitgezien. **Joost**, als mede-Kleesj-alumnus kwam ik natuurlijk met de juiste papieren op het BMT-lab te zitten. Het is mooi om te zien hoe jij je CircAdapt-club steeds verder weet uit te bouwen. Bedankt dat ik ook (een klein beetje) deel van je club heb mogen uitmaken.

I would like to thank **prof. Alun Hughes** of UCL for our collaborations, amongst others, on the non-invasive pressure-volume loop project. The arterial haemodynamics conference in London which you co-organised was one of the most valuable

experiences I had in my PhD. The opportunity to not only present my work but also attend the lectures of the eminent scientists; profs. Westerhof, Parker, and O'Rourke is something I will never forget.

Beste **Bouke, Jos en Rob**, toen ik begin 2018 bij jullie aanklopte om te vragen of er (met redelijke urgentie) een vasculaire ultrageluid/MRI-data set vergaard kon worden waren jullie meteen aan boord. Dankzij jullie inzet hebben we in rap tempo de benodigde data bij elkaar verzameld, waardoor hoofdstuk 5 van dit boekje er uiteindelijk van gekomen is. Oja, en Rob, ik wil je ook nog bedanken voor je aandeel in alle ongein die we bij menig (studenten-)feestje hebben uitgehaald. Het gezegde "ik wou dat ik naar huis wou" was hierbij veelvuldig van toepassing.

Ik wil alle BMT-ers die voor zo'n prettige werksfeer zorgden bedanken. Beste **Ben, Erik, Letty, Mehrdad, Myrthe, Nick, Pamir en Raoul**, jullie zijn samen een superleuk clubje mensen! Natuurlijk wil ik **Kujtim en Tamara** als collega's van weleer maar bovenal studiemaatjes niet vergeten te bedanken. Beste **Claire**, dankzij jouw organisatietalent kon ik me haast volledig richten op het onderzoek. **Jeroen**, het was echt top om met je te kunnen praten over het ultrageluidverleden van de afdeling.

Beste **Ciprian, Kenny en Koen vdW**, veel succes met jullie carrières. Ik hoop dat jullie met plezier terugkijken op jullie stage, afstudeeropdracht of Erasmus project.

BM2Wielers, squashers en voetballers (**Alberto, Aurore, Frank B, Frank vR, Job, Niek en Tijmen**): Dank jullie wel voor alle sportieve momenten en gezelligheid.

Een hoogtepunt van de winter was de PhD ski-trip waarin we met goed (internationaal) gezelschap richting de Alpen trokken. I'd like to thank **Lauren, Margaux, Martijn, Peter, Radek**, and all the other nice people who joined these trips over the years. You guys made it really enjoyable. Whether it was tossing business cards on the ski slopes during the day, or throwing ski helmets across the bar at night, it was always a great laugh.

Een bijzonder dankjewel aan mijn paranimfen. Beste **Koen vK**, we kennen elkaar al ons hele leven. Wat mooi dat we, ondanks dat we elkaar soms tijden niet spreken, zulke goede vrienden zijn gebleven. Beste **Sjeng**, naast het zijn van mijn "go-to" collega vind ik het ook fantastisch om buiten het werk met je te praten over muziekinstrumenten, *underground* optredens en al het moois gemaakt vóór 1990.

Als laatste wil ik mijn familie bedanken. Lieve mama, papa en Lena, jullie waren zo belangrijk de afgelopen jaren.

About the author

Curriculum vitae

MAARTEN Heusinkveld was born on 28 March 1991 in Sittard, the Netherlands. From 2003 to 2009, he attended atheneum (pre-university education) at Trevianum Scholengroep in Sittard. He started his academic education in September 2009 at Eindhoven University of Technology (TU/e). During his undergraduate studies, Maarten performed a six-month internship at the Department of Biomedical Engineering, Maastricht University (UM). In Maastricht, he discovered that his principal interest lies in the interface between engineering and clinical research. After obtaining his Bachelor's degree in August 2012, he enrolled in the Master Medical Engineering (TU/e in collaboration with UM, 09-2012 to 03-2015). His Master's program included an international internship at the Laboratory of Biorheology and Medical Ultrasonics of the Centre de Recherche du CHUM in Montréal (08-2013 to 11-2013). In Canada, he worked in the lab of prof. dr. Guy Cloutier on vulnerable carotid plaque detection using vascular ultrasound strain analysis. Maarten returned to Maastricht for his Master's graduation project on computational modelling of heart-vessel interaction (supervised by dr. ir. Koen D. Reesink and dr. ir. Bart Spronck). In December 2014, Maarten was awarded a Kootstra Talent Fellowship from Maastricht University Medical Centre. This Fellowship enabled him to continue his graduation project as a PhD candidate at the Department of Biomedical Engineering (UM, 04-2015 to 04-2019). His PhD research was performed under the supervision of prof. dr. Tammo Delhaas, dr. ir. Koen D. Reesink and dr. ir. Wouter Huberts, and resulted in the present dissertation. As of May 2019, Maarten works as a product manager of cardiac ultrasound analysis software at Pie Medical Imaging.
