DOI 10.5073/jka.2018.463.113

Abstract

In this research, both Turkish diatomaceous earth from Central Anatolia and SilicoSec? was evaluated against *Tribolium confusum* Jacquelin du Val (Tenebrionidae: Coleoptera), *Rhyzopertha dominica* (F.) (Bostrychidae: Coleoptera) and *Sitophilus granarius* (L.) (Curculionidae: Coleoptera) adults. Different rates (0, 250, 500, 750, 1000, 1500 ve 2000 mg/kg wheat) of diatomaceous earth from both sample mixed with wheat were evaluated for 1, 2, 3 and 4 -weeks exposure period at 55% r.h. and 25 adult/vial insect density in ten replicates. Mortalities were determined at the end of exposure, whereas F1 adult production were determined at 8 weeks after mortality

observation. Mortalities and F1 adults of *T. confusum*, *R. dominica*, and *S. granarius* was significantly changed by the rates of diatomaceous earth. In untreated wheat mortality was less than 10% for three species. Mortalities at 2000 mg/kg wheat applications at the end of 4-week of exposure against *S. granaries* were found to be 95.6% and 98% for SilocoSec and local DE, respectively. For *R. dominica* adults, mortalities were recorded as 90% and 92.4% for SilocoSec and local DE, respectively. Additionally, mortality of *T. confusum* at 2000 mg/kg wheat was 100% for both DE samples. Results showed that local DE and SilocoSec are equally effective against three major stored grain pests.

The Effectiveness of Silicosec, Diatomaceous Earth Against the Lesser Grain Borer, *Rhyzopertha dominica* (L) (Coleoptera: Bostrichidae)

Abstract

In this research, the efficacy of SilicoSec was assessed in two sets of experiments. In the first set of experiment, the efficacy of SilicoSec at the rates of 0, 250, 500, 1000, 1500, 2000, 2500 and 3000 mg/kg wheat were evaluated against *Rhyzopertha dominica* adults at 55% r.h and 25°C. Insect counts were performed at the end of 3 week of exposure for the mortality. F1 progeny assessment were made after 8 weeks.

In the second set of experiment, the efficacy of SilicoSec against the same insect pest was evaluated at dose rates of 0, 250, 500, and 1000 mg/kg wheat for three months of exposure. In each experimental vial there were 10 adults per 250 g wheat with 10 replicates. Insect counts as dead and alive were made at the end of three months of exposure. For each vial, progeny production was determined as total insects excluding 10 adults introduced at the beginning of the experiment.

According to results, increase in dose rates increased the adult mortality, while it decreased the progeny production. As the exposure time increased, mortality rates were also increased. At the dose of 2000 mg/kg, 98.5% adult mortality and 10.55 adult progeny per vial were obtained.

For three months exposure, population development was inversely proportional to dose rates. According to results, increase in dose rates increased the adult mortality, while it decreased the progeny production. Population confinement was achieved at 1000 mg/kg dose rate of SilicoSec for three months of exposure.

Abstract

Most stored product insects are either beetles or moths. Moth pests are important hazards to the storage of a wide variety of products. Natural enemies are applied commercially against stored-product moths in Central Europe .So, the host-preference and parasitic capacity of four local *Trichogramma* spp.(*T. bourarachae*, *T. cordubensis*, *T. euproctidis* and *T. cacoeciae*) , towards four species of stored product moth eggs were investigated in laboratory experiments in order to select new candidate species for use in mass rearing and biological control against moths in storages. The results were compared with *T. evanescens,* the common wasp used commercially for biological control. The naturally occurring *Trichogramma* species were collected for the first time in Egypt from two representative olive growing areas in arid area (170 km south of Alexandria) and semi-arid area (60 km west Alexandria, near the coast). All these wasps were also bred from naturally parasitized host eggs during

favorable and even at unfavorable temperature conditions of June-August. The presence of warm weather wasp-strains may suggest the existence of well-adapted wasp species or strains which may be appropriate candidates for the control of stored product pests. The strains had also been collected in late winter and summer, thus demonstrating activity also during less favorable weather conditions, raising again the possibility of using these egg parasitoids as an inundative biological control agent in stored products.

Experiments were carried out by offering eggs of the Indianmeal moth *Plodia interpunctella* (Hübner), the Mediterranean flour moth *Ephestia kuehniella* Zeller, the warehouse moth *E. elutella* (Hübner), and the almond moth *Cadra cautella* (Walker) in choice and no-choice assays to a single female parasitoid. Two different choice experiments were used to certify the same conclusion in both methods. The bioassay for host-preference of *Trichogramma* spp. was carried out by offering a single female wasp the choice between equal numbers of host eggs on square cards "Petri dish tests "and /or strip cards "strip card tests". In both methods ,countingthe number of*Trichogramma* developing in the host eggs (parasitism) show the preference of the wasp for ovipositingand indicated theabilityof theparasitoid todevelopin theseeggs (i.e., host suitability).

In Petri dish tests, *E. kuehniella* was a highly accepted host species for *T. bourarachae*, *T. euproctidis*, and *T. cacoeciae* wasps while *E. elutella* and *C. cautella* eggs were more accepted by *T. evanescens* and *T. cordubensis,* respectively. In the strip card tests, *E .kuehniella* eggs were highly accepted by *T. bourarachae, T. cacociae* and *T. evanescens*. Eggs of *E. elutella* and *C. cautella* were more acceptable for *T. euproctidis* and*T. cordubensis,* respectively. Furthermore, a comparative study of the parasitic capacity of the *Trichogramma* spp. was carried out under 'no choice conditions' by exposing a freshly emerged single wasp to an unlimited number of host eggs. Significant differences were found among the parasitic capacity of the tested *Trichogramma* spp.: *T. bourarachae* showed a good parasitic potential against *S. cerealella* and *E. kuehniella; T. evanescens and T. cacoeciae* against *S. cerealella*; *T. cordubensis* against *S. cerealella* and *P. interpunctella* and *T. euproctidis* against *P. interpunctella.* However, dissection of host eggs with wasp-emergence holes showed that all tested wasps had a propensity to superparasitize the host eggs. Results of the present work suggest that the test wasps failed to discriminate parasitized hosts eggs among a large number of non-parasitized eggs, thus superparasitism occurred. Also, both of Petri dish and strip cards methods may underestimate the actual parasitization capacity due to self-superparasitism and mortality in black eggs that suffered desiccation during the early stages.

T. cordubensis, *T. euproctidis* and *T. bourarachae* showed promise for further investigation into selecting new biological control agents against some stored product lepidopterous pests.

Abstract

The Indian meal moth *Plodia interpunctella* became a major pest in bulk grain storage in Germany in recent years. Monitoring with adhesive pheromone-baited traps revealed a dependence of the number of generations of the moth from the temperature conditions in store, which themselves depend on insulation of the storage structure. The larval parasitoid *Habrobracon hebetor* was monitored with the help of cone traps placed in the grain. Baiting these traps with moth webbings significantly increased the number of female wasps trapped in 5 cm depth in wheat. Field trials showed both the pest and the beneficial can be monitored in stores, but more research is needed to develop a biological control strategy for *P. interpunctella*.

Keywords: stored products, bulk grain, Pyralidae, Trichogrammatidae, Braconidae

Introduction

Monitoring of pest populations is a basic prerequisite for biological control of stored-product pests (Zimmermann 2004), but difficult in large quantities of bulk grain. Within the frame of a project on the application of beneficials in long-term grain storage of grain, the phenology oft the Indian meal moth *Plodia interpunctella* (Hübner, 1813) (Lepidoptera, Pyralidae) was studied in different grain flat

stores. In German grain storage, large populations of the Indian meal moth were observed in the past six years resulting in significant damage and repeated control activities, consequently new control options were evaluated. The Indian meal moth is laying up to 400 egges close to the stored product. The emerging larvae typically develop through five instars in grain. A first signal of infestation are webbings on the grain surface produced by the larvae, produced presumably for protection. The last larval instar shows increased mobility in order to find a pupation site, and is consequently called wandering larva (Mohandass et al., 2007).

For the development of a biological control strategy a monitoring oft he beneficials is helpful. The larval parasitoid *Habrobracon hebetor* (Say, 1836) is naturally occuring in Central Europe, among its hosts are the Indian meal moth, the warehouse moth *Ephestia elutella* (Hübner, 1796) and the flour moth *E. kuehniella* Zeller, 1879 (Prozell & Schöller 2001).

In this study, the effectiveness of different monitoring techniques for parasitoids is described and the potential release of benefials within the frame of an integrated control concept discussed.

Materials and Methods

Monitoring of the Indian meal moth *P. interpunctella*: The phenology was studied in different flat grain stores. Various methods were applied, i.e. adhesive surfaces for larvae and adults, artificial pupation aid structures for larvae, and pheromone-baited traps for adults (Fig. 1).

Monitoring of the larval parasitoid *H. hebetor*: 20 kg grain, wheat or oats, respectively, were filled in a Hobbock. Per Hobbock, one cone trap was placed (Fig. 1). The cone trap has two components, a vial and a perforated lid. The lid is regularly vaulted, this is where the insect enter. The diameter of the holes in the lis is approximately 2 mm. Liquid teflon is added to the upper rim oft he vial, in order to hinder the insects to move back tot he lid. The cone trap was placed either on the grain surface, or 5 cm deep in the grain. The cone traps on the surface were carefully placed in one level with the grain surface. The cone traps were either unbaited, or baited with 5 g of webbings of the flour moth. Per Hobbock, 50 *H. hebetor* were released, i.e. 25 females and 25 males. The Hobbocks were closed and stored for 14 days at 20.8°C ± 0.95°C (mean ± SD) and 43.6% ± 5.5% RH (mean ± SD). After that period, the cone traps were removed and the traped *H. hebetor* counted. The sex ratio of *H. hebetor* was determined. Moreover, six cone traps each were placed in different grain flat stores (3000–4000 metric tons wheat) and removed ca. four weeks after parasitoid release, again the number of insects traped was counted.

The number of trapped insects were compared with the help of a t-test, in case data were not normally distributed, the Mann-Whitney Rank Sum Test was applied. Statistical analyses were performed using the software package SigmaStat 3.1.

Fig. 1 Cone trap used for monitoring of *Habrobracon hebetor* (a) and adhesive trap baited with sex pheromone (ZE-TDA) (b) for monitoring of *Plodia interpunctella* in flat grain storage.

Fig. 2 Records of adult *Plodia interpunctella* (green bars) in a non-isolated store in Northern Germany, 2015. Left axis: surface temperature [°C], right axis: no. of moths. Blue line: mean temperature, red line: maximum temperature.

Results

Monitoring *of P. interpunctella*: In a non-isolated storage building in Northern Germany, adult moths were recorded already in June, 2015 (Fig. 2), while in a well isolated storage building in Southern Germany, adult moth activity started in August (Fig. 3). At that time, a second generation of adults developed already in the non-isolated store (Fig. 2). A peak in the number of adult moths in the non-isolated store was reached in August.

While the F_2-moth progeny in the non-isolated store overwintered in the last larval instar, only one moth generation was recorded in the well-isolated grain store (Fig. 3).

Monitoring of Habrobracon hebetor:

(1) Unbaited cone traps: both in wheat (t-Test, t = 8.061, DG=4, P<0.001) and in oats (t-Test, t = 8.061, DG=4, P<0.001), significantly more wasps were traped in 0 cm compared to 5 cm depth (Fig. 4). On the surface, significantly more wasps were traped in wheat compared to oats (t-Test, t = -3.742, DG=4, P = 0.020). In 5 cm depth, no difference in recapture was detected comparing wheat and Oats (t-Test, t = -0.707, DG=4, P > 0.05).

(2) Baited cone traps: baited with webbings, cone traps on the surface, caught more wasps in oats compared to such unbaited traps on the surface (t-Test, t = -8.721, DG=4, P <0.001) (Fig. 4). In wheat, baited traps caught on the surface a larger number of wasps, however, this difference was not significant (t-Test, t = 2.286, DG=4, P = 0.084).

Baited traps placed in 5 cm depth in wheat caugth more wasps compared to unbaited traps (t-Test, t = -3.530, DG=4, P = 0.024). In oats, no difference in wasps caught in traps placed in 5 cm depth was detected whether the traps were baited with webbings or not (t-Test, t = -1.444, DG=4, P = 0.222). More female wasps were caught in total with baits (t-Test, t = -2.119, DG=22, P = 0.046), but the presence of webbings as bait did not increased the number of males traped (Mann-Whitney Rank Sum Test, T = 125.5, n=12, P = 0.163).

Fig. 3 Records of adult *Plodia interpunctella* (red bars) in a well-isolated grain store in Southern Germany in 2015. Left axis: surface temperature [°C], right axis: no. of moths. Blue line: mean temperature, green line: maximum temperature.

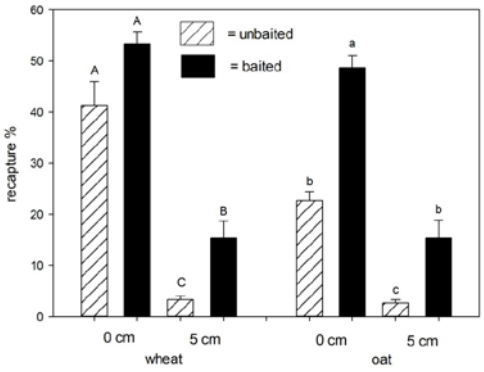

Fig. 4 Recapture of *Habrobracon hebetor* with the help of cone traps in percent, with or without 5 g webbings of *Ephestia kuehniella* as bait in wheat or oats. 50 *H. hebetor* (males and females) released. Different caps indicate significantly different recapture, major caps for wheat, small caps for oats (p<0.05).

Discussion

Under field conditions, pupation of moth larvae and the start of flight of the adult Indian meal moths in spring are mainly depending on temperature in the store. While in a non-isolated store the progeny of the second generation overwintered as larvae, in an isolated cooler store only one generation was observed anually, These observation under practical conditions is well explainable by the developmental time known from laboratory data (Mohandass et al., 2007).

The attractiveness of moth webbings in the cone traps placed in grain on the females confirms olfactometer laboratory trials showing kairomonal activity of webbings produced by different species of pyralid Lepidoptera for *H. hebetor* (Strand et al. 1989). Moreover, foraging H. hebetor were shown to enter into bulk grain in previous studies (Schöller, 2000). In the present study, female *H. hebetor* were shown to exploit signals from moth webbings in bulk grain, too. Consequently, parasitisation of Indian meal moth larvae can be expected below the grain surface, too. This behaviour of *H. hebetor* can also be used to monitor the foraging behaviour of the wasps under practical conditions of storage. In wheat, more *H. hebetor* were traped compared to oats. This might be due to the three-dimensional structure of the bulk grain.

Both male and female *H. hebetor* were caught with the cone traps. The capture of females in unbaited traps indicates this trap type is able to record passivly the movement activity oft the parasitoids. Males could potentially be attracted by already caught females, however, in our trials, a signicantly higher number of females in the baited traps did not result in a significant increase in the number of males caught.

The results on monitoring showed the possibility to record data on the phenology oft he Indian meal moth and *H. hebetor* under practical field conditions. The abiotic conditions in differnt grain stores are subject to wide variation, consequently more field trials are needed in order to develop recommendations for biological control of the Indian meal moth.

Abstract

Cheyletus malaccensis (Oudemans) is a species of predatory mite, which is widely distributed in grain storage, and is a potential natural enemy of stored-product pests. Based on the typical temperatures and humidities that occur in granaries, the growth and development of *C. malaccensis* was studied at 24°C with different relative humidities (RH 65±2%, 75±2%, 85±2% and 95±2%). During this study, *C. malaccensis* was fed on *Acarus siro* (Linnaeus), a very important stored grain pest to investigate its potential to control this pest and production of this natural enemy in the laboratory. The results showed that *C. malaccensis* has five developmental stages, egg, larva, protonymph, deutonymph and adult. The deutonymph stage is absent in males. For females, the developmental time from egg to adult was shortest at 85±2 % RH and averaged 16.3 days; developmental time was longest at 65±2 % RH and averaged 18.6 days. The male mites in the 95±2% RH trials had the shortest developmental time which averaged 12.6 days; it was longest at 65±2% RH where it averaged 14.7 days. At 95±2

% RH, the male adult lived 83.5 d and its longevity from egg to adult was 95.8 d. Humidity had a significant effect on how long the adults lived and the duration of all developmental stages. At 85±2 % RH, the maximum average number of eggs per female, oviposition period and daily fecundity were 493.0, 46.2 d, and 10.3, respectively. This study provides basic biological parameters for *C. malaccensis*, a potential biological control agent for mite pests infesting stored grain.

Abstract

An insecticidal efficacy of two **newly developed** grain protectant formulations were assessed against lesser grain borer *Rhyzopertha dominica* (Fabricius) (Coleoptera: Bostrichidae) on wheat and corn after 6 months period of. Tested formulations, marked as F_1H and F_2H, based on inert dust, laurel leaves, lavender essential oil, corn oil, silica gel (both F_1H and F_2H) and pyrethrin (only F_2H) were tested at six doses (from 100 ppm to 600 ppm) depending on formulation and type of grain. The appropriate weights of each formulation, were added seperately to plastic containers containing 10 kg of wheat or corn. An initial population of 200 adults of *R. dominica* were added into each container and left under natural environmental conditions for up to 6 months. A commercial diatomaceous earth (DE) insecticide, Celatom® Mn 51, was used for the comparison of the results, in addition to the untreated control. After six months, both formulations showed higher insecticidal effect than DE Mn 51 in corn and in wheat. Furthermore, the initial population of *R. dominica,* introduced in wheat was suppressed almost completely, with only 0.7%-5.3% live adults found, depending on formulations and dose. The order of efficacy was $F_1H>F_2H>$DE Mn 51. Similar suppression of the initial population was recorded in corn, where F_2H was slightly more effective than F_1H with 2.0%-10.6% and 4.1%-9.5% live adults found, respectively. At the same time, in the treatments with DE Mn 51 there were 4.7%-74.7% and 33.4%-56.1% live adults in wheat and corn, respectively.

Keywords: inert dust, botanicals, grain protectant, stored product insects, insecticidal effect

Introduction

Minimising food commodity losses, both qualitative and quantitative, during longer period of storing represents a main challenge for all economies. Stored-product insects play a significant role in postharvest losses, causing losses in grain weight, affects on baking quality and seed viability (Sánchez-Mariñez et al., 1997; Stejskal et al., 2015), which lower cereal market value. The use of synthetic insecticides is globally the most common way of controlling stored product insect pestsof the negative effects of pesticides on stored products includes: toxic residues (Fang et al., 2002), resistant strains within the insect populations (Chaudhry, 2000; Boyer et al., 2012), adverse effect on human health and environment (Fields and White, 2002). Thus there is an urgent need for alternative strategies which would be sufficiently effective against insects but less toxic for the environment.

The use of inert dusts, especially diatomaceous earth (DE), suits most of those requirements. Its main advantages are low mammalian toxicity and stability (Maceljski and Korunic, 1972; Subramanyam and Roesli, 2000) and an efficient insecticidal activity without leaving hazardous residues (Korunic, 1998; Shah and Khan, 2014; Liška et al., 2015; Korunić et al., 2017.). Despite this there are several limitations which hinder wider commercial use of DE for direct mixing with grains and are described by Korunić (2016). Diatomaceous earths, inert dusts in general, have physical mode of action and therefore act more slowly than conventional contact insecticides. Depending greatly on ambient conditions, it could take a several days to control most target insect species (Korunić et al, 2016), providing enough time for oviposition. Further, there are different sensativities of insect species to DEs, varying effects of DE on insects depending upon the commodity being treated and a negative effect on bulk density (Korunic, 2016; Korunić et al, 2017). Possible solutions for minimising or avoiding those implications include incorporating DE with other methods, such as extreme temperature (Dowdy, 1999), mixture with synthetic insecticides (Athanassiou, 2006; Korunic and Rozman, 2010), mixture with entomopathogenic fungi (Batta and Kavallieratos, 2018) or with botanicals (Korunic et al, 2014; Adarkwah et al, 2017).

Most experiments with inert dusts and their mixtures are carried out in controlled conditions, and less in the real conditions where various environmental and storage conditions could impact efficacy and subsequently, storage duration of the commodity.

The objective of this study was to test insect activity of two new developed formulations based on Croatian inert dust, bay leaves, lavandin essential oil, bait, corn oil, silica gel and pyrethrin against *R. dominica* in wheat and corn grain after six months period of storage.

Materials and Methods

Test insects

A local strain of *R. dominica*, was used in the experiments. Insects were reared on clean soft whole wheat kernels under controlled conditions (28±2°C, 65±5% RH, in dark). Two hundred, unsexed adults (7-21 days old) were used for each treatment.

Commodity

Locally available commercial corn and soft wheat were used in the treatments. Commodities were sifted prior to tests in order to segregate broken kernels and other impurities. Grain moisture content and grain temperature were measured by the GAC 2100-Agri Grain analysis computer (Dickey-john). The initial measurements were 11.1 % m. c. and 23.2°C for wheat, and 10.7 % m. c. and 23.3°C for corn. Ten kg of clean wheat and corn grain was used for each treatment.

Formulations

Two powder formulations labelled as F_1H and F_2H, were based on an inert dust of Croatian origin, dried and milled bay leaves, essential oil of lavandin (Lavender x Intermedia), bait, corn oil, silica gel

and pyrethrin (only F_2H). A commercial DE insecticide, Celatom® Mn 51, was used for the comparison of the results. It belongs to a group of DE's with medium to high efficacy against stored-product insects. Formulations and DE were tested at different doses depending on the treatment. In wheat, F_1H and DE Celatom® Mn 51 were tested at 300, 400 and 500 ppm, and F_2H at 100, 150 and 200 ppm, while in corn F_1H and DE Celatom® Mn 51 were tested at 400, 500 and 600 ppm, and F_2H at 200, 250 and 300 ppm.

Bioassay

The dose rates of the tested formulations and DE were chosen based on results of preliminary laboratory test (unpublished data). Plastic containers of 15 L volume were filled with 10 kg of clean wheat or corn respectively. The appropriate weights of the formulations or Celetom DE were added into each container and mixed thoroughly with a power drill. Containers with untreated grain served as controls. After the dust had settled, 200 unsexed, 7-21 days old adults of *R. dominica* were added into each container which were then closed with perforated plastic lids. The bioassay was conducted for six months storing the containers in a wooden structure which simulated an average floor warehouse. The air temperature during the entire period of storing varied between 18.5°C and 23.0°C and relative humidity between 55.0% and 82.0%. After the end of the bioassay trial, the entire content of the plastic containers was sieved and all insects, dead and live, were counted.

Results

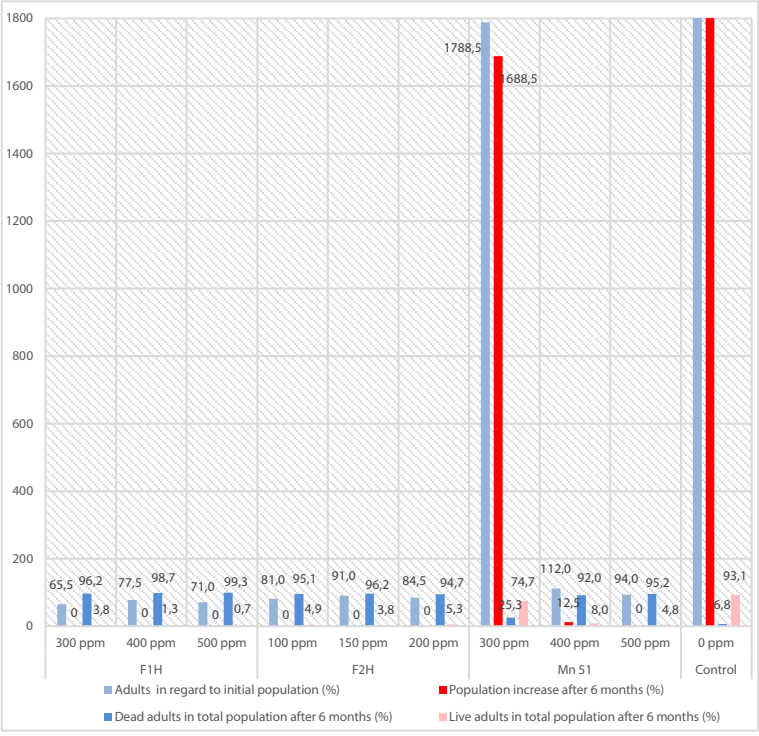
After six months of storing of treated corn and wheat, tested formulations F_1H and F_2H showed different efficacy against *R. dominica* depending on the cereal type and the applied dose.

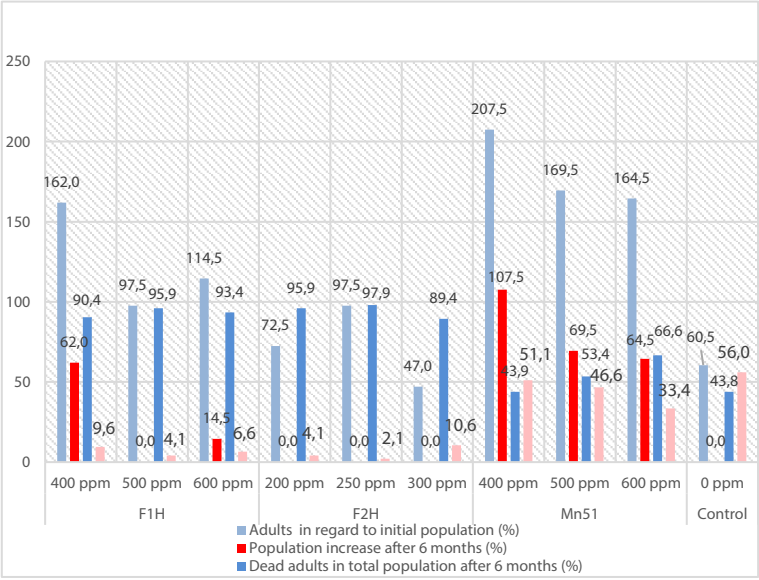
In wheat (Figure 1), both formulations successfully preserved grain quality against *R. dominica* during the period of six months. Even at the lowest dose, both formulations (300 ppm of F_1H and 100 ppm of F_2H) almost completely suppressed the initial population of *R. dominica,* therefore after six months, there was no population increase with only 0.7-3.8% (depending on dose of F_1H) and 3.8-5.3% (depending on dose of F_2H) of the original live adults found. For comparison, Celatom® Mn 51 at the lowest dose was not effective, resulting in a population increase (1688.5% higher than the initial population) within 74.7% live insects found. Population increases were also observed in the control treatment in wheat where number of insects from the initial 200 individuals increased up to 11817 within 93.13% live adults.

In corn (Figure 2), both formulations also showed better efficacy then Celatom® Mn 51. According to the number of adults found at the end of the testing period, formulation F_2H was more effective in regard to F_1H. Further, even at the lowest dose (200 ppm) no population increase was observed, while F_1H resulted with 62% and 14.5% of the population increase (at the dose of 400 ppm and 600 ppm, respectively). However, in the treatment with DE Mn 51, the highest dose (600 ppm) was not efficient enough to control *R. dominica,* and the population increase was in the range from 64.5 to 107.5% (higher than initial population) (depending on dose) within average of 45.4% live adults found. Concerning control treatments, unlike in wheat no population increase was observed in corn. Due to high temperature and high moisture content of the grain during six months fungi developed intensively and the whole stock become glued mass, so insects could not survived in those conditions.

Fig. 1 Efficacy of the formulations F_1H and F_2H against *R. dominica* after six months of wheat storing

Fig. 2 Efficacy of the formulations F_1H and F_2H against *R. dominica* after six months of corn storing





Discussion

Increased efficacy of the tested formulations against *R. dominica,* compared to DE alone was expressed because of the mixture of different active ingredients within their composition and due to their different modes of action. Besides inert dusts, the main composition of the formulations are the botanicals powdered bay leaves and lavandin essential oil. These compounds possess fast toxic activity against many coleopteran pests of stored products (Kostyukovsky et al 2002; Rajendran and Sriranjini, 2008; Nerio et al 2010; Koutsaviti et al, 2018). Comprised of volatile monoterpenoids and sesquiterpenenoids, the essential oils interfere with basic metabolic, biochemical, physiological and behavioural functions in insects possessing contact, inhalation and ingestion toxicity, antifeedant activity, developmental delay of adult emergence and fertility, different effects on oviposition and repellent activity (Obeng-Ofori 2007; Caballero-Gallardo et al, 2012; Nenaah 2014; Germinara et al, 2017). DEs and general inert dusts, with physical mode of action, are slow acting protectants (Korunic, 1998). Apparently, as a mixture of plant powders, essential oils and inert dusts, our formulations accelerate the knock down effect of the adults within the initial population of *R. dominica* which resulted in prevention of mating and reduced oviposition. Food grade bait composed within our formulation probably also accelerated insect mortality. Presumably, it attracted insects which kept them in the contact with inert dust for longer period. Consequently, insects picked up more inert dust particles on their body which led to faster desiccation (Korunić et al, 2016).

Adarkwah (2017, 2017a) reported faster activity of the mixture of DE and plant powders against three different stored product insects.While, mentioned authors conducted their trials in laboratory conditions and only during 7 days of exposure, our tested formulations secured effective control of the tested pest during the whole testing period of six months in conditions that might more realistically represent true storage conditions.

Overall two developed formulations, as a combination of inert dusts and botanicals could be promising insecticides with residual effect for protecting stored wheat and corn against insect infestation.

Abstract

Parasitoids can suppress populations of their host and thus play a primary role in Integrated Pest Management. In the stored product environment, stimuli deriving from plant products, damaged plant products and hosts might be important for host location by the parasitoids. We studied foraging cues in *Holepyris sylvanidis* (Hymenoptera: Bethylidae), a larval parasitoid of *Tribolium* species and *Cephalonomia waterstoni* (Bethylidae), a natural enemy of the rusty grain beetle *Cryptolestes ferrugineus* (Coleoptera: Cucujidae). Our studies in a four-chamber olfactometer revealed that the host complexes of both *Tribolium* species and different living host stages attract naive *H. sylvanidis* females, whereas no reaction was observed to uninfested substrates. The olfactory response of *C. waterstoni* was found to be strongly elicited both by chemicals emitted by the dust, adult *C. ferrugineus* and *C. ferrugineus* third and fourth instar larvae. Our findings may contribute to the development of biological control strategies of *T. castaneum*, *T. confusum* and *C. ferrugineus* with parasitoids.

Keywords: natural enemies, Bethylidae, stored product pests, biological control

Introduction

The bethylid wasp *Cephalonomia waterstoni* Gahan is an external, arrhenotokous idiobiont larval ectoparasitoid. Hosts are *Cryptolestes ferrugineus* (Stephens), *C. pusillus* (Schönherr) and *C. turcicus* (Grouvelle) (Coleoptera: Cucujidae) (Finlayson, 1950a; 1950b). *C. waterstoni* is able to find hosts by recognizing residual kairomonal cues on infested substrates, similar to other parasitoids (Howard & Flinn, 1990). Hagstrum (1987) and Reichmuth et al. (2007) reported the ability of *C. waterstoni* to maintain the population of rusty grain beetles below the economic threshold.

The parasitic wasp *Holepyris sylvanidis* (Brèthes) (Hymenoptera: Bethylidae) is a larval parasitoid of *Tribolium confusum* Jacqueline du Val and *T. castaneum* (Herbst) (Coleoptera: Tenebrionidae), the economically most important stored product pests worldwide (Athanassiou et al., 2005; García et al., 2005). The host-searching behaviour of *H. sylvanidis* is influenced by the presence of host faeces, in which two compounds are thought to be responsible for the attraction: (*E*)-2-nonenal and 1-pentadecene (Fürstenau et al., 2016). The ability of *H. sylvanidis* to penetrate cracks and crevices makes it a promising natural enemy against stored-product pests. Pest larvae are often hidden under thin layers of substrate, in aeration ducts, in machines and in areas that are difficult to clean, but this wasp is able to access these critical environments.

Materials and Methods

Olfactory responses of *C. waterstoni*

The experiments were carried out in a static four-chamber olfactometer proposed by Steidle & Schöller (1997). The experiments evaluated the parasitoids response towards the following odour sources: (1) healthy grain (HGR), consisting of undamaged and uninfested wheat harvested in Germany in 2013; (2) grain infested by *Sitophilus granarius* (L.) (Coleoptera, Dryophthoridae) (IGR), which was obtained from the stock rearing of Hohenheim University; (3) a mixture of grain dust from the mass rearings of *Rhyzopertha dominica* (F.) (Coleoptera, Bostrichidae), *Oryzaephilus surinamensis* (L.) (Coleoptera, Silvanidae) and *C. ferrugineus* on durum wheat (DST), which was collected from cultures kept at 30°C and 60 % relative humidity (RH), the insects and the wheat were kept in a 100 l bin for about 6 months; (4) dust which was obtained by sieving infested durum wheat after being fed on by adult S. granarius from Hohenheim's University laboratory (DSH); (5) diet without *C. ferrugineus* (DIT), consisting of big oats, small oats and wheat in the ratio 1:1:2, this diet also contained one tea-spoon of yeast and water, respectively; (6) diet plus *C. ferrugineus* (DCR), which was like the diet without *C. ferrugineus*, but in this case 50 randomly chosen adults were added, (7) male and female *C. ferrugineus* adults (ADU), (8) mixed larvae (LRM), i.e. 50 randomly chosen larvae of *C. ferrugineus*.

Olfactory responses of *H. sylvanidis*

In the experiments we studied the parasitoid females reaction towards the following odour sources: (1) *T. castaneum* host complex (CAH) consisting of 0.5 g whole grains, 0.5 g broken grains, first to second instar larvae (n = 2), fourth instar larvae (n = 2), pupae (n = 2) and adults (n = 2); (2) *T. confusum* host complex (COH) consisting of 0.5 g whole grains, 0.5 g broken grains, first to second instar larvae (n = 2), fourth instar larvae (n = 2), pupae (n = 2) and adults (n = 2); (3) whole grains (WHG) consisting of 1 g whole grains (*Triticum durum*); (4) flour (FLR) consisting of 1 g of flour (*Triticum aestivum*); (5) *T. castaneum* first to second instar larvae (CA1-2) (n = 10); (6) *T. castaneum* fourth instar larvae (CA4) (n = 10); (7) *T. confusum* first to second instar larvae (CO1-2) (n = 10); (8) *T. confusum* fourth instar larvae (CO4) (n = 10); (9) *T. castaneum* pupae (CAP) (n = 5); (10) *T. confusum* pupae (COP) (n = 5); (11) *T. castaneum* adults (CAA) (n = 5); (12) *T. confusum* adults (COA) (n = 5).

Results

Olfactory responses of *C. waterstoni*

Table 1 Substrates tested and mean walking time upon each odour source.

Substrates	Mean Time ± SE	P-value
DCR vs DIT	189.50 (±27.70) – 96.80 (±14.00)	P<0.05
DST vs EMP	202.43 (±28.10) – 94.22 (±15.70)	P<0.05
DSH vs EMP	198.16 (±28.40) – 110.70 (±17.70)	P<0.05
DST vs HGR	272.54 (±24.80) – 77.36 (±13.70)	P<0.05
DST vs IGR	214.53 (±33.03) – 71.30 (±20.50)	P<0.05
DCR vs DST	203.50 (±33.50) – 107.75 (±17.70)	P>0.05
ADU vs 3-4 L	164.16 (±31.40) – 95.39 (±21.80)	P>0.05
LRM vs ADU	121.74 (±28.10) – 102.64 (±22.80)	P>0.05
LRM vs EMP	178.29 (±15.40) – 114.43 (±10.70)	P<0.05
3-4 L vs 1-2 L	166.50 (±25.60) – 103.90 (±22.30)	P<0.05

Olfactory responses of *H. sylvanidis*

Table 2 Substrates tested and mean walking time upon each odour source

Substrates	Mean Time ± SE	P-value

CAA vs COA	164. 38 (±72.04) – 152. 18 (±59.85)	P<0.05

Discussion

C. waterstoni is an arrhenotokous ecto-parasitoid ables to locate hosts recognizing their kairomonal cues left on infested substrates (Amante et al., 2017 b,c; Howard & Flinn, 1990). Among the odours tested in the host habitat experiments, dust was the most attractive. The dust contains host faeces and particles from the host's feeding substrate, i.e. plant materials. Our study showed dust from infested products plus larvae and adults were most attractive to the parasitoid *C. waterstoni*. Consequently our study suggests laboratory reared *C. waterstoni* released for biological control would be arrested in areas infested by *C. ferrugineus*, but would not stay in uninfested stored products.

The present study demonstrates that *H. sylvanidis* primarily relies on volatile chemical cues from all host stages for host location. Our results demonstrate that the host complexes of at least two *Tribolium* species, *T. castaneum* and *T. confusum*, release volatile chemical signals, which are attractive for naive *H. sylvanidis* females. In our experiments designed to identify the attractive elements of the host complex, naive wasps did not react to uninfested whole grains and flour, but to most of the host stages of both *Tribolium* species. Whether the kairomonal cues identified could be used to manipulate the behaviour of these parasitoids in order to increase the effectiveness of biological control has to be investigated in future studies (Amante et al., 2017 a, b, c).

Veröffentlichungen des JKI

Das **Julius-Kühn-Archiv** setzt die seit 1906 erschienenen Mitteilungshefte, eine Reihe von Monographien unterschiedlichster Themen von Forschungsarbeiten bis zu gesetzlichen Aufgaben fort. Alle bisher erschienenen Ausgaben sind OPEN ACCESS kostenfrei im Internet (https://ojs.openagrar.de) zu lesen.

Öffentlichkeit und Fachwelt versorgen wir zusätzlich mit verschiedenen Informationsangeboten über alle Aspekte rund um die Kulturpflanzen. Hierfür stehen Broschüren, Faltblätter, Fachzeitschriften und Monographien, Datenbanken und Themenportale im Internet zur Verfügung.

Seit 2009 wird vom Julius Kühn-Institut als wissenschaftliches Fachorgan das **Journal für Kulturpflanzen – Journal of Cultivated Plants** (vormals Nachrichtenblatt des Deutschen Pflanzenschutzdienstes) monatlich herausgegeben (https://www.journal-kulturpflanzen.de).

Weiterführende Informationen über uns finden Sie auf der Homepage des Julius Kühn-Instituts unter **https://www.julius-kuehn.de.**

Julius Kühn-Institut
Bundesforschungsinstitut für Kulturpflanzen

Julius Kühn-Institut, Bundesforschungsinstitut für Kulturpflanzen (JKI)
Das Julius Kühn-Institut ist eine Bundesoberbehörde und ein Bundesforschungsinstitut. Es umfasst 17 Institute zuzüglich gemeinschaftlicher Einrichtungen an 10 Standorten (Quedlinburg, Braunschweig, Kleinmachnow, Dossenheim, Siebeldingen, Dresden-Pillnitz) und eine Versuchsstation zur Kartoffelforschung in Groß Lüsewitz. Quedlinburg ist der Hauptsitz des Bundesforschungsinstituts.

Hauptaufgabe des JKI ist die Beratung der Bundesregierung bzw. des BMEL in allen Fragen mit Bezug zur Kulturpflanze. Die vielfältigen Aufgaben sind in wichtigen rechtlichen Regelwerken, wie dem Pflanzenschutzgesetz, dem Gentechnikgesetz, dem Chemikaliengesetz und hierzu erlassenen Rechtsverordnungen, niedergelegt und leiten sich im Übrigen aus dem Forschungsplan des BMEL ab. Die Zuständigkeit umfasst behördliche Aufgaben und die Forschung in den Bereichen Pflanzengenetik, Pflanzenbau, Pflanzenernährung und Bodenkunde sowie Pflanzenschutz und Pflanzengesundheit. Damit vernetzt das JKI alle wichtigen Ressortthemen um die Kulturpflanze – ob auf dem Feld, im Gewächshaus oder im urbanen Bereich – und entwickelt ganzheitliche Konzepte für den gesamten Pflanzenbau, für die Pflanzenproduktion bis hin zur Pflanzenpflege und -verwendung. Forschung und hoheitliche Aufgaben sind dabei eng miteinander verbunden.
Weiterführende Informationen über uns finden Sie auf der Homepage des Julius Kühn-Instituts unter **https://www.julius-kuehn.de**. Spezielle Anfragen wird Ihnen unsere Pressestelle (**pressestelle@julius-kuehn.de**) gern beantworten.

Julius Kühn-Institut, Federal Research Centre for cultivated plants (JKI)
The Julius Kühn-Institut is both a research institution and a higher federal authority. It is structured into 17 institutes and several research service units on the sites of Quedlinburg, Braunschweig, Kleinmachnow, Siebeldingen, Dossenheim und Dresden-Pillnitz, complemented by an experimental station for potato research at Groß Lüsewitz. The head quarters are located in Quedlinburg.
The Institute's core activity is to advise the federal government and the Federal Ministry of Food and Agriculture in particular on all issues relating to cultivated plants. Its diverse tasks in this field are stipulated in important legal acts such as the Plant Protection Act, the Genetic Engineering Act and the Chemicals Act and in corresponding legal regulations, furthermore they arise from the new BMEL research plan.

The Institute's competence comprises both the functions of a federal authority and the research in the fields of plant genetics, agronomy, plant nutrition and soil science as well as plant protection and plant health. On this basis, the JKI networks all important departmental tasks relating to cultivated plants – whether grown in fields and forests, in the glasshouse or in an urban environment – and develops integrated concepts for plant cultivation as a whole, ranging from plant production to plant care and plant usage. Research and sovereign functions are closely intertwined.
More information is available on the website of the Julius Kühn-Institut under **https://www.julius-kuehn.de**. For more specific enquiries, please contact our public relations office (**pressestelle@ julius-kuehn.de**).

Abstract

While investigating the preservation of the aroma of various spices we compared the effects of hermetic conditions, vacuum and carbon dioxide versus aerated storage. The quality of the tested spices stored under hermetic conditions was comparable to those stored in vacuum after 120 d of storage. At a given temperature, a substance with higher vapor pressure vaporizes more readily than a substance with a lower vapor pressure. Throughout the investigation on specialty coffee, the volatility was evaluated as particularly important because coffee taste and aroma are influenced by compounds that are volatile. We hypothesize that hermetic storage reduces the rate of the volatiles to spread to the atmosphere. Dry food commodities can be stored for extended periods, provided there is no insect infestation and their water activity is low enough to prevent microbial growth. However, in aerated storages quantitative and qualitative losses still occur. If the moisture content is maintained sufficiently low, insects and quality loss remain the main concern for the quality preservation of durable agricultural commodities. Although in hermetic storage, the major emphasis is placed on the control of insect pests, for quality preservation just maintaining the vapor pressure in the sealed structure is sufficient. Quality preservation under hermetic conditions remains an aspect that deserves more attention. This characteristic of hermetic storage is the tendency to maintain within the hermetic structure the substances that have the ability to vaporize.

Key words: Hermetic storage, vapor pressure, volatile substances, aroma, quality preservation, modified atmospheres, low oxygen, vacuum, stored-product insects, stored-product microflora.

Introduction

Hermetic storage is a type of modified atmosphere (MA) that can be applied for the protection of commodities. This method takes advantage of sufficiently sealed structures that enable insects and other aerobic organisms in the commodity or the commodity itself to generate the MA by depleting the O_2 and increasing the CO_2 concentrations through respiratory metabolism (Navarro, 2006).

Dry food commodities can be stored for extended periods, provided there is no insect infestation and their water activity is low enough to prevent microbial growth. However, in aerated storages quantitative and qualitative losses still occur. Qualitative losses, for example, may consist of changes in physical appearance, in color change, loss of flavor, in nutritional degradation due to oxidation and increase in free fatty acids, the presence of insects or their fragments, or contamination by mold or the presence of mycotoxins. If the moisture content is maintained sufficiently low, insects and quality loss remain the main concern for the quality preservation of durable agricultural commodities (Navarro and Donahaye, 2005). Although in hermetic storage, the major emphasis is placed on the control of insect pests, for quality preservation just maintaining the vapor pressure in the sealed structure is sufficient.

Vapor pressure is a less investigated characteristic of hermetic storage. It is the tendency to maintain within the hermetic structure the substances that have the ability to vaporize. Such volatility is directly related to a substance's vapor pressure.

In chemistry and physics, volatility is the tendency of a substance to vaporize. Volatility is directly related to a substance's vapor pressure. At a given temperature, a substance with higher vapor pressure vaporizes more readily than a substance with a lower vapor pressure.

According to Weast et al. (1987) "vapor pressure is the pressure exerted when a solid or a liquid is in equilibrium with its own vapor. The vapor pressure is a function of the substance and of the temperature".

Vapor pressure or equilibrium vapor pressure is "the pressure exerted by a vapor in thermodynamic equilibrium with its condensed phases (solid or liquid) at a given temperature in a closed system" (Wikipedia Vapor pressure 2018). The equilibrium vapor pressure is an indication of a liquid's evaporation rate. It relates to the tendency of particles to escape from the liquid (or a solid). A substance with a high vapor pressure at normal temperatures is often referred to as volatile. The pressure exhibited by vapor present above a liquid surface is known as vapor pressure. As the temperature of a liquid increases, the kinetic energy of its molecules also increases. As the kinetic energy of the molecules increases, the number of molecules transitioning into a vapor also increases, thereby increasing the vapor pressure.

There are many examples for commodities with volatiles that make the aroma, the taste and the flavor special. For example, in spices and beverages like cocoa, coffee and spices, volatility is particularly important because taste and aroma are influenced by certain compounds that are relatively volatile. Retaining those volatiles during storage period of time has not been possible in aerated storage, but hermetic storage gave excellent results.

Quality preservation under hermetic conditions remains an aspect that deserves more attention. In the present paper, this aspect of hermetic storage in the quality preservation capacity of volatile substances that are emitted from the products is emphasized. The objective of this presentation was to explore the significance of vapor pressure in quality preservation of stored commodities under gastight conditions.

Materials and methods

A- Laboratory trials

Source of spices:

The spices were freshly imported from Bangladesh from a spices company interested in exploring the effects of vacuum and other storage methods on quality preservation of spices. The selected spices for test were: cumin seeds (Vijayanand et al., 2001), chili pods (Duman, 2010), coriander seeds (Bandoni et al., 1998) and turmeric rhizomes (Goyal and Korla, 1993).

Samples of spices:

Prior to tests, five samples from each spice were taken. Samples sizes were: 100 g of cumin seeds, 100 g of turmeric rhizomes, 100 g of coriander seeds, and 50 g of chili pods. The experimental samples were kept in a room at 27±2°C and 65±5% relative humidity (r.h.) for 120 d.

Relative Humidity:

The equilibrium relative humidity (ERH) of the spices was checked using Defensor® Novasina model ms1, Switzerland, with box sensor enMBRK-3. The equilibrium r.h. values expressed in this paper as percentages are equivalent to the decimal values in terms of water activity (a_w) which is the ratio of the water vapor pressure in the agricultural commodity to the water vapor pressure of pure water at the same temperature. Tests were carried out at 26.0-26.3°C. The ERH of the cumin seeds was 52.2%, chili pepper pods was 43.3%; coriander seeds was 44.5% and turmeric rhizomes was 75.4%.

Storage conditions of spices: The spices were stored under the following conditions:

a- *Control under continuous airflow:* burlap sack was filled with a sample of the tested spice. Each sack was then inserted into a separate 500 mL glass container (for the chili pods we used 1,000 mL

glass container). A plastic tube was then inserted from the top of the container and placed at the bottom below the burlap sack. The plastic tube was then connected to a small aquarium air pump allowing the air to flow through the sack at in airflow of 350 mL/min. The glass container remained open at the top for the entire duration of the test .

b- *Hermetic storage:* Each of the tested spices was sealed in a separate 1,000 mL glass jar. The jars were hermetically sealed for the entire duration of the test.

c- *High CO_2 (90% to 100%) atmosphere*: Each of the tested spices was sealed in a separate 750 mL glass jar. The jars were saturated with 100% CO_2 inserted through a rubber sealer at the jar lead. The CO_2 concentrations were examined periodically (once a week) and corrected when needed to adjust to CO_2 concentrations higher than 90%.

d- Vacuum: Each of the tested spices was sealed in a 500 mL vacuum glass container. The pressure in the container was initially reduced to 6.5 mmHg absolute pressure. The pressure was examined periodically (once a week) and maintained below 25 mmHg. In some samples higher pressures than 25 mm were recorded due to the difficulty in maintaining the low pressure. Those pressures were immediately rectified to the target pressure.

e- Burlap sack without aeration (also used as control): Each sack was filled with the tested spice. All burlap sacks were placed on shelve, exposed the room temperature and humidity.

Quality test: After 120 days of storage, all treated spices were removed from their experimental containers and placed in a container covered with a plastic Petri dish. The treatments were given a score from 1-5 for aroma and color 1 (dark color or other defects) represent the poorest and 5 best aroma and the best color (bright red color with no defects).. For these tests 15 individuals (6 women and 9 men) from the Department of Stored Products of the Israel Agricultural Research Organization were asked to score the sensory evaluation. Only chili pods were scored for color change and their pungency by smelling. Comparisons for all pairs were analysed using Tukey-Kramer HSD (honest significant difference) test method (SAS, 2014)

B- Field trials

The following two field trials were conducted by commercial companies that market chili pepper. Test results reported to the authors were not complete, but they were supported by available data description of the tests and pictures taken during and at the end of the trials.

Field Trial 1: One set of trial was conducted by the company HAJISONS at Kunri of District Umar Kot in the Province of Sindh area of Pakistan during the period of 7 months between December 3 - 9, 2016 and July 5, 2017. The area has foggy winter (Nov –Feb) with few western disturbances causing rain; pleasant spring (Feb –April); summer (April – June) with dust, rain storms and heat wave periods and rainy monsoon (July – August). The hottest month is June, where average highs routinely exceed 40°C. Coldest month is January with average high 19.8°C. Dry chili was stored in jute bags that served as control and compared with GrainPro hermetic bags indoors.

Field Trial 2: The second set of demonstration trial was conducted within the facilities of Olam Agro India Limited at District Guntur, Andhra Pradesh, India. The trial lasted for 6 months. The climate in Guntur is tropical. The average temperature is warm to hot year-round. The average annual temperature is 28.5°C. The trials were conducted by Mr. Madhu Nagaraj and Mr. Hari Babu of the Olam Agro India Limited. The practice was storing the whole dried RCPs (red chili pepper). However, this method requires a lot of space in a storage facility or during transport. It was recommended to test storing dried RCPs in powdered form to maximize capacity for storage and transport. Various parameters were measured every month for 6 months of storage including weights, moisture, colour, pungency and aflatoxins.

Results

Results of Laboratory Trials:

Results of blind test are shown in Table 1 which indicates that the control with airflow and in burlap sack gave the poorest results with scores below 2. For aroma tests best results obtained after 120 d under hermetic storage and vacuum. Although high CO_2 provided better preservation compared to controls, it was still inferior to hermetic and vacuum. The purpose of providing an active airflow in the control was to demonstrate that aerating to remove the aromatic volatiles would be more effective than the static control without aeration in burlap sack. The fact that airflow provided better results than the burlap sack may indicate that the jars where airflow of 350 mL/min were exposed was not sufficiently aerated compared to the volatiles that were evaporated from the burlap sacks.

Statistic test of comparisons for all pairs using Tukey-Kramer HSD showed that there was no significant difference for all spices stored under vacuum or hermetic storage. The storage under high CO_2 showed also no significant difference from stored under vacuum or hermetic storage excluding turmeric rhizomes. In both, storage in burlap sack or airflow showed the poorest performance compared with the other treatments. Vacuum storage gave best results followed by hermetic storage and high CO_2.

Table 1- Blind tests (Mean ± SE) for aroma of spices stored for 120 d at 27°C and 65% r.h.

Treatment	Cumin seeds	Chili pods*	Coriander seeds	Turmeric rhizomes
Airflow (control)	1.9 ± 0.31	1.5 ± 0.31	1.5 ± 0.40	1.4 ± 0.22
Hermetic storage	4.2 ± 0.36	3.7 ± 0.49	3.9 ± 0.36	4.1 ± 0.54
High CO_2	3.6 ± 0.40	4.0 ± 0.49	3.5 ± 0.31	2.7 ± 0.56
Vacuum	4.1 ± 0.36	4.1 ± 0.45	4.4 ± 0.45	4.6 ± 0.27
Burlap sack (control)	1.1 ± 0.13	1.2 ± 0.36	1.5 ± 0.40	1.3 ± 0.22

The Standard d Error of all means was 0.2

*For chili pods pungency tests served as criteria instead of aroma.

Table 2 shows results obtained using blind test for color difference of chili pods. Statistic test of comparisons for all pairs using Tukey-Kramer HSD showed that there was no significant difference for the color of the chili pods stored under vacuum or hermetic storage. This in spite of the fact that vacuum has better results. Storage under high CO_2 showed no significant difference from stored under hermetic storage, but was significant difference for those stored under vacuum.

In both, storage in burlap sack or airflow showed the poorest performance compared with other treatments. vacuum storage gave best results followed by hermetic storage and high CO_2.

Table 2- Blind tests (Mean ± SE) for color and pungency of chili pods stored for 120 d at 27°C and 65% r.h.

Treatment	Chili pods
Airflow (control)	1.0 ± 0.0
Hermetic storage	4.2 ± 1.2
High CO_2	3.5 ± 0.5
Vacuum	5.0 ± 0.0
Burlap sack (control)	1.5 ± 0.8

Results of Field trials

Field trial 1:

Test results of the are shown in Table 3 which gave a good indication of quality preservation capacity of dry chili peppers after 7 months of storage. In this case the quality parameters of color preservation, pungency, freshness, moisture preservation and fruit weight were well preserved in hermetic storage compared to lower quality observed in chili peppers stored in jute bags.

The weights of both whole and powdered chili peppers (RCP) remained constant throughout the 6-months storage period. For RCPs stored in Cocoon Indoor, the moisture content for whole RCP remained stable at 7.15%, while for powdered RCP, no change in moisture content was observed. For whole RCPs stored in SuperGrainBags (SGB), fluctuating moisture was observed taking into consideration the moisture analyzer that was utilized and the non-uniform moisture content of RCP

lots that were stored. Cocoon Indoor and SGBs are designed to prevent moisture ingress during storage, maintaining moisture of the stored commodity. It is a must that properly dried agricultural commodity are dried and stored in safe moisture to inhibit mold growth thus preventing aflatoxin or mycotoxin production. In the case of RCPs, a final moisture content of about 8% is ideal, as moisture content above 11% allows mold growth and below 4% causes excessive color loss.

Table 3- Results recorded at the end of storage period of dry chili peppers in GrainPro hermetic bags and jute bags at Haji Sons, Pakistan after 7 months.

	Hermetic	Jute bag
Color	No discoloration, shined red	Discolored, dull
Pungency	Same as fresh/high	Diluted
Freshness	High	Low
Moisture	No change	Increased
50 fruit weight (g)	36	24

Field trial 2:

The initial pungency of both whole and powdered RCPs measured in heat units were comparable to the heat units taken from RCPs stored for 6 months. Pungency of the spices is caused by several compounds, such as capsaicin for RCPs, which are volatiles. In a gastight system such as SGBs and Cocoon Indoor, these volatiles create equilibrium within the storage, trapping these compounds thus preserving pungency of RCPs.

Colour of whole and powdered RCPs were observed to decline during the storage period. The coloring pigment of chilies is carotenoid which is sensitive to light. Carotenoid pigments degrade when exposed to light, thus storing RCPs in the cold storage or dark room have low rate of color loss. During the trial at Olam, the set-up was placed outdoor since there was not enough space indoor. Even though RCPs were placed in woven polypropylene bags along with SGBs and Cocoon Indoor, light could still penetrate the stack leading to change in color of RCPs.

Light and oxygen contributed to the rate of colour loss. Color degradation of whole RCPs were more evident compared to powdered RCPs since it is less compact allowing more light to enter the stack.

The aflatoxins of RCPs were observed to be 0.5 ppm initially up to 6 months, except on 2nd month for powdered RCPs and 3rd month for whole RCPs in SGBs. These fluctuations in reading might be brought by limitations of the method of analysis for aflatoxin. SGBs and Cocoon Indoor were effective in preventing aflatoxin production during storage. In the previous discussion, moisture ingress is prevented when using SGBs and Cocoon Indoor thus inhibiting molds by maintaining safe moisture for dried RCPs during storage. When molds are inhibited, production of mycotoxins, including aflatoxins is also prevented.

During the trial, whole and powdered dried RCPs were stored. The capacity of SGBs was maximized when storing powdered RCPs (i.e. 40 kg/SGB) compared to storing whole RCPs (i.e. 8 kg/SGB). Several parameters were tested including moisture, colour, pungency, weight and aflatoxin. For 6 months of storage, these parameters measured from powdered and whole RCPs were comparable. Moreover, the colour was observed to be better when storing powdered RCPs compared to whole RCPs.

Discussion

Ambient humidity is an abiotic factor of the air surrounding the commodity. Within the confined storage space, the moisture of the commodities, tend to reach equilibrium with the humidity of the intergranular air. Its greatest influence is on molds, which begin to develop at intergranular air humidities above 65% (Navarro and Donahaye, 2005).

Micro-organisms are the biotic factor composed of molds, yeasts and bacteria. They are universally present on the grain, but are inactive when the equilibrium relative humidity is below 65% .

When discussing microflora activity and preservation of grain quality, it is more meaningful to consider the moisture content of the intergranular environment or the equilibrium relative humidity (ERH) corresponding to a particular commodity moisture content. This is because various grain types may have different moisture contents at the same ERH. The microfloral activity and susceptibility of grain to deterioration is correlated to the ERH. An additional term frequently used in food microbiology is "water activity". Water activity (a_w) and ERH are numerically equivalent, but ERH is expressed as a percentage and aw as a decimal of ERH, thus a_w 0.8 = 80% ERH (Lacey et al. 1980).

Favorable conditions occur when the moisture content of the grain or the relative humidity of the intergranular atmosphere rises above a certain threshold. This threshold is generally considered to be around 75% RH (termed the critical relative humidity) or the corresponding equilibrium moisture content of the grain (e.g. for wheat it is about 14%) - often termed its critical moisture content. Beyond this threshold, microflora become activated, and starts to grow, accompanied by active respiration, liberation of metabolic heat and water. At humidity or moisture conditions above this level, deterioration increases at an exponential rate .

The availability of water in the food medium is a vital factor determining both the types of bacteria or fungi capable of growth, and the rate at which they can grow. It is usually measured in term of water activity, and is a function of the moisture content of the food.

Bacteria grow best at water activities near to unity, and will not grow at a water activity less than about 0.95. Yeasts occupy an intermediate range, and they will grow at water activities as low as 0.85. Fungi are more resistant to the effect of dry conditions, although the vast majority are inhibited by water activities lower then 0.70, a very few species will show some growth at a water activity as low as 0.65 (Lacey et al. 1980).

Tests were carried out in various climate conditions to observe product preservation under hermetic conditions. Among other quality parameters such as insect infestation, milling recovery, head rice, yellow kernels, germination, and weight loss, changes in moisture content of hermetic and non-hermetic storage of paddy was reported (Navarro et al,1997). Accordingly they report paddy stacks of capacities ranging from 13.4 to 31.9 tonnes that were stored outdoors in flexible enclosures for 78 to 183 days. The quality of the paddy was compared with that of three control stacks (5.3–5.6 tonnes capacity) held under tarpaulins in the open for 78–117 days. The trials were conducted at the NAPHIRE compound, Nueva Ecija, the Philippines (Navarro et al., 1997). There was a real trend towards an increase in moisture content in the two control stacks during the wet season and toward a decrease in moisture content in the control stack stored during the dry season. No significant changes were noted, in the eight hermetic stacks and two silos. These field trials indicated that the changes in moisture content and weight of the grain changed only very slightly within the stacks and the silos due to hermetic storage.

Lane and Woloshuk (2017) studied small hermetic bags (50 and 100 kg capacities) used by smallholder farmers in several African countries as a low-cost solution for preventing storage losses due to insects. In their study they compared the effects of environmental temperature and relative humidity at two locations (Indiana and Arkansas) on dry maize (14% moisture content) in woven polypropylene bags and Purdue Improved Crop Storage (PICS) hermetic bags. The results indicated that the PICS bags prevented moisture penetration over the three-month storage period. In contrast, maize in the woven bags increased in moisture content. The work of Lane and Woloshuk (2017) is an additional indication that hermetic storage enables maintaining the water vapor as expressed as humidity in their work. They concluded that the PICS hermetic bags are effective at blocking the effects of external humidity fluctuations as well as the spread of fungi to non-infected kernels.

The more volatile the compound is the faster it will vaporize. This is why the coffee brewing temperature is so important; it allows proper and fast extraction of nonvolatile components, while preserving the volatile ones. Espresso extraction is a few degrees lower than drip

coffee. Pressure helps extract more total dissolved solids (TDS) at a lower temperature, while preserving volatile components. TDS is a measure of the combined content of all inorganic and organic substances contained in a liquid in molecular, ionized or micro-granular suspended form. Generally the operational definition is that the solids must be small enough to survive filtration through a filter with two-micrometer (nominal size, or smaller) pores (Wikipedia, TDS, 2018).

Ribeiro, et al. (2011) evaluated the physical, chemical, and sensory qualities of green coffee beans (*Coffea arabica* L.) during storage in different types of packaging. Coffee was stored in a warehouse in Brazil. The treatments consisted of two types of packaging (hermetic big bags with the injection of up to 60% CO_2 in a controlled atmosphere; similar bags but without the injection of CO_2 in a modified atmosphere). The storage of green coffee beans under these conditions was viable over a 12-month period. The coffee packed in big bags maintained its quality and exhibited an intensification of the green coloration of the grains during storage. Sensory analysis of coffee beans stored in a controlled atmosphere showed that the medium sampling position yielded the best ratings. The results of Ribeiro, et al. (2011) analysis demonstrated that the tested storage technique can potentially increase the effectiveness in preserving the sensory quality of coffee beans.

In another study Borém et al,. (2013) commercially validated the effects of an artificial atmosphere on the color, flavor and aroma of green coffee beans stored after 12 months. The coffees were evaluated by a sensory panel composed of 13 tasters who were judges certified by the Specialty Coffee Association of America and who operate commercially in various coffee-producing regions of Brazil. The evaluation consisted of hermetic big-bags with and without CO_2 injection. Two additional treatments served as controls: jute sacks and GrainPro sacks. The beans were qualitatively evaluated for their color and for their beverage quality attributes including their fragrance, sweetness, acidity, flavor, body and aftertaste. The beans packaged in hermetic big-bags with a CO_2 injection maintained a specialty coffee classification. Impermeable packaging preserved the initial color of the coffee beans. Coffee storage in hermetic packaging preserved the desirable aromas of the coffee. In these studies Borém et al,(2013) showed that undesirable flavors and aromas predominated in the coffees packaged in jute sacks. In all these studies with coffee it is most possible that the quality preservation under sealed conditions, weather under vacuum, hermetic storage or CO_2 assisted modified atmospheres, the packages were maintained sealed that most possible the escape of the volatiles from the coffee to maintain its organoleptic qualities.

We do not have a current method to assess the vapor pressure of the volatiles in the commodities. However, all these studies are in line with the basic understanding that hermetically sealed storages maintain the vapor pressure of the volatiles enabling the commodities better quality preservation. Whereas in all tested aerated storages loss of the volatiles dues to their vapor pressure that should have maintained, was accompanied with loss of quality. Therefore, the conclusions from these studies lead to the understanding for the preservation of the quality of spices and beverages the preferred method of storage should be hermetic sealed storage. Additional supporting research should be carried out on quality preservation of the hermetic storage as an added benefit to the control of insects.

Acknowledgements

We thank Dr. Simcha Finkelman and Mrs. Miriam Rindner of the Israel Agricultural Research Organization for conducting the tests reported in this manuscript and Mr. Tom deBruin of GrainPro for providing field tests on spices preservation under hermetic conditions. Mr. Madhu Nagaraj and Mr. Hari Babu of the Olam Agro India Limited for the field test results in India, and to Mr. Ishtiaque for field tests of HAJISONS at Kiunri District:Umar Kot of Pakistan for field test results in Lahore, Pakistan.

Abstract

Storage pest management practices have relied on synthetic pesticides comprising: dust powders, liquid formulations and fumigants. Reduced efficacy against targeted species, negative health-related issues and increase in consumer awareness on potentially detrimental effects of synthetic pesticides have led to a shift towards safer and environmentally-benign alternatives. Hermetic technology is a pesticide-free storage alternative currently being used in Zimbabwe and other African countries. In the current paper, we review forms and characteristics of the hermetic technology available, organisations driving the technology, research and development (R&D) initiatives, and access and uptake trends in the country. The review draws out future prospects in terms of: stakeholder partnerships and roles, up-scaling/adoption options, R&D gaps, capacity building, and funding mechanisms for effective and sustainable uptake. Critical areas identified in the review include: the need for increasing the number of hermetic plastic liner brands available to enhance access and competitive pricing, improved distribution mechanisms for hermetic storage containers for easy access in remote areas, and generation of evidence-based efficacy data on the various hermetic storage containers in preserving quality of commercial, parent and foundation seed. Future opportunities include use of hermetic containers in the disinfestation of organic horticultural products using carbon dioxide gas hermetic fumigation. However, supporting policies are necessary to ensure sustainable adoption of the hermetic technology at subsistence and commercial scales.

Keywords: synthetic pesticides, pesticide-free storage, gas hermetic fumigation, hermetic technology adoption

Introduction

Agriculture is the primary source of livelihoods in developing countries accounting for up to 15 % of the Gross Domestic Product (GDP) in sub-Saharan Africa (SSA)(OECD, 2016). The crop sector constitutes 85 % of the total production value in SSA. Efficiency along the crop value chain is important to ensure that whatever is produced reaches the end user in optimum quality and quantity. Noxious pests and unfavourable ambient conditions are among factors that are associated with bio-deterioration of agricultural products along the value chain (Kumar and Kalita, 2017; Bradford *et al.*, 2018). Insect pests are among the major loss causing agents during the storage stage (Snelson, 1987; Muatinte *et al.*, 2014) and control strategies have been centred on synthetic pesticide use (Chaudhry, 1997; Daglish, 2006). However, negative attributes have been associated with use of chemical pesticides which include development of resistance by storage insect pests (Chaudhry, 2000; Boyer *et al.*, 2012), toxicity against untargeted species (Isman, 2006; Sarwar, 2015), health hazards to users (Aktar *et al.*, 2009) and health risks posed to consumers as a result of pesticide residues in food products (Navarro *et al.*, 2012). This has led to a paradigm shift towards research on, promotion, uptake and adoption of, environmentally-benign non-chemical pest control methods.

Hermetic storage is an environmentally-benign method being used globally for postharvest handling and disinfestation of agricultural commodities (Navarro *et al.*, 1993; Jayas and Jeyamkondan, 2002; Villers *et al.*, 2010). The method allows commodities to be stored without using any chemicals but by sorely utilising airtight storage conditions which deprive storage pests (arthropods and fungi) of oxygen leading to mortality as a result of asphyxiation (Villers *et al.*, 2006). Use of hermetic storage containers in Africa is increasing especially for handling of dry agricultural commodities at smallholder farmer level (Mvumi *et al.*, 2013; Murdock and Baributsa, 2014; Baoua *et al.*, 2015) and commercial sector (Jonfia-essien, 2012). However, hermetic technology use is not widespread in Zimbabwe although it is increasingly being adopted as a result of promotional activities by development agencies in partnership with various stakeholders including government, research institutions and farmers (Mvumi *et al.*, 2013). Hermetic storage options available on the commercial market in SSA are: small-scale storage options (hermetic bags) eg Purdue Improved Crop Storage (PICS) Bags, AgroZ® and AgroZ® Plus bags, SuperGrain™ Bags (SGB), ZeroFly® bags, Ecotact bags, metal silos and plastic silos; large-scale storage options eg GrainSafes, GrainPro Cocoons™, SiloBags; and transport options eg TranSafe Liners (TSLs) and SGB Oceans. Except for metal and plastic silos, hermetic storage containers readily available on the market in SSA are flexible plastic liners that are manufactured using high density polyethylene (HDPE) and polyvinyl chloride (PVC) (Baributsa *et al.*, 2010; Villers *et al.*, 2010) (Table 1). The hermetic containers are being used for storage and/or transportation of dry agricultural commodities like coffee, cocoa, spices, cereals and pulses (Jonfia-Essien et al. 2010; Villers et al. 2010; Mvumi et al. 2013; Baoua et al. 2015; Walker et al. 2018).

Locally available hermetic storage options, use and scale

Various hermetic technology options are now available in Zimbabwe (Table 1). The hermetic technology was first promoted in the country by FAO in 2012 in eight districts focussing on metal silos and hermetic bags (Mvumi et al., 2013). The project included Government of Zimbabwe and an NGO (Practical Action) as implementing partners focussing on training artisans in the fabrication of hermetic metal silos and introducing both the silos and hermetic bags to smallholder farmers, as alternative grain protection methods. In the same year CIMMYT partnering Government of Zimbabwe, the private sector, an NGO and the University of Zimbabwe also embarked on a similar project in two districts. In 2013, GrainPro Philippines Inc, a green and not only for profit company, and one of the leaders in the manufacturing of hermetic products for handling dry agricultural commodities, partnered Farm & City, an agricultural inputs retailer as its sole distributor in Zimbabwe. This eased local availability of hermetic plastic liner products. Use of hermetic plastic liners is increasing with promotional work being carried out by more NGOs in smallholder farming

communities (Table 2). Catholic Relief Services also imported PICS bags from Malawi in 2017 to assist farmers in reducing storage losses in the arid southern parts of Zimbabwe. The total national usage of hermetic bags is around 100 000 units per season based on estimates from various project interventions. This is a small figure in relation to the approximately 1.5 million smallholder farmers in the country especially considering that 70 % of the population rely on agriculture for their livelihood. Therefore, the product has potential for wide-scale adoption by more smallholder farmers.

Initially, hermetic storage options being used were mainly for household food security purposes. However, in 2015 WFP Zimbabwe realised the opportunity of enhancing smallholder farmers' income through grain aggregation and partnered Fintrac with funding from the USAID to promote community aggregated maize grain storage (Fig 1). This initiative allowed farmers to store grain soon after harvesting and then sell later to take advantage of favourable prices that exist during the lean season. The project donated GrainPro Cocoons™ (5 MT and 10MT) to farmers in two maize producing districts. However, sustainability of such commercial-oriented initiatives is usually hampered by fluctuating harvests, lack of business acumen and management capacity by communities, and conflicting objectives among community members. Ever since the WFP project, there has been a slow but gradual increase in use of GrainPro Cocoons™ by farmers and private sector. Anectodal evidence suggest that use of GrainPro Cocoons have enabled poultry farmers to store grain meant for stockfeed production for periods exceeding eighteen months with insignificant bio-deterioration. This increases the profit margins of farmers because they are able to buy grain soon after the harvest season when prices are low and then use the grain during the lean season when prices are high. On the other hand, SGB Premium is also being used for storing coffee by small-scale coffee producers in the Eastern Highlands of Zimbabwe. The use of SGBs for coffee storage is common in Latin America (Villers et al., 2010) while cocoons were tested at large-scale in storing cocoa beans in Ghana (Jonfia-Essien et al. 2008) and maize grain in Zimbabwe (Chigoverah et al. 2016) Maize seed is being exported to Asia and West Africa in TSLs to limit the effect of fluctuating weather conditions and insect pest development, hence preserving germination in transit. Silobags are also being used in large-scale storage of bulk maize and soyabean seed.

Fig. 10 Community aggregated maize grain stored in a 5MT GrainPro Cocoon in Gokwe South district, Zimbabwe (Source: Authors).

There is need to improve the distribution network for hermetic storage options especially in remote areas where the majority of smallholder farmers are located. Although Farm and City has a nationwide branch network, they have no presence at village level which results in farmers having to travel considerable distances to access hermetic bags at town or district centres. The company can enhance its distribution network by partnering with smaller agro-dealers who operate in smallholder areas. This will increase accessibility of these products to smallholder farmers and enhance adoption (Baributsa et al., 2010).Poor road networks and long distances from district centres of some of the communities can increase the final cost of products.

Tab. 6 List of hermetic containers available in Zimbabwe and their respective capacities (Compiled by authors, 2018).

Manufacturer	Product	Use	Available capacities (based on maize)	Commodities being handled	Source
GrainPro Philippines Inc	SuperGrainBag Farm	Crop Storage	50 kg	Dry cereals and pulses	Farm & City Pvt Ltd (has countrywide distribution network)
	SuperGrainBag Premium		50 kg, 90 kg	All dry agricultural commodities (cereals, pulses, oilseeds, spices, retained seed)	
	GrainSafe		1.3 MT		
	GrainPro Cocoon		5 MT, 10 MT, 20 MT		
	TranSafe Liners	Transportation	20 Ft	Commercial seed maize	
Ministry of Lands Agriculture and Rural Resettlement	Metal Silos	Crop Storage	50 kg, 100 kg, 0.5 MT, 1 MT, 3 MT	Dry cereals and pulses	Manufacturers
Peak Trading Pvt Ltd	Metal Silos	Crop Storage	50 kg, 100 kg, 0.5 MT, 1 MT, 3 MT	Dry cereals and pulses	Manufacturers
Farmyard Investments	Metal Silos	Crop Storage	50 kg, 100 kg, 0.5 MT, 1 MT, 3 MT	Dry cereals and pulses	Manufacturers
Local artisans	Metal Silos	Crop Storage	50 kg, 100 kg, 0.5 MT, 1 MT, 3 MT	Dry cereals and pulses	Manufacturers
SiloBag International	SiloBags	Crop Storage	200 MT	Dry cereals and pulses	RadZim Pvt Ltd

GrainPro Cocoons	WFP (2015/16)

Availability of metal silos is also a challenge. Even though artisans have been trained in some communities, low demand has resulted in most of the artisans switching to fabricating high demand products like watering cans and cooking pots. Furthermore, metal silo manufacturing companies are few in the country and the Government of Zimbabwe through Ministry of Lands Agriculture and Rural Resettlement (MLARR) have conducted capacity building initiatives to private companies to increase the number of service providers. Despite these efforts, there are only a few manufacturers and they cannot service the sparsely distributed smallholder farming communities. This has resulted in MLARR also providing the service through its Postharvest Department which is centrally located in Harare. There is need for more players to enable farmers to easily access the product. However, both Farm & City and RadZim are strategically located to be able to fully service the commercial sector and farmers near major towns and district centres.

Hermetic plastic liners being distributed by Farm and City and RadZim are imported from the Philippines and Latin America, respectively. The products are charged import duty which increases cost which in turn is transferred to the end-users. Cost is usually a major adoption factor especially for resource-constrained African smallholder farmers who tend to opt for low-cost pest control

alternatives regardless of the efficacy of the product (Nukenine *et al.*, 2010).The issue can be addressed by enforcing tax exemption on imported hermetic plastic liners. There is only one brand of hermetic bags (SGB) currently available in the country; hence the need for more players to come on board to avoid monopoly on the market. Competition can also lower prices thereby enhancing affordability by smallholder farmers. In East Africa local manufacturing of hermetic bags has also lowered costs (Baributsa *et al.*, 2010) and enhanced perennial supply of the product on the market. There is need for local plastic manufacturers to also consider venturing into this line of business.

Evidence-based performance of hermetic technology

Research findings have reported hermetic storage products namely SGBs, metal silos (Chigoverah and Mvumi, 2016; Mlambo *et al.*, 2017; Nyanga and Ambali, 2017), and GrainPro Cocoons (Chigoverah *et al.*, 2016) to be effective in suppressing storage pest-induced bio-deterioration of maize and pulses under simulated and field conditions. Metal silos and SGBs were also reported to be more effective than conventional pesticides in suppressing storage insect pests development and consequently preserving germination of commodity maize grain over a storage period of up to one year (Chigoverah and Mvumi, 2016). These findings have led to widespread acceptance of the technology by government, farmers, private sector and development agencies. However, knowledge gaps exist on the reusability of the hermetic containers across storage seasons, maintenance of hermeticity at the Cocoon zipper, performance of plastic liners in areas with severe rodent and *P. truncatus* infestation, performance of other hermetic technology options like SiloBags, GrainSafes and TSLs under local conditions although unconfirmed reports suggest that they are effective in comparison to non-hermetic methods. Furthermore, most research has been centred on commodity grains namely maize and pulses; thus, there is need to generate evidence-based performance data on other commodities like spices, herbs, seed (commercial and foundation), dried fruits and stock feeds.

Future prospects

There is potential for increased use of hermetic technology in Zimbabwe judging by increase in sensitisation initiatives and positive feedback from end users (Nyanga and Ambali, 2017). However, supporting policies are essential to enhance participation of more industry players. Policies which include removal of, or reduction in, import duty tax on hermetic plastic liners and metal silo sheets can significantly reduce costs. Metal sheets constitute the largest proportion of the total cost of the metal silo averaging 60% (Kimenju et al., 2009). The Government of Zimbabwe included metal silos in the country's economic blueprint document (ZIMASSET) as key agricultural equipment that can be useful in enhancing household food security (ZimVac, 2014). There has been lobbying by stakeholders for the country to formulate a Postharvest Policy which if in place can also enhance promotion and uptake of hermetic storage options.

Hermetic technology presents various opportunities especially in the handling of oilseeds like groundnuts and sesame, and disinfestation of organic horticultural products (Navarro, 2010). Groundnuts are usually stored in shells (Harish *et al.*, 2014) which is inefficient in terms of space utilisation. Shelled groundnuts are less bulky but are susceptible to insect infestation and aflatoxin contamination. Hermetic storage (Gas Hermetic Fumigation) has been reported to be effective in storing shelled groundnuts and other oilseeds (Navarro and Navarro, 2014).

Financial constraints faced by local companies and farmers willing to invest in hermetic technology can negatively affect uptake and adoption. Intervention by financial institutions offering credit to both companies and farmers can catalyse availability and adoption of hermetic containers. Farmer groups can also approach retailers of hermetic bags with a payment plan which can facilitate access to the bags on credit terms for payment upon marketing of their harvested commodities. Similarly, trained artisans need access to quality equipment for manufacturing metal silos. They need to be facilitated to approach financial institutions as associations or groups and access soft loans. They also need to be trained in agribusiness so that the investment is sustainable. Given that agricultural

production is seasonal in SSA, most farmers face financial challenges at the onset of the storage season hence end up selling their crops at a lower price. Moreover, lack of appropriate storage technologies also force farmers to sell soon after harvesting to minimise risks associated with prolonged storage (Tefera and Abass, 2012). Capacitating farmers with effective storage facilities enables selling at a higher price during the lean season thereby enhancing household income security. A credit facility will enhance livelihoods and also stimulate demand for the storage products among both smallholder and larger-scale farmers.

Hermetic storage cannot be effective as a standalone postharvest loss reduction strategy but should be complemented by sound crop postharvest management practices and continuous training of both artisans and farmers. There is need to capacitate users on recommended handling practices for both commodity and hermetic storage containers. Users should be made aware that commodities to be stored for long periods of time should be adequately dried prior to loading into the storage containers. Furthermore, some hermetic storage options should be placed in clean spaces free from sharp or overhanging objects and wild animal species. This is critical for hermetic plastic liners which are susceptible to damage by sharp objects and storage pests. Followups of trained personnel followed by refresher training workshops are essential to reinforce the skills and promoting co-learning from practice. Standardised manufacturing procedure for metal silos is critical to ensure optimum performance of the product and avoid sub-standard material. There is need for MLARR to come up with standardised fabrication and testing procedures that will be used during training of artisans to minimise faulty products.

There is an increase in awareness by consumers on the benefits associated with hermetic storage and demand is likely to increase. This might lead to an increase in the manufacturers and suppliers of hermetic storage products. Henceforth, MLARR should engage Standards Association of Zimbabwe formalise hermetic standards for metal silos and hermetic plastic liners. This will enable Government of Zimbabwe to effectively monitor in future the quality of products available on the market. Inferior hermetic bags have been reported in West Africa leading to PICS bags manufacturers branding their bags for easy identification by customers (Baributsa *et al.*, 2010). Standardisation will be key to branding of the hermetic products.

Abstract

Grain losses due to moulds during on-farm storage increase food insecurity, result in economic losses, negatively affect farmers' livelihoods, and increase exposure to mycotoxins that can harm human and animal health. Hermetic storage technologies provide a reliable solution for maize grain that may also preserve food safety. Several studies report the effectiveness of these technologies against post-harvest insects in Africa but provide limited evidence on effectiveness against mould proliferation and mycotoxin contamination. Hermetic technologies were superior to farmer practice in reducing insect infestations and mycotoxin accumulation. Among hermetic technologies, there were no significant differences ($P>0.05$) in performance between metal silos and hermetic bags for mycotoxin accumulation and insect infestation regardless of the mode of infestation. In non-inoculated grain, fungal populations were varied but included mycotoxin-producing *Aspergillus* and *Fusarium* spp., indicating that the grain was naturally contaminated and acted as a good reservoir for these fungi. Mycotoxin levels increased with higher moisture even in non-inoculated grain. Meanwhile, aflatoxin and fumonisin levels at 4 months were not significantly different from baseline values in dry inoculated grain across all storage technologies ($P>0.05$), indicating that hermetic technologies can prevent mycotoxin contamination in dry grain for at least 4 months of storage. Aflatoxin and fumonisin were significantly higher by 1.69 ppb and 0.25 ppm respectively in non-inoculated grains at high moisture indicating the need to adequately dry grain before storage in hermetic technologies. This trend was observed collectively in all the technologies registering 2.03 ppb and 0.311 ppm respectively. In inoculated grains at high moisture, there was an increase in aflatoxin in both hermetic treatments and the control by 5.7 ppb and 12.14 ppb respectively. Therefore, a trial was conducted to compare hermetic technologies with farmer practice in their effectiveness against both insect infestation and mycotoxin contamination.

Keywords: Insect infestation, mycotoxin contamination, stored maize, hermetic storage, food security

1. Introduction

Maize (*Zea mays* L.) can conveniently be classified as the most important cereal crop owing to its nutritional value and utilization of its by-products. Grain losses due to insect pests during on-farm storage increase food insecurity, result in economic losses, negatively affect farmers' livelihoods, and increase exposure to mycotoxins that can harm human and animal health (Obeng-Ofori, 2008). Among these mycotoxins, the two commonest and highly toxic mycotoxins compound encountered in maize in the tropical and sub-tropical region of the world are aflatoxins and fumonisins (Krska *et al.,* 2008). Aflatoxins are toxic metabolites produced by fungal species during their growth under favorable conditions of temperature and moisture. The major aflatoxin producing species are *Aspergillus flavus* and *Aspergillus parasiticus*. The main cereals affected are maize, sorghum, rice and wheat and other crops like groundnuts and cassava. Aflatoxin-producing fungi have very few nutritional, environmental and reproductive requirements, and that is their strategy to survive and develop (Wu *et al.,* 2011). Fumonisins are mycotoxins produced by the grain moulds *Fusarium verticilliodes* and *Fusarium proliferatum,* which is frequently a universal inhabitant of corn. Fumonisins are categorized as, B1, B2 and B3 and are usually found to be greater than 1

ppm in the corn samples tested. However, the FDA/USDA advises less than 4 ppm in corn meant for human consumption and less than 50 ppm for cattle feed. Fumonisins are not always produced where the fungi have colonized on the kernels, but many factors contribute to the subsequent mycotoxin contamination, including host susceptibility and environmental conditions. All these factors together determine the incidence and severity of mould contamination on the grain. The conditions that favor fumonisin production are not well known; *Fusarium* moulds thrive well in hot followed by cool conditions, in wet conditions during pollination and ear development. The magnitude of the effect of mycotoxin exposure is facilitated by the level and exposure period, as well as health, age and the species of the animal.

Damages caused by insect pests represent a huge setback in the world's effort to achieve food security globally. According to Ileleji *et al*. (2007) and Nukenine, (2010) an estimated 1% to 5% of stored grain in developed countries and 20% to 50% of stored grain in developing countries are lost due to insect damage. Cracked or broken grains provide an entry point for infestation by insects and moulds during storage. Variation in temperature and humidity has been identified to support the metamorphosis of *Prostephanus truncates* (Horn) (Hodges and Meik, 1984). They lay eggs which hatch in about three days at 27 **°C** day temperature and the dust provide the nourishment to the larvae. Larva development to adult stage takes place within 27 days and is facilitated by ideal conditions of 32 °C and 80% relative humidity (Hodges, 1986). Maize weevil, *Sitophilus zeamais* (Motschulsky), is one of the cosmopolitan pests of stored cereals, especially maize (Throne, 1994). It damages stored maize and of cob maize prior to harvest. It may also infest other cereals if the moisture content is moderate or high (Longstaff, 1981). Eggs are laid at temperatures between 15 and 35 °C (with an optimum around 25 °C and at grain moisture contents over 10%). Subsequent infestations in stores result from the transfer of infested grain into store or from the pest flying into storage facilities, probably attracted by the odour of the stored grain. Dry weight loss from *S. zeamais* infestation alone averaged about 5% by weight after six months of storage. The 5% dry weight loss translates into 22% of total grains displaying damage (Holst *et al*., 2000). As a start, it should always be recognized that an intact grain is an essential item for successful storing.

Insect infestation could have significant impact on the mycotoxin contamination of maize. It is worthwhile to know that, the level of insect damage influences the extent of mycotoxins contamination. Insects act as vectors by carrying spores of mycotoxin producing fungi from plant surfaces to the interior of the stalk or kernels or create infection wounds through their feeding habits (Munkvold, 2003). Insects attack in storage could also be devastating because their level of damage influences the extent of mycotoxin production in the store. Hermetic storage technologies provide a reliable solution for maize grain that may also preserve food safety.Several studies report the effectiveness of these technologies against post-harvest insects in Africa but provide limited evidence on effectiveness against mould proliferation and mycotoxin contamination. Hermetic bags have also been known to preserve the quality of grain, appearance and aroma by reducing mould growth (Moussa *et al.,* 2014). Hermetic technology works synergistically to promote conditions of limited oxygen and high carbon dioxide levels produced by aerobic metabolism of insects, micro-organisms and grain respiration, creating a non-toxic, cost effective and environmentally friendly option over the use of chemicals in the control of insects and mycotoxin contamination in stored maize (Williams et al., 2014). Aerobic metabolism uses up oxygen and produce carbon dioxide to levels that are lethal to insects in the grain mass (Yakubu *et al.,* 2011). In the world today, concerns on the environment and food safety have increased and consumers are demanding high quality products that are free from chemical residues, aflatoxin and insect contamination (Weinberg *et al.,* 2008).

Improved storage technologies at both household and national levels which reduce losses by preventing mould growth are important component of food security. Improved storage technologies, based on hermetic sealing in high density polyethylene bag or metal and plastic silos provide affordable and more effective storage alternative for farmers, especially the vulnerable

women, that would markedly contribute to food security (Gitonga *et al.,* 2013; Obeng-Ofori, 2011; Ndegwa *et al.,* 2016; Mutambuki *et al.,* 2012).

This study is, therefore to analyze the synergy effect of hermetic storage to control mould proliferation as well as mycotoxin contamination in safe and environmentally friendly system. The generated data from this study will facilitate sustainable adoption of the hermetic technologies among smallholder farmers in Sub Saharan Africa. This study suggests the ideal storage options for the small holder farmers considering the robustness and cost of the hermetic storage that will have been identified as effective and less expensive. The study also tries to answer the question of how the use of improved storage technology impact the quantity and quality of grain stored and also the length of storage while holding other factors constant at farmers' practice level.

2. Materials and methods

The trial was conducted at CIMMYT/KARLO Kiboko Research Centre (Makuen icounty), 170 km from Nairobi in a semi-arid region in Eastern Kenya. The trial site was selected for being a trouble spot for aflatoxin outbreaks in Kenya. Two factors were used in the design of this study: 1) low (12-13%) or high (14-15%) grain moisture levels; 2) ten storage technologies. The hermetic storage technologies under study were metal and plastic silos, while the hermetic bags were: Super Grain IV-RTM, AGRO-Z with pesticides, AGRO -Z without pesticides, PICS, Elite and ZeroFly. The two controls were two farmer practices, the standard woven polypropylene bags, one with grain treated with insecticide and one without insecticide treatment. The experimental design was a 2 x 10 randomized complete block design (RCBD) with 3 replications. The duration of the experiment was 4 months with non-destructive sampling at baseline and every 120 days afterwards. Each grain sample was divided in two for insect pest testing and mycotoxin analysis.

2.1 Sample collection and preparation

About one kilogram of sample was required for the analysis. Sampling was done from five different points, about 1 inch from the walls of the storage technology using a grain sampling spear. Sampling was done carefully not to puncture the linings of the bags and the spear cleaned with cotton dampened with 75% ethanol before sampling the next storage technology to avoid cross contamination. The sampled grain was transferred into the ziplock plastic bag and sealed carefully to exclude air. Three people were involved in the sampling procedure; one person opens the storage technology, draws samples and transfers to the plastic sample bags held by another person while the other person immediately tightly seals up the bag/silo.

2.2 Materials

The grain used for this study was of H614 and H618 hybrid, purchased from farmers in Nakuru county and Naivasha sub-county. The untreated grain was cleaned by sieving to remove chaff, broken and rotten kernels. At the onset of the experiment, the grain was mixed and conditioned at the appropriate moisture content before transferring in the respective study technologies.

2.3 Grain moisture

The high moisture content (14-15%) was achieved by subjecting the grain to high relative humidity and tests were carried out progressively to determine the required moisture contents. The grain spread on plastic sheet was sprayed with potable water for 1.5 to 2 days. The water was calculated from the formula below:

$$Quantity\ of\ water\ required\ (g) = weight\ of\ grain\ x\ \frac{mcf - mc}{100 - mc}$$

Where *mcf* is the final moisture content; and *mc* the initial moisture content (Kiburi *et al*., 2014).

To achieve the moisture range of 12-13%, the grain will be sun dried in the case their moisture content was above 13%.

Insects assessment

One kilogram of the grain was analyzed for the dead and the alive of insects. This was done to investigate whether the storage technologies are able to prevent entry of insects/encourage insects' activities. The number of live and dead insects, both adult weevils and larger grain borers was counted and recorded. The grains of the subsample were sorted into undamaged, damaged and discolored fractions. The number of kernels and the weight of each fraction were recorded to investigate the extent of damage if any as follows:

$$Discolored\ grain(\%) = \frac{Number\ of\ discolred\ grain}{Total\ number\ of\ grain} \times 100$$

$$weight\ loss(\%) = \frac{[(Wu \times Nd) - (D \times Nu)]}{Wu \times (Nu + Nd)} \times 100$$

Where W_u = Weight of undamaged grain; N_u = Number of undamaged grain; W_d = Weight of damaged grain and N_d = Number of damaged grain

Grain weight loss was determined by count and weight method (Boxall 1986).

Aflatoxin and fumonisin analysis

Aflatoxin and fumonisin levels were determined in each working sample collected at cero and four months after stocking using the VICAM method (VICAM Science Technology, 1998), as describe by (Fandohan *et al.*, 2005). Three samples from each bag were taken.

Statistical analysis

Variances of insect count, (x) was stabilized by log transformation Y=log(x+1) whereas percentage data (P) was arcsine Y=sin−1$\sqrt{P}$), transformed, where Y is the result of transformation. The transformed data was then be subjected to analysis of variance (ANOVA) using Stata SE version 12 (StataCorp LP, Texas, USA). Further due to inherent limitations of ANOVA in describing difference in progression of variables over time, the analysis of covariance (ANCOVA) which combines features of both ANOVA and regression were applied to test effects of treatment and storage duration, and the interaction effects. Means were separated using Bonferroni adjustment at 95% confidence level (Ognakossan *et al.*, 2014).

Results

Aflatoxin and fumonisin

Aflatoxin contamination increased with relative humidity in both hermetic and farmer practice storages at a significance level of P<0.001, it was also observed that aflatoxin contamination increased in all the inoculated storage technologies and very high in the farmer practice (Fig. 1 and table 3). The treatment type had an effect on the level of aflatoxin contamination at the significance level of <0.001 with the mean value of 2.93, 1.31, 2.59, and 1.65 for high humidity, low humidity, inoculated and in not inoculated grains respectively. The level of fumonisin contamination increased in woven storage bags while hermetic storage technologies reduced fumonisin contamination (Table 5 and 6). There was a relationship between moisture levels, mode of inoculation and the fumonisin contamination in the storage technologies with the grand mean of 0.315 and 0.275 respectively, Fig 2. However, there was not a significant difference observed between treatment and the level of fumosin contamination (Table 1). There was no interaction between the aflatoxin and the fumonisin P>0.05 but a strong correlation between the insects and the aflatoxin contamination at P<0.05 and the number of dead insects was linked with the type of storage where hermetic bags had less insects infestation than the farmer practice. At high relative humidity, the aflatoxin, fumonisin and insects was significantly high regardless of the mode of inoculation compared with the dry grains Fig.1.

Discussion

Hermetic storage technologies can be an effective solution to reduce insect infestation and mycotoxin contamination during on-farm storage, thereby reducing potential human and animal exposure to mycotoxins. However, if farmers do not adequately dry grain, even hermetic storage technologies may not be effective in the control of mycotoxin contamination, and contamination will be even greater underconventional storage systems. This observation is in agreement with Cotty (2007), who described water activity as one of the conditions that encourage aflatoxin development high levels of fumonism in woven bags could be attributed to large open spaces that allow for free flow of air hence contamination. Hermetic storage technologies restrict gaseous exchange and act as a barrier hence reduced contamination. There was a correlation between inoculation and insect infestation where insect infestation was higher in the maize that was not inoculated. This is because maize already infested with aflatoxin and fumonism may have reduced in the nutritional components and palatability desired by the insects. This is also agreeable with the findings that mycotoxins development increases with the insects activities in the grain (Munkvold, 2003). This work supports the promotion of both hermetic storage technologies and improved drying practices. Currently the analysis of samples after eight months of storage is ongoing and will also be presented.

Acknowledgement

I acknowledge the generous financial support from the International Wheat and Maize Improvement Center and its support staff in Kiboko research center for the invaluable work done in setting up the experiment and collecting the date. In the same way I am grateful for the support from the AgroZ company and Purdue University for the financial support offered during the final quarter of the experiment. Most importantly, I also acknowledge the Albert Baker Fund for my Masters sponsorship awarded for the two years program at the University of Nairobi.

Postharvest treatment research at USDA-ARS: stored product fumigation

Spencer S. Walse*#[1], Matthew Rodriguez[1], John S. Tebbets[1]

[1]USDA-ARS San Joaquin Valley Agricultural Sciences Center, 9611 S. Riverbend Avenue, Parlier, California, USA, 93648-9757

DOI 10.5073/jka.2018.463.123

Abstract

The overall goal of this USDA-ARS research is to ensure the protection and quality of stored product foodstuffs. The results of this research directly enhance production, distribution, and safety of foodstuffs, promote and retain access of United States-grown crops to domestic and foreign markets, and protect the United States and trading partners from the agricultural, ecological and economic threat posed by quarantine and invasive pests. In general, USDA-ARS research related to the fumigation of stored products focuses on the development of techniques to rapidly disinfest raw products of field pests, control pests in processed products amenable to re-infestation and microbial infection, and reduce reliance on fumigation as a stand-alone measure for postharvest disinfestations and disinfections. Specific research objectives include: comparative evaluation of alternative fumigants to methyl bromide in postharvest applications, development of novel technologies to reduce and eliminate atmospheric emissions from chambers used in postharvest fumigation, and design production strategies that allow for a more strategic postharvest use of methyl bromide and alternative fumigants. Recent research findings will be presented and discussed, including: exposure requirements of phosphine on key stored product pests (as related to resistance management), the establishment of efficacy and experimental criterion for quarantine applications, and the development of models to quantitatively understand the underpinnings of fumigations and related phytosanitary treatments.

Keywords: food security, food safety, quarantine treatments, postharvest methyl bromide

1. Introduction

The use of postharvest phosphine fumigation as a quarantine phytosanitary requirement is increasing coincident with the globalization of agriculture. However, operational and regulatory framework for implementing and certifying efficacious treatments have not bee firmly established. In this work we describe a postharvest fumigation with phosphine to control Warehouse beetle, *Trogoderma variable* (Ballion) (Coleoptera, Dermestidae), a pest of concern to certain countries that import Dried Distillers Grains (DDGs) from USA. A series of laboratory-scale exploratory fumigations with phosphine at 10.0 ± 0.3 ºC ($\bar{x} \pm 2s$) were conducted to evaluate the postharvest control of

eggs as well as diapausing larvae of *T. variable*, the most phosphine-tolerant life stages of this pest. Models of the duration-mortality response predicted >99% mortality when headspace concentrations of phosphine, [PH3], are maintained at levels ≥ 0.8 mgL^{-1} (500 ppmv) and ≤ 1.5 mgL^{-1} (1000 ppmv) for ≥ 120 h, as estimated by the lower boundary limit of the 95% confidence interval. A fumigation schedule is proposed based on the results of this research and the seminal studies of Vincent and Lindgren (1975) as well as Banks and Cavanaugh (1985). Data is presented and discussed in the context of controlling *Trogoderma variable* following commercial fumigations for export of DDGs.

2. Materials and Methods

Insects and egg collection

Specimens were cultured in the insectary at the United States Department of Agriculture-Agricultural Research Service (USDA-ARS), San Joaquin Valley Agricultural Sciences Center, Parlier, CA (USDA, 2012). Cultures were housed in an 15.2-m^3 rearing unit maintained at 27 ± 1°C ($\bar{X} \pm s$) and 60 ± 5% RH ($\bar{X} \pm s$) with a photoperiod of 16:8 (L:D) h, unless otherwise noted. Rearing procedures and diets, briefly mentioned below, were as reported in the Crop Protection and Quality Research Unit electronic rearing manual (USDA, 2012). Methods for collection of eggs and diapausing larvae are detailed below.

Warehouse beetle (WHB), *Trogoderma variable* (Ballion) (Coleoptera, Dermestidae), was originally collected in 1967 from whereabouts unknown in Fresno County, California USA. WHB adults (200 to 300) were transferred to a 946-mL glass jar filled with 20 to 25 g of a dried dog food substrate. The jar was sealed with filter paper (Whatman® #1, 90-mm diameter) followed by a wire screen (U.S. #40 mesh, 90-mm diameter) and both were secured a top the jar with a threaded metal ring. The jar was transferred to the rearing unit for a 72-h ovipositional period, after which, eggs were separated from the adults and flour using a stack of sieves (Seedburo Equipment Company, Des Plaines, IL). The contents of the jar were poured into the top sieve (U.S. #25, 0.71 mm^2 openings) and shaken vigorously for a few minutes. The eggs were retrieved from the underlying sieve (U.S. #60, 0.25 mm^2 openings) by decanting them into a glass Petri dish (100 mm diameter x 15 mm h). Counting eggs required for treatments was performed under the microscope by transferring small amount of eggs into a trough made out of black construction paper. Using a small, horsehair brush, ca. 100 eggs were transferred onto black velour paper that lined the inside of a 35-mm diameter Petri dish (Falcon, Oxnard, CA). Wheat bran diet (5 g), prepared as described in the rearing manual (USDA, 2007), was placed in each of several 10-cm diameter plastic Petri-dish cages. The diet was spread concentrically to the outer edge of each cage bottom and a single 35-mm Petri dish, containing the < 72-h old eggs, was placed in the center of the void. After fumigation treatment, or concomitant use as non-treated control specimens, the Petri-dish cages were lidded.

As described in Banks and Cavanaugh (1985), larvae known to be in diapause were obtained by isolating single larvae taken from stock cultures. Each larvae was introduced, along with 0.5 g of diet, 7-dram clear plastic "snap cap" cages modified with 8-mm diameter stainless-steel 100 wire mesh gas-portals on the bottom, snap cap, and side. The cages were incubated at 30 ± 1°C ($\bar{X} \pm s$) and 60 ± 5% RH ($\bar{X} \pm s$) with a photoperiod of 16:8 (L:D). Larvae that had not metamorphosed after 6 wk were considered to be in induced diapause, as described by Burges (1961, 1965).

Chemical Analysis and calibration of standards

Cytec Canada, Inc. (Niagara Falls, Ontario, Canada) provided the 300-lb cylinders of 1.6 % (v/v) phosphine balanced with nitrogen. A source cylinder (300-lb) of breathing air was obtained from Airgas (Fresno, CA, USA). The 1.6% PH3 mixture was used as the source for gas chromatography calibrations and the exploratory fumigations. [PH3] and steady-state concentrations thereof, $[PH3]_{ss}$, were measured using gas chromatography (GC); retention time (PH3, t_r = 3.2 ± 0.2 min, $\bar{X}$

$\pm s$, n = 10) was used for chemical verification and the integral of peak area, referenced relative to liner least-squares analysis of a 5-point concentration – detector response curve, was used to determine concentration. Detector response was determined by diluting known volumes of gases into volumetric gas vessels. A response curve was generated respective to each sampling interval with each sample referenced to the response. [PH3] levels were reported as average (±) standard deviation ($\overline{X} \pm s$) from duplicate measurements (vide infra). Analyses were with a Varian 3800 and splitless injection (140 °C) using a gas sampling port with a 10 μL-sample loop, a Teflon column (L = 2 m, OD = 2 mm) packed with Porpak N (80/100 mesh) held at 130 °C for 10 min, and a pulsed flame photometric detector (PFPD) detector (13 mL/min H_2, 20 mL/min air, and 10.0 mL/min N_2 make-up) at 250 °C that received only 10% of the 15 ml He/min column flow.

Exploratory fumigations

Laboratory-scale exploratory fumigations were conducted in a matching set of 24 Labonco® 28.32-L vacuum chambers housed in a walk-in environmental room with programmable temperature and humidity (USDA, 2010). Temperature and humidity set-points were 10.0 °C and 80% RH, respectively. A series of exploratory experiments was used to determine the treatment duration, ranging from 24 to 168 h, required to control larvae with applied doses, and subsequently, steady-state concentrations of phosphine in chamber headspace (i.e, $[PH3]_{ss}$) of ca. 250 (0.4), 500 (0.8), 1000 (1.5), or 2500 ppmv (μLL^{-1}) (3.7 mgL^{-1}) phosphine, respectively. Each of five chambers was loaded with an egg dish; four of the chambers were, respectively, subject to the phosphine treatments above and the fifth was not fumigated to yield non-treated control specimens. In addition, the control chamber and the chamber treated with 1000 ppmv (μLL^{-1}) (1.5 mgL^{-1}) $[PH3]_{ss}$ were loaded with 30 caged larvae. Each "block" of five chambers was subject to treatment durations of 24, 48, 72, 96, 120, 144, and 168 h. Each "block" was conducted in triplicate, which yielded a total of ca. 300 eggs at each $[PH3]_{ss}$ and each treatment duration, as well as 90 larval specimens treated with 1000 ppmv (μLL^{-1}) (1.5 mgL^{-1}) $[PH3]_{ss}$ at each treatment duration. This design corresponded to a total of 630 and ca. 2100 control larvae and eggs, respectively.

Loaded chambers, 300-lb source cylinders of breathing air (Airgas, Fresno, CA, USA) as well as 1.6 % (v/v) phosphine balanced with nitrogen, and gas-tight syringes were acclimated to fumigation temperature (i.e., tempered) within the walk-in environmental room for at least 24 h prior to treatment. Air temperature in the walk-in room was confirmed prior to fumigation by a HOBO data logger (HOBOware version 2.7). Chamber lids were then clamp-sealed in preparation for treatment. A slight vacuum of approximately 76-127 mmHg was established in each chamber. Gas-tight super-syringes (Hamilton ® 500, 1000, or 1500 mL) were filled with a volume of phosphine from the 300-lb source cylinder of 1.6 % (v/v) phosphine to achieve the requisite dose as predetermined in preliminary calibration studies. The syringe was fitted to a LuerLok ® sampling valve, which was subsequently opened so that fumigant was steadily drawn into the chamber. The syringe was then removed and normal atmospheric pressure (NAP) was reestablished; this marked the beginning of the exposure period.

Flow from 300-lb source cylinders of breathing air (Airgas, Fresno, CA, USA) and 1.6 % (v/v) phosphine were metered, respectively, into each of four gas blending manifolds (Aalborg Model G gas proportioner meter) that allowed for tunable $[PH3]_{ss}$ to exit the manifold, and ultimately enter a respective chamber. Exit flow from the manifold, which totaled 25 $mLmin^{-1}$ regardless of $[PH3]_{ss}$ (i.e. breathing air was the make-up gas), was directed to the input port/valve on the chamber; ¼'-diameter Teflon tubing was used for all plumbing and all connections were with standard stainless-steel Swedgelock fittings, unless otherwise noted. Flow exiting the chambers was directed through a LuerLok® sampling port into a centralized ventilation system (USDA, 2010). $[PH3]_{ss}$ and air inputs were tuned to the desired level in preliminary calibration studies, prior to the introduction of any test specimens into the chamber.

A gas sample of the chamber headspace was acquired using the LuerLok® sampling valve, which accessed the effluent of the respective chambers. A B-D® 100-mL gas-tight syringe was allowed to slowly fill to ~ 40 mL with the chamber effluent. Contents of the syringe were quantitatively analyzed with gas chromatography (GC) as described below. In the exploratory fumigations, the standard sampling interval for measurement of $[PH3]_{ss}$ was at 0.12 h (initial) and every 12 h thereafter through the duration of the treatment. Carbon dioxide and oxygen concentration were measured with a gas sampling pump connected in series between a port accessing chamber effluent and an atmospheric gas analyzer (GFC-7000E, Teledyne Instruments, City of Industry, CA), which recorded at standard temporal intervals over the duration of treatment.

After the final sampling of $[PH3]_{ss}$, cylinder valve-stems were shut, thereafter inputs of breathing air and phosphine ceased, chamber valves were opened to atmosphere, and a 30-min aeration period was initiated. Chamber lids were then opened and the treated as well as non-treated specimens were retrieved and transferred to an incubator at 27.0 ± 1.0 °C and 80 ± 2% RH ($\overline{X} \pm s$) in prelude to mortality evaluation (vide infra).

Mortality evaluation

Mortality of diapausing larvae was diagnosed visually by discoloration, while survivability was diagnosed by locomotion or by prodding-induced motion 14 to 21 d post treatment. Ultimately, however, evidence of pupation served as diagnostic of survival. Egg mortality assessments were conducted using a dissecting microscope (8 to 10 x magnification) 14 d after treatment, as the 5 to 7 days typically required for hatching was delayed due to physiological suppression at the 10°C treatment temperature.

Mortality was calculated as a percentage of the response per treatment. Mortality of control specimens was assumed to be equal to that in fumigation trials, per the method of Abbott (1925), and was included as a natural response in modeling the efficacy results from exploratory trials. The total number of specimens that were treated for each exploratory-trial was estimated by summing the numbers treated, while the total number of specimens treated (*n*) across exploratory-trials was estimated by summing the numbers from each respective trial. Mortality was analyzed via probit analysis of Finney (1944 & 1977) at the 95% confidence level, as further derived in Couey and Chew (1986) as well as Liquido and Griffin (2010).

3. Results

Exploratory fumigations

The average air temperature ($\overline{X}$), 10 °C, was calculated across all trials. Deviation in temperature was assumed to follow a normal distribution with the estimated margin of error reported as ± 2*s*, 0.3 °C, the 95% confidence interval (Quinn, 1983). Of the 630 untreated diapausing larvae, only 24 expired with no more than 3 deaths per 30-specimen control grouping. As for mortality in 2,106 untreated eggs, 45 expired with no more than 5% mortality in each control grouping of ca. 100. While the control mortality of the diapausing larvae was consistent with previous reports (Banks and Cavanaugh, 1985), control mortality of eggs was ~15 % less than observed by Vincent and Lindgren (1975).

Respective duration-mortality regressions for (applied doses and) $[PH3]_{ss}$ of 250 (0.4), 500 (0.8), 1000 (1.5), or 2500 ppmv (μLL^{-1}) (3.7 mgL^{-1}) were modeled using Polo Plus (LeOra Software, 2002-2007) with the mortality of control specimens included as a natural response. The number of egg specimens treated (250 ppmv: 2105 subjects; 500 ppmv: 2112 subjects; 1000 ppmv: 2109 subjects, 2500 ppmv: 2093 subjects), the regression heterogeneity (H), the projected durations to cause 50, 95, and 99% mortality in the treated population (respectively LT_{50}, LT_{90}, and LT_{99}), and the bounds (upper (UL) and lower (LL) limits) at the 95 % confidence level (CL) are shown in Figure 1. Likelihood ratio-based hypothesis testing of equality was rejected ($P < 0.05$, $\chi^2 = 621$, $df = 6$), indicating that the

slopes as well as the intercepts of the regressions respective to $[PH3]_{ss}$ were significantly different. Likelihood ratio-based hypothesis testing of parallelism was rejected ($P < 0.05$, $\chi^2 = 44.7$, $df = 3$), indicating that the slopes of the regressions respective to $[PH3]_{ss}$ were significantly different.

Fig. 1 Mortality of warehouse beetle, *Trogoderma variable* (Ballion), eggs following phosphine fumigation at 10.0 ± 0.3 ºC ($\bar{x} \pm 2s$) and probit regression analyses (Polo Plus, LeOra Software, 2002-2007) of the duration-mortality response respective to applied doses and steady state headspace concentrations, $[PH3]_{ss}$ of ca. 250 (0.4), 500 (0.8), 1000(1.5), or 2500 ppmv (μLL^{-1}) (3.7 mgL^{-1}), showing the number of specimens treated, the regression heterogeneity (H), the projected durations to cause 50, 95, and 99% mortality in the treated population (respectively LT_{50}, LT_{90}, and LT_{99}), and the corresponding estimates of the bounds (upper (UL) and lower (LL) limits) at the 95 % confidence level (CL).

Lethal time ratios (LTRs) were calculated with (+/-) 95 % confidence intervals (CI) across the durations projected to cause 10 to 99% mortality in the treated population. Figure 2 shows that fumigation with $[PH3]_{ss}$ of 250 or 2500 ppmv required longer treatment durations, relative to 1000 ppmv, to yield the same egg mortality response as noted by respective LTRs < 1 (unity) (Fig. 2). On the other hand, the LTRs for $[PH3]_{ss}$ of 500 ppmv overlapped or superseded a value of 1 (unity) respective to all projected durations > LT_{10}, indicating that time required for a particular percentage of egg control is equivalent when $[PH3]_{ss}$ is 500 or 1000 ppmv.

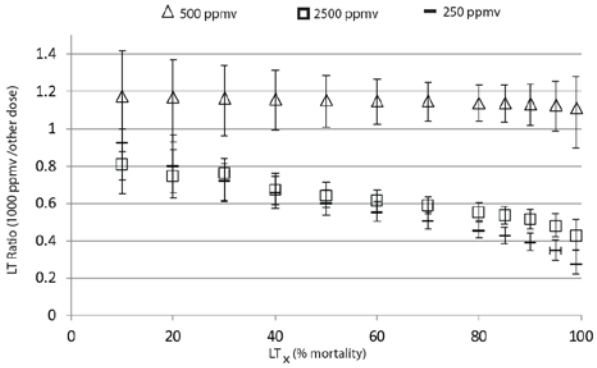

Fig. 2 Lethal time ratios (LTRs) associated with steady-state headspace concentrations, $[PH3]_{ss}$, of ca. 250 (0.4), 500 (0.8), 1000 (1.5), or 2500 ppmv (μLL^{-1}) (3.7 mgL^{-1}) were calculated ± 95% confidence intervals across the treatment durations projected to cause 10 to 99% mortality in the treated population of warehouse beetle, *Trogoderma variable* (Ballion), eggs. LTRs respective to durations predicted to yield >10% mortality overlapped a value of 1 (unity) for 500 ppmv, indicating that maintaining $[PH3]_{ss}$ at 500 ppmv was no more efficacious than maintaining $[PH3]_{ss}$ at 1000 ppmv levels. However, LTRs were less than a value of 1 (unity) for 250 and 2500 ppmv, indicating that these treatments required significantly longer durations to evoke an equivalent response in the treated populations, relative to treatments with $500 \leq [PH3]_{ss} \leq 1000$ ppmv.

Additionally for a $[PH3]_{ss}$ of 1000 ppmv, LTRs were calculated ± 95% confidence intervals across the treatment durations projected to cause 10 to 99% mortality in the treated population of eggs and diapausing larvae. LTRs respective to durations predicted to yield >10% mortality overlapped a value of 1 (unity), indicating that equivalent treatment durations resulted in equivalent response of eggs relative to diapausing larvae (Fig. 3). This finding is consistent with that of Banks and Cavanaugh (1985) in that neither study establishes diapausing larvae as being more phosphine-tolerant than eggs, which are clearly more phosphine tolerant than all other life stages of *T. variable* (Vincent and Lindgren, 1975).

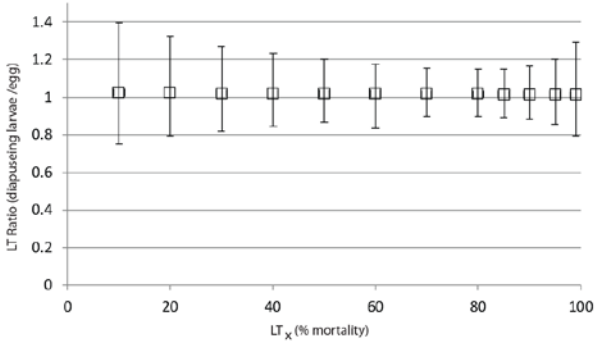

Fig. 3 Lethal time ratios (LTRs) associated with steady-state headspace concentrations, $[PH3]_{ss}$, of 1000 ppmv (μLL^{-1}) (1.5 mgL^{-1}) were calculated ± 95% confidence intervals across the treatment durations projected to cause 10 to 99% mortality in the treated population of warehouse beetle, *Trogoderma variable* (Ballion), eggs and diapausing larvae. LTRs respective to durations predicted to yield >10% mortality overlapped a value of 1 (unity), indicating that equivalent treatment durations resulted in equivalent response of eggs relative to diapausing larvae.

Figure 4 shows the projected durations to cause 99% mortality in the treated population (LT_{99}) of eggs varies as a function of $[PH3]_{ss}$. To rationalize this result, note the seminal work of Winks on phosphine (1984, 1985, 1986, 1994) as related to Haber's Rule ($C^z t = \omega$), which forms the basis for relating concentration (C) and time (t) to toxicological efficacy (ω), at least with respect to fumigation science (Bliss, 1940; Miller et al., 2000). For phosphine, z, the response evoked by a

specific toxicant in a particular organism, changes with *C*. When considering data on mortality collected at "fixed" concentrations over varying times, such as was done in the exploratory fumigations, the applied dose correlative to the onset of deviation (i.e., change in *n*) is termed the "narcosis threshold", the concentration above which further change in z results in the narcotic effect of phosphine and an increased tolerance. Recently, the work of Walse et al. (2013, 2016, 2017) has expanded on the concept of the "narcosis threshold" in the context of quarantine treatments as well as mitigation strategies for phosphine resistance. The results from the exploratory studies indicates the "narcosis threshold" of *T. variable* eggs spans the range 500 ≤ $[PH3]_{ss}$ ≤ 1000 ppmv and is centered at 750 ppmv.

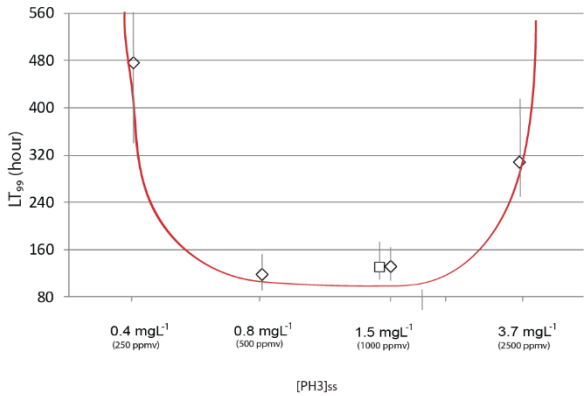

Fig. 4 The projected durations to cause 99% mortality in the treated population (LT_{99}) of warehouse beetle, *Trogoderma variable* (Ballion), eggs (◇) varied as a function of steady-state headspace concentrations, $[PH3]_{ss}$, over the range 250 to 2500 ppmv. However, an equivalent mortality response was observed when at $[PH3]_{ss}$ of 500 and 1000 ppmv, indicating that variability in $[PH3]_{ss}$ within the range 500 ≤ $[PH3]_{ss}$ ≤ 1000 ppmv, will not change the efficacy of fumigation. It is critical to note that the predicted duration required to control 99% of a treated population of diapausing larvae (□) is equivalent to that required for eggs. Error bars are the estimates of the upper (UL) and lower limits (LL) at the 95% confidence interval (see Fig. 1). The "narcosis threshold" for *T. variable* (Ballion) eggs spans the range 500 ≤ $[PH3]_{ss}$ ≤ 1000 ppmv as indicated by horizontal portion of the red trace.

The LL (95% CL) of the durations predicted to cause 99% mortality in the treated population (LT_{99}) of eggs and diapausing larvae were ca. 120 h. Moreover, none of the specimens (1,815 eggs & 270 diapausing larvae) survived fumigation with 500 ≤ $[PH3]_{ss}$ ≤ 1000 ppmv for a duration ≥ 120 h, results that suggest fumigation at ≥ 10.0 ˚C will control *T. variable* infestations if [PH3] is maintained at ≥ 500 and ≤ 1000 ppmv for a duration ≥ 120 h. In general, an increase in treatment temperature is commensurate with an increase of insect metabolism and increase in the efficacy of a fumigant (Monro, 1969). The work of Vincent and Lindgren (1975) supports this conclusion with respect to *T. variable*, as fumigation at 21.1 ºC with 500 or 750 ppmv for 72 h resulted in complete mortality of 1- to 6-d old eggs. Collectively, results provide the technical framework of a fumigation schedule:

Phosphine concentration maintained at 750 ppmv (μLL^{-1}) (1.1 mgL^{-1}) or higher for 72 h or greater at commodity temperature of 20.6 ºC or greater

Phosphine concentration maintained at 750 ppmv (μLL^{-1}) (1.1 mgL^{-1}) or higher for 96 h or greater at commodity temperature of 15.0 ºC but less than 20.6 ºC

Phosphine concentration maintained at 750 ppmv (μLL^{-1}) (1.1 mgL^{-1}) or higher for 120 h or greater at commodity temperature of 10.0 ºC but less than 15.0 ºC

4. Discussion

The use of postharvest phosphine fumigation as a quarantine phytosanitary requirement will only increase in years to come. Here we provided operational and regulatory framework for

implementing and certifying efficacious treatments. Although ISPM 27 ultimately leaves efficacy acceptance criterion to the discretion of the importer, interantional scientific consensus helps guide such reguialtory decisions.

Quantifying grain storage structure leakage by testing effects of environmental conditions on pressure loss

Carol Jones*, Taylor Conley

Abstract

A major concern in grain storage and management facilities is the effective control of insects and pests that reside in stored grain. Currently, the best studied method of subduing these insects is fumigating the grain bins with phosphine. However, many grain storage insects have developed a resistance to phosphine due to its misuse over the years, partially due to bin leakage, leading to minimum pest control in grain and increased product damage. The first step in managing the issue of fumigant leakage is by identifying environmental conditions that may impact the bins' total air loss, and ultimately, fumigant loss. One way to quantify the leakage potential of a structure is to perform pressure tests. Data collected from these tests statistically quantify the significance of atmospheric conditions on bin leakage, as well as quantify leakage area in the bin. These tests were performed on a 500 bushel grain bin filled with canola seed, sealed with plastic sheeting and Gorilla duct tape. A PVC pipe "arm" and shop vacuum (Shop-Vac® 5-gallon 6-Peak HP) contraption was designed for pressure application. Constant pressure testing methods were performed to collect data for calculations of leakage area. Tests were repeated in varying environmental conditions. Data analysis included performing single sample t-tests to determine significance of environmental conditions, as well as using previously established relationships to quantify predicted leakage area in each scenario. It was concluded that atmospheric conditions significantly affect gas leakage from structures ($p < 0.001$), so pressure test conditions should match fumigation conditions for an accurate initial fumigant dosage. Constant pressure tests accurately predict equivalent leakage area of bin, with areas demonstrating a variance of 3.4×10^{-5}. Future tests to improve fumigating processes could include relationships between phosphine concentration and the leakiness of the bin, as well as automated constant pressure testing devices.

Keywords: Phosphine resistance, fumigation, grain storage, leakage area, pressure testing.

1. Introduction

With populations across the world continuing to grow at an exponential rate and increasing life expectancies, it is inevitable that food production and storage will need to be continuously innovated to meet this growing need. One method that has been used for centuries is storing agricultural products, such as grain, as long as possible to ensure they are available when needed after harvesting season. Grain is known to last for long periods of time in storage facilities after drying due to lower moisture content. Nevertheless, it is still susceptible to damage from pests. The most effective way of controlling these pests is by utilizing fumigants and chemicals to eradicate their populations before the grain incurs too much damage. Over the years, the public has developed a growing concern regarding their foods, especially unfamiliar chemicals. Despite adverse public response, some chemicals, such as fumigants (i.e., phosphine, methyl bromide, etc.), are necessary to keep food products safe from disease-carry pests, specifically in stored products such as grain. These pests are not just detrimental to the fate of stored grain, but they have also proven extremely difficult to eradicate from the storage bin due to their resistance to most toxic chemicals. Grain pests include: *Rhyzopertha dominica* (F.), commonly known as the lesser grain borer; *Sitophilus oryzae* (L.), the rice weevil; *Tribolium castaneum* (Herbst.), also known as the red flour beetle; and *Oryzaephilus surinamensis* (L.), the saw-toothed grain beetle. While there are many other stored product insect pests, the aforementioned are four of the more commonly studied species. Not only do the insects damage the grain, they also leave waste product in the grain, which quickly diminishes the quality of grain. If left untreated, these insects have the ability to cause detrimental damage on the grain they are infesting.

One of the most common and cost effect methods of eliminating insects from grain is through fumigation. Attempts to eradicate pests through fumigation involve introducing a chemical toxic to the pests, such as phosphine or methyl bromide. However, due to its ozone-depleting properties,

methyl bromide has been banned as a fumigant in developed countries. Sulfuryl fluoride is a fumigant that is gaining popularity, but phosphine is still the most commonly used fumigant worldwide due to its low cost and minimal residue on treated grain. Moreover, due to incomplete fumigations using phosphine, grain storage pests have developed resistance (Daglish, 2004; Lorini et al., 2007; Price, 1984). A cause of incomplete fumigation is leakiness in grain storage structures. One way to predict the leakage area of grain storage structures prior to fumigation is by performing pressure tests, such as half loss time or constant pressure tests. Half loss pressure tests, also known as half loss time (HLT) have been used extensively in many studies (Chayaprasert et al., 2012), but it has been proven to not be the most reliable method of predicting the estimated leakage area from the bin (Mann et al., 1999). In this study, the constant pressure testing method is utilized since it has potential to be a more reliable method of pressure testing. It is also known that there is an expected correlation between atmospheric conditions, such as wind speed, temperature, and relative humidity, but previous studies have not used field trial data to statistically quantify this correlation (Chayaprasert et al., 2009). Therefore, this study will focus on using constant pressure testing methods to determine whether atmospheric conditions significantly affect gas leakage from grain storage structures, as well as estimating the leakage area using constant pressure data to predict a more accurate phosphine dose to reduce development of insect resistance.

2. Materials and Methods

Initial bin modifications

A selected grain storage bin at Oklahoma State University's Stored Product Research and Education Center (SPREC) was modified prior to testing. Modifications included drilling a hole and developing an extension arm that allowed for a shop vacuum hose to connect to the headspace of the bin (Fig. 1). The selected grain bin was a 500 bushel (12.5 metric tonnes approximately) steel bin bolted to a concrete slab and filled with canola seed. External valves correlated with various depths of the bin were already installed, and were used in the experiments to measure gauge pressure. To create an opening for an airflow source to perform pressure testing, a 1 ½ inch hole was drilled into the headspace of the bin. A 1 ½ inch PVC pipe fitting was then sealed into the hole using silicone caulking. To keep out moisture and other atmospheric conditions between testing, a cap was placed over the fitting. In order to create a path for air to flow from a pressurization source (shop vacuum) to the bin, a 90° elbow, which connected to the fitting in the headspace, was attached to one end of a three foot section of 1 ½ inch PVC pipe. A 60° PVC elbow was attached to the other end to connect a seven foot section, which went down the outside wall of the bin. To control airflow going into the bin (for the constant pressure/variable flow testing), a PVC ball valve fitting was attached to the other end of the seven foot PVC section. All PVC connections were made using PVC primer and cement. The arm was utilized to pressurize the bin by sealing the end of the shop vacuum hose to the ball valve using Gorilla duct tape.

Fig. 1 Extension arm created from PVC pipe to extend down side of bin for pressurization using shop vacuum

Fig. 2 HOBO Wind Speed Smart Sensor attached to top of pole to measure wind speed free from obstruction

Constant pressure tests with varying weather conditions

In order to correlate grain bin leakage with weather conditions, added instrumentation was installed to measure relative humidity (r.h.) and temperature inside and outside of the bin, and wind speed outside of the bin. To measure wind speed, an Onset HOBO® Wind Speed Smart Sensor was attached to a 15 foot pole (Fig. 2) near the grain bins and above obstructions. An Onset HOBO® micro station data logger was connected to the wind speed sensor to record wind speed data. Temperature and r.h. were measured using Onset HOBO® Pro v2 temp/RH sensors. One of the sensors was placed outside next to the bin according to manufacturer's directions. The second sensor was taped to the inside entry latter of the bin with Gorilla duct tape. All sensors were launched using HOBOware v. 3.7.8 and were programmed to take measurements once every 30 seconds starting at the time of each test.

There were four varying weather conditions in which the constant pressure tests were performed: hot and windy, hot and still, cold and windy, and cold and still. Conditions for each test can be seen in Table 1. Constant pressure tests were conducted by first resealing the aeration fan intake and the hatch entrance with tape and double-layered plastic sheets. Other leakage-prone areas that were previously sealed with tape were re-sealed prior to testing. Next, the extension arm was inserted into the headspace of the bin, and the shop vacuum hose was securely sealed to the ball valve. A Pitot tube was inserted upstream of the ball valve in the extension arm, and worked in conjunction with a Fluke 922 Airflow Meter to measure the air velocity going into the bin. Testing began by turning the shop vacuum on with the ball valve 100% open, and monitoring the U-tube manometer until a constant pressure was reached. As soon as the pressure stabilized, a timer was started and the air velocity was measured and recorded. For each varying weather condition constant pressure test, five trials were performed at each ball valve position, where air velocity and pressure data were collected once every thirty seconds for 15 minutes. To create control data, additional testing was performed on a day with an average temperature of 75°F and average wind speed greater than 8 mph and less than 10 miles per hour. Five trials were performed by adjusting the ball valve position to vary the air velocity. Once the pressure readings from the inside of the bin stabilized, the pressure value was recorded as well as the average air velocity at that pressure. Ten data points representing different input air velocities and stabilized internal bin pressures were collected for each test. A total of five tests were performed to create a standard curve for predicted pressure retention at given input air velocity into the bin.

Statistical analysis of effects of weather conditions on air leakage

Single sample t-tests with a confidence interval of 0.005 were performed in order to statistically quantify the effect of varying weather conditions on gas leakage rate from bins during pressure testing and fumigation. A standard model to predict pressure retention in the bin at a given input air velocity was developed using data from the neutral conditions (average temperature of 75°F and wind speed of no less than 8 mph, and no greater than 10 mph). This model was developed by plotting the data in a scatter plot, then matching a curve to the data. The resulting equation can be useful for this particular bin to decide if the bin is sealed to a standard level according to its pressure retention with a given input velocity. However, in this case, it was used to determine if weather conditions significantly affect gas leakage rate from bins. Average velocity for each stabilized pressure was calculated in order to perform t-tests on the data collected from the varying weather conditions. T-tests compared the average velocities needed to maintain the stabilized pressures for each weather condition with the predicted pressure that should be maintained at the given velocity, taken from the developed standard model.

Determining estimated leakage area (ELA) from constant pressure tests

In a previous study by Lawrence et al. (2012), ELA was calculated using constant pressure tests on a flour mill using Equation 1:

$$A_L = 10{,}000 Q_r \frac{\sqrt{\rho / 2 p_r}}{C_D}$$

[Eq. 1]

Where A_L is the predicted leakage area (cm^2), Q_r is the airflow rate (m^3/s), ρ is the air density (1.15 kg/m^3), p_r is the reference pressure (inch H_2O, $P_{gauge} - P_{atm}$ in this case), and C_D is the discharge coefficient (0.61 in this case, taken from Mann et al., 1999). This same equation was used to determine the ELA of the tested grain bin from constant pressure test data. Air flowrate was calculated by multiplying the input velocity by the diameter of the drilled hole in the headspace of the bin (0.0312 m^2). Air velocity values for Q_r that were used for this model were the average flow rates for each weather condition, and p_r was the correlated constant pressure with the air flowrate.

3. Results

Results from single sample t-tests

Weather conditions were tested on days with the conditions seen in Table 1:

Tab. 1 Weather conditions (temperature and wind speed ranges) for constant pressure test to ensure varied weather data to correlate with gas leakage rate.

Weather Condition	Avg. Wind Speed Range	Avg. Outside Temperature Range
Hot & Windy	> 10 mph	> 80°F
Hot & Still	< 8 mph	> 80°F
Cold & Windy	> 10 mph	< 70°F
Cold & Still	< 8 mph	< 70°F

After collecting data from constant pressure tests for all varying weather conditions and control data, the control data was plotted to develop a model to predict the ideal relationship between input air velocity and the maintained constant pressure at that velocity:

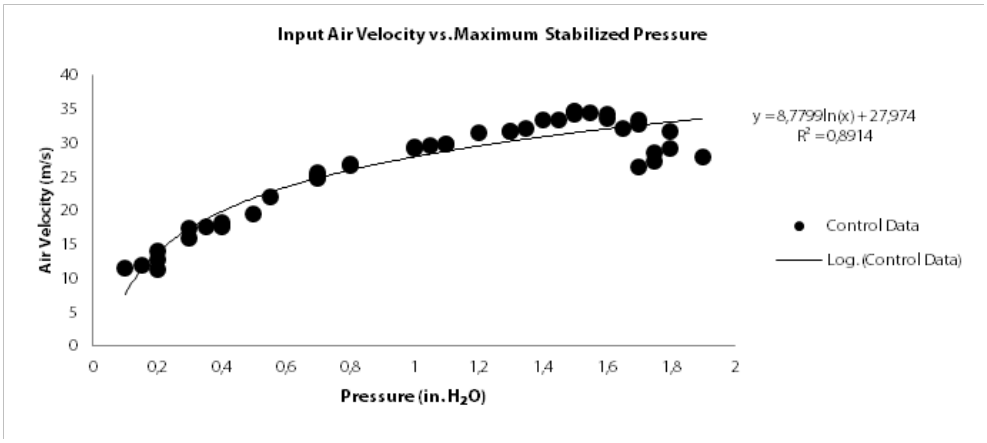

Fig. 3 Model of control data for constant pressure test.

The logarithmic equation developed from this model was used to predict the air velocity at the given constant pressure. Constant pressure test data from varying weather conditions were then compared to these predicted values. Single sample t-tests compared the predicted pressure for the average measured input air velocity with the actual maximum stabilized constant pressure maintained during the testing period. T-tests were performed for each constant pressure observed for each varying weather condition. The resulting p-values indicated if the weather factors had a significant impact on air leakage from the bin based on the maximum pressure that can be achieved in ideal weather conditions compared with maximum pressure maintained at the same input air velocity/flowrate in non-ideal conditions.

Tab. 2 Results from t-tests for constant pressure test in varying weather conditions, comparing theoretical constant pressures with actual constant pressures maintained in non-ideal weather conditions.

Weather Condition	Air Velocity (m/s)	Pressure (in.H_2O)	p-value
Hot and Windy	32.887	1.75	<0.0001
Hot and Windy	31.534	1.5	<0.0001
Hot and Windy	26.015	0.8	<0.0001
Hot and Windy	13.843	0.2	<0.0001
Cold and Windy	32.101	1.6	<0.0001
Cold and Windy	31.297	1.46	<0.0001
Cold and Windy	27.431	0.94	<0.0001
Cold and Windy	13.843	0.2	<0.0001
Hot and Still	23.489	0.6	<0.0001
Cold and Still	26.443	0.84	<0.0001

Predicted equivalent leakage areas (ELA) were also calculated using these same averages from the constant pressure test data in varying weather conditions to validate that constant pressure testing is an accurate method of estimating the ELA. Using Eq. 1, the ELA was calculated for each average input air velocity measured from the varying weather condition data.

Tab. 3 Estimated ELA for the same bin under varying weather conditions.

Q_r (m^3/s)	P_{gauge} (Pa)	A_L (m^2)
1.03	435	0.06
0.98	373	0.06
0.81	199	0.07
0.43	50	0.08
1	398	0.06
0.98	363	0.06
0.86	234	0.07
0.43	50	0.08
0.73	149	0.07
0.83	209	0.07

Average predicted ELA from this data is 0.07 m^2, with a standard deviation of 0.006 and variance of 3.4×10^{-5}.

4. Discussion

From the calculated p-values, it is evident that weather conditions significantly impact the air leakage rate from grain storage structures. This indicates not only that a higher dosage of phosphine (or other fumigant) may be needed in non-ideal conditions, but also that the atmospheric conditions at which the pressure testing takes place should match the conditions during the fumigation period for a more effective fumigation. Constant pressure testing used as a method of predicting leakage area from a grain storage structure is further validated by using the varying weather data to calculate the estimated ELA. The resulting ELA demonstrated low variance (3.4×10^{-5}), even though the air leakage rate from the same bin varied significantly with weather conditions. For future fumigations, constant pressure testing should be considered as not only a viable but more accurate method of estimating ELA than pressure HLT testing. Fumigations that utilize data from constant pressure testing to calculate the initial phosphine dose are likely to be more effective, and thus reduce the development of insect resistance to phosphine in grain storage. Future studies will automate the constant pressure test, as well as correlate initial phosphine dosage with leakage area predicted from constant pressure tests.

Abstract

A major breakthrough of Nigerian Stored Products Research Institute (NSPRI) is in the development of Inert Atmosphere Metal Silo (IAMS) in bulk grain storage for suitability of the climate, adoption and utilization in Nigeria. This technology uses nitrogen gas to achieve a controlled atmosphere (N2-CA) or environment for the control of stored products pests infestation and damage. Achieved 100% mortality of all life adults and immature stages of stored products insect pests; inhibited mould growth, maintained biochemical composition of stored grain and germinability (85% -91%) recorded at 12 months of storage. The system has been used to effectively store white maize, groundnut, Ife brown cowpea, wheat, paddy rice and yellow sorghum for periods of 12 – 48 months. The only system that has ability to store cowpea which cannot be stored in conventional silos. Research activities commenced from laboratory trials to pilot scale and later to medium and commercial levels. Shading the IAMS top against direct sun effect with palm fronds or hood for insulation prevented moisture migration and condensation, and maintained temperature below 30 °C in stored grain. A return per unit on investment of 0.44 was recorded when utilized for storage of wheat for a period of 48 months. IAMS has economic advantages over conventional silos which require frequency of pesticides application, turning of grains to prevent caking, food poisoning and high cost of labour. The recent utilization of this technology is due to increased awareness and demands for availability of grains for food safety, quality and nutrition. IAMS is being taken up by some entrepreneurs, marketers and Landmark University, Omu-Aru, Kwara state for grain storage in Nigeria. This technology is available for use at smallholder, medium, commercial and strategic grain reserve levels. Three and half decades of application of IAMS technology in grain storage in Nigeria is discussed.

Keywords: Inert atmosphere metal silo (IAMS), Nitrogen, grain storage and quality, control of pests, utilization.

1. Introduction

The Nigerian Stored Products Research Institute (NSPRI) is one of the National Agricultural Research Institutes (NARIs) in Nigeria, being supervised by Agricultural Research Council of Nigeria (ARCN)

and a parastatal under Federal Ministry of Agriculture and Rural Development (FMARD). NSPRI has been conducting research in technology development suitable for postharvest handling, storage and preservation of grains for food safety and quality for over fifty years. Nigeria is the world largest producer of cowpea. Other cereal and pulses grains are produced in large quantities and consumption of safe and quality food for good nutrition and health is imperative. Research into use of phosphine and other conventional insecticides shoed that several insect pests have developed resistance ([1]). In late 1970s Nigerian Stored Products Research Institute (NSPRI) has developed improved warehouse, improved ventilated maize cribs and hermetic grains storage bags/containers ([2,3]). These technologies are not only effective in reduction of postharvest loss in cereals and pulses but reduce the impact of aflatoxin contaminations ([4]). However, handlers and operators are exposed to health hazards, poisoning and resistance to pesticides by stored products pests are developed ([5,6]). In 1980 the need for alternate pest control became imperative and the Institute in line with best global practices developed a non-chemical technique for storage of agricultural produce. Researches started with laboratory trials on susceptibility and insect infestations in mini IAMS of 0.65m^3 and 4-ton volumetric capacity; to pilot scale of 45 ton volumetric capacity in Ibadan for storage of maize ([7,8,9,10,11,12]). Due to 2006 bean scare incident due to reckless misuse and abuse of pesticides for control of stored products pests by the farmers and grain aggregators in Nigeria, which resulted in accidental poisoning and deaths, NAFDAC one of the regulatory agencies banned importation and use of pesticides in stored products food ([13]). NSPRI seized the opportunity and stored cowpea under nitrogen in a 45-ton volumetric capacity Inert Atmosphere Metal Silo (IAMS) at NSPRI Ibadan. The release of the stored cowpea in 2008 attracted Federal government intervention in construction of other battery of 2 units of 50-ton volumetric capacity IAMS in Ilorin and Kano in 2010 and 2013 respectively. In 2015, some of Nigeria agricultural produce were rejected and cowpea was banned by the European Union countries due to misuse and abuse of pesticides on grains ([14]). By 2013 utilization of IAMS was introduced as there was increasing awareness on food safety and quality. NSPRI being the only Federal Government agency mandated by its Act of establishment to conduct research among other issues into the postharvest activities of agricultural crops in the country became part of the problem solving mechanism. By 2015 entrepreneurs, marketers, industrialists, university and other relevant stakeholders became interested in the utilization of IAMS due to increased awareness on grain availability for food safety and quality and the successful application of nitrogen controlled atmosphere in grain storage. Researches have proved use of N2-CA as safe alternative to synthetic pesticides for protection of grains from attack of stored products insect pests ([14,15]). Low temperature and controlled atmospheres (CA) are internationally standard recognized grain storage technologies. The two principal types of atmosphere that could be used for controlled atmosphere (CA) storage and disinfestations of grains are: low concentration of Oxygen (O_2) and high concentration of Carbon Dioxide (CO_2)([14]). The principles and operation of Nitrogen Controlled Atmosphere (N_2-CA) in grain storage involve maintenance of food safety and grain quality by control of storage pests, inhibiting storage fungi, prevention of re-infestation of storage insects, maintenance of viability and germinability of stored seeds and delaying deterioration of grain quality ([15]). The use of N_2 gas as a medium of modifying atmosphere is most preferable and suitable for grain storage in Nigeria. IAMS is therefore a promising alternative for appropriate storage of grains under nitrogen. This technology does not require use of any synthetic pesticides for control of stored products pests, no residues in stored grains and no food poisoning involved. Also resistance to pesticides and hazards to operators are eliminated ([5]).

The research in IAMS technology has moved from laboratory trials to pilot scale, to medium scale and finally to commercial and industrial levels. It is necessary to appraise the research efforts of this technology to further sensitize the public on the importance, relevance and benefit of the technology, as well as open up more research opportunities and collaboration for improvement studies. The research work carried out and development of IAMS technology for grain for the smallholder, medium, commercial and strategic reserve levels for storage in Nigeria are reviewed subsequently.

2. Materials and Methods:

Construction of Inert Atmosphere Metal Silo (IAMS)

In the laboratory trials, an airtight mini-silo of a battery of 2 units volumetric capacity 0.65m3, were constructed in NSPRI Ibadan and Kano respectively. The IAMS was installed under shade ([9]). The mini silo was provided with three sampling points located at the bottom, middle and top positions of the metal silo. A dial bi-metallic thermometer probe was fitted midway of the silo with sensing probe penetrating to the central axis. Nitrogen was supplied to the metal silo through a nitrogen distribution system consisting of a pressure cylinder and a gas flow instrument panel from the silo downward through the stored grain. A pressure relief valve was fitted at the base of the mini silo ([9]).

In the pilot trials, an airtight mini metal silo of a battery of 4 units volumetric capacity 4-ton were erected at the premises of NSPRI Ibadan supported by point load bearer concrete columns and structural bars, in such a way that they were fully exposed to varied effects of the sun, wind and rain throughout the experimental period. The mini silos were all painted white so as to increase the reflectivity of the surface and thus cause a cooler environment inside. The whole body and top of silo was insulated with 5 cm glass wool and galvanized sheets but not shaded; or top of silo was insulated with 5 cm glass wool but not shaded; or no part of silo was insulated or shaded; or silo not insulated but shaded on the top with palm fronds ([16]).

In the medium level, an airtight Inert Atmosphere Metal Silo of a battery of 2 units volumetric capacity 45-tons were constructed at the premises of NSPRI Ibadan in such a way that they were fully exposed to varied effects of the sun, wind and rain throughout the experimental period. The IAMS was made up of bin, plinth, gallery, gas supply network, monitoring devices and handling equipment. The bin is a cylindrical structure with conical top constructed of food grade coated steel plate. It has three outlets for loading, discharging and accessibility. The plinth is constructed of reinforced concrete and the basement supports the bin and the gallery. The gallery comprised of ladder and walkway designed for the silo accessibility. The gas supply system of the silo is responsible for nitrogen supply to the bin. The components of the system included gas cylinder, gas line, gas control valve and gas regulators. The gas line is supported with gas line tray and vertical support. The monitoring devices included pressure gauge and temperature probes. The pressure gauge is used to measure the pressure level in the silo especially during purging while the temperature probes are installed at different gradients in the silo to monitor the temperature at different levels of the grain mass in the silo. The handling equipment are accessories for operation of the silo include grain bunker, grain sampling probe, loading and unloading auger conveyors. The silo is also provided with a generator powered augur for mechanized loading with grains. The top of the silo shaded with palm fronds ([14,16,17]).

In the commercial level an airtight IAMS of a battery of 2 units of 50-tons capacity each were constructed at the premises of NSPRI Ilorin and Kano. Similar procedure as in medium levels was followed. While 4 units of 5-ton capacity was installed at Dawanu grain market in Kano.

At the Industrial level, NSPRI was commissioned by a private university, Landmark University, Omu-Aru, Kwara State, Nigeria, where it constructed and installed 2 units of 250-ton capacity IAMS.

Principles and operation of IAMS

IAMS is an airtight system with facilities to purge out the air content of the enclosure and replace it with nitrogen gas (N_2), thereby making the system inert and inhabitable for stored products insect pests.N_2 released into the silo eliminated O_2 in the process and created inert condition within the bin that could not support the growth or survival of any organism irrespective of its developmental stages. Operation of IAMS and maintenance of grains in the structure entail three major operations; loading of grain, purging of silo and unloading of grain from the bin.

Loading of grain: Dried grain stored at safe moisture content (≤ 13 % depending on the grain) determined with in-situ moisture test before the commencement of the loading operation were

used. The grain bunker (for receiving the grains) and the bins were properly cleaned, dried and made free from dust and other extraneous materials. Thereafter, the air tightness was guaranteed to prevent gas leakage. All openings were properly sealed using bolts and nuts except the loading spout. Setting up of the loading conveyor preceded the conveyance of the grains into bin. After loading, the loading spout was properly sealed, and provision was made for appropriate insulation on the bins to reduce direct impact of the sun ([16,17]).

Purging of bin: This is a process of replacing the air content of the silo with N_2 gas. After loading the silo with grain, the interstitial atmosphere within the bulk was purged by introducing nitrogen at the bottom of the silo at a conveniently high rate. All valves that aided the supply of gas through the gas line were adequately opened to supply N_2 to the bin. The gas was allowed to fill the bin for some time after which the gas release valve was opened. The waiting time is a function of the size of the silo. It was 1h 30 mins for the 45-ton silo. The oxygen gas content of the bin was measured with the aid of oxygen analyser and less than 5%. Immediately this condition was achieved, the gas supply line was then switched off after the water in the purging container has bubbled for 5 minutes in case of silos of less than 2 tonnes and for 30 minutes for 50 tonnes capacity silo and for 1 - 2 hours for 250 tonnes silo and above. The O^2 concentration within the silo was checked once every week, and after every purge which followed sampling for analysis ([14,16,17]).

Sampling of grains from IAMS and quality assessment: Initial sample of different grains used for studies were drawn by opening IAMS top tight lid to sample at intervals of 6 month storage from the top, middle and bottom levels of the mini silo, 45-ton or 50-ton by means of silo sampling dip tool. The samples from the three different points were bulked and quartered for triplicate sampling 100 g each for assessment and quality parameters. Oxygen concentration within the silo was checked with the Taylor Servomex oxygen analyzer, type OA 272 forth nightly, and after every purge following grain sampling. The samples were subjected to the following tests: insect infestation count, insect damage kernel, mould count, proximate composition, viability and germinability, organoleptic evaluation according to standard methods ([8,9,11,14,16,17,18]).

Temperature fluctuations and relative humidity inside the silo: Each mini 4-ton silo was equipped with 5 temperature probes each containing 5 thermistors. Two of these were located axially while the other 3 were located radially round the silos so that temperatures can be measured axially and radially at the surface of the bins and at various depths in the stored grain. The temperature probes were led into a programmable electronic temperature recorder system, making it possible to record the temperatures at pre-set time intervals. Similar procedure for 45-ton and 50-ton IAMS ([16,19]).

Discharging of stored grains: After cleaning of the conveyor, the unloading spout of the bin was opened for grain discharge with aid of the unloading conveyor. The collected grains were later packaged in bags.

Research works carried out on IAMS by NSPRI for three and half decades

A battery of two units of 45 tons (in Ibadan) and a battery of two units of 50 tons capacity (in Ilorin and Kano) air tight metal silos were constructed at NSPRI offices located in different ecological zones in the country for bulk storage of grains. Apart from these capacities, there are laboratory and pilot scale capacities for experimental purposes only. Prominent among grains that have been successfully stored in the silos under nitrogen at the three locations were white maize, yellow maize, brown cowpea, wheat var. *Atilla gans atilla* and *Cetia*, paddy rice 'Faro 2' and yellow sorghum. The storage was carried out at different intervals spanning a total of 36 years. Series of research activities have been carried out on the aforementioned crops since inception of the technology.

Storage of maize: Experiments on storage of maize in inert atmosphere metal silo were carried out at five different levels and time. Six experiments were conducted in Ibadan in 1980, 1982, 1983 and 1984. The first experiment was on susceptibility of the life stages of *Sitophilus zeamais* and *Trogoderma granarium* larvae to nitrogen atmosphere in mini silos. This was carried out to determine how effective the technology was to control stored products insects attack in maize

storage. The mini silos with capacity of 5 tons each were used for the experiment. The second was application of artificial controlled atmosphere in grain storage in Nigeria. The third experiment on maize storage was a laboratory examination of yellow maize stored under nitrogen in Nigeria. The fourth research was on microbiological studies on yellow maize stored in sealed mini-silo filled with nitrogen in two metal silos of 0.65m^3. The fifth research on maize was on the effect of shading and insulation on maize stored under nitrogen in 4 mini-metal silos of 4-ton capacity each. The sixth storage of maize was in 45-ton silo at commercial level for 24 months.

Storage of rice and cocoa: The study was carried out in two airtight, stainless steel mini-silos labelled A and B of 0.65m^3 capacity each erected under shade at the premises of NSPRI Ibadan in 1984 to determine the effects of nitrogen atmosphere on the adults and immature stages of some stored products insects: (eggs, larvae, pupae and adults of *Dinoderus porcellus* Lense, *Lasioderma serricorne* (F), *Callosobruchus maculatus* (F.), *Rhyzopertha dominica* (F.), *Dermestes maculatus* (DeGeer) and *Necrobia rufipes* Degeer) when used for storage of rice and cocoa.

Brown cowpea: Experiments on cowpea storage were carried out at Kano (North West) and Ibadan (South West). The Kano experiment which lasted 30 months was at the laboratory level to test the efficacy of the technology in controlling of insect pests in stored cowpea as well as its ability to maintain the quality of cowpea stored under the condition. Another study carried out on cowpea at the laboratory level was to establish the effect of insect infestation of cowpea stored under N_2 on biological evaluation of protein quality. The second stage of the experiment was at the commercial level. One of the 45-ton metal silos in Ibadan was used for storage of cowpea. A 45-ton metal silo was loaded with Ife brown cowpea variety for storage under nitrogen in NSPRI Ibadan. The IAMS was refurbished and purged with nitrogen to 0.05% level to remove O_2 and continuously maintained at regular intervals throughout the storage period. Sampling was done on monthly basis for evaluation of moisture content, microbial count, insect infestation, seed damage, aflatoxin level, germinability and organoleptic assessment which was carried out at the end of 24 months storage period.

Wheat seed: Two different wheat seeds (*Atila gan atila and Cetia*) were stored in silo facility located at the headquarters of NSPRI in Ilorin (North Central of Nigeria). An aspect of the study was to monitor temperature fluctuation in the silos, while the other two focused on maintenance of wheat seed germinability and nutritional quality. Another important area of the study was effect of the technology on mortality of insects at different developmental stages. The wheat was stored for 48 months (2010 to 2014). The germinability test was terminated after 12 months of storage, while the other parameters continued.

Paddy rice: The storage of paddy rice research was conducted in Ibadan at commercial level. The study was carried out to establish the potential of IAMS in preservation of the germinability and nutritional qualities of the paddy rice. The research work lasted for 24 months (2010 to 2012).

Yellow sorghum: This experiment was conducted in Kano for 30 months (2014 to 2016). The storage was at commercial level and was carried out to ascertain the effect of the storage conditions on nutritional qualities of sorghum.

Economic appraisal: The economic appraisal of the technology was conducted to establish how cost effective it is, and the expected return on investment. Different economic tools were jointly adopted to carry out the exercise. Such tools included budgetary analysis and profitability analysis in 1987 and 2015 ([20,21]).

Promotion and utilization: Series of steps have been taken to aid the adoption and utilization of the technology. The techniques adopted for this include training of grain stakeholders on importance and principles of operation of the silo and installation of smaller capacity at grain markets as government intervention in postharvest management of grains. The utilization component covers rentage of the facility to interested individual for storage of grains and installation for individual or corporate ownership. The Institute was commissioned by Landmark University, Omu-Aru, Kwara State, and a battery of 2 units of 250 tons IAMS were constructed on their Research Farm. In late

February 2018 loading of white and yellow maize harvested from their farm is ongoing. The loading is being carried out and supervised by Staff of NSPRI Postharvest Engineering Research Department.

3. Results

Construction of IAMS

Silo at NSPRI Headquarters is used as case study for all others. All the materials required for construction and installation of the functional IAMS were readily and locally available in the country. The silo consisted of two units of 50-ton inert atmosphere metal silo located at Headquarters, Ilorin. The geometry of the silo is shown below: Diameter and cylinder of cone = 4 m; Height of the cylinder = 5.4 m; Total height of silo = 6.4 m; Based on the geometry of the silo structure, the dimension of the cellular raft foundation base is as follows: Total width = 12 m; Total breadth = 6 m with top slab thickness = 300 mm; Width of the beam – 600 mm; Height of the beam = 1000 mm; Bottom raft thickness = 400 mm (Fig. 1) ([19]).

Impact of IAMS on insect control in stored grains

Results obtained by the authors showed that exposure time required to achieve 100% mortality at 28±2°C in inert atmosphere for adults and of larvae which developed internally varied from that required for the eggs stage. Adults of internally developing species such as *Sitophilus zeamais* Motsch, *Trogoderma granarium Dinoderus porcllus* Lense, *Callosobruchus maculatus* Fab..and *Rhyzopertha dominica* F. were more tolerant to N_2 gas than those of *Dermestes maculatus* DeGeer, *Lasioderma serricorne* F which develop externally. Susceptibility of these insects to the atmosphere varied both between species and the various stages of development within each insect species ([8,12]). White maize, brown cowpea, wheat, paddy rice and yellow sorghum under nitrogen in IAMS 45-ton or 50-ton capacity stored for 48, 24, 48, 24 and 30 months respectively and 100% mortality of all life stages of each insect species was recorded, inhibited zero mould growth and no re-infestation.

During the commercial utilization of the technology for cowpea storage, the quantity of N_2 gas used was 101.25m^3 for the 24 month period. It was observed that 40.7% of N_2 gas was used during the first month of storage. A greater quantity of N_2 is needed at the initial stage to establish complete purging of the silo, which in turn is required to maintain the IAMS. This decreased with length of storage period. The moisture content increased form initial 9% to 10.13% at the end of 24 months storage within safe moisture content limit.

Microbial load at the top of the silo ranged from 400-9000 colony (cfu/ml after 6 months), while at the bottom of the silo the value was below 300-4000 cfu/ml which are below safe limits ([23]).

Physical observation showed that the cowpea grains stored in IAMS were clean and without any mould growth. There was no insect infestation or seed damage. Percentage cowpea seed damage decreased from initial 13.64% to 12% after 24 months.

Nutritional quality of grains stored under N_2

Results of analyses carried out on grains stored under N_2 showed that the technology is not just efficient in insects control but also in maintenance of nutritional quality of grains. The outcome of the study carried out on brown cowpea showed that free fatty acid (FFA) contents increased from 2.60% to 6.51% under nitrogen, but increased rapidly to 58.60% in the control cowpea ([14]). Results of previous researchers carried out using the technology showed that crude protein content increase observed in grains stored as controls was not applicable to grains stored under nitrogen, this was attributed to excretory products of the insects that infested the control grains ([10]). Organoleptic tests carried out stored cowpea under N_2 after 24 months to assess the palatability of the stored cowpea and fresh cowpea by processing the cowpea into wet paste and made into bean cake showed no difference in taste and appearance in the fried “akara” balls.

Effects of IAMS on germinability of seeds

Seed germinability and grain quality were also maintained. Germinability of the stored paddy rice was maintained (≥85%) for 3 months in 45-ton IAMS at NSPRI Ibadan ([12]).The germinability of cowpea seeds stored in the inert atmosphere silo in 0.65m^3 at NSPRI Kano was maintained above 85% at 12 months of storage, which shows that the technology is effective for seeds storage ([14]). Germinability of Ife brown cowpea stored under N_2 in a 45-ton capacity IAMS at NSPRI Ibadan was maintained from initial 94% to 80% at 24 months. Also, the result of wheat seed variety *Atlila gans Atilla* stored under N_2 in a battery of 2 units 50-ton at NSPRI Ilorin showed that the technology was able to maintain the germinability 91 % at 12 month of storage.

Moisture migration and condensation in IAMS

Shading with palm fronds or hood to provide insulation for the silos prevented moisture migration and condensation that are peculiar to the conventional metal silos ([10, 11, 16]).The technology was able to maintain the temperature of the grain stored in the silo below 30 °C even when the ambient was as high as 36 °C during the hot season in Ilorin. The mean temperatures at the top, middle and the bottom of the inert atmosphere silos when used to store wheat in Ilorin were approximately 29.35 °C, 28.19 °C and 26.51 °C respectively. This depicts a temperature decrease from the top of grain bulk towards the floor of the inert atmosphere silos ([19]).The recorded temperatures in the silo used for storage of brown cowpea in NSPRI Kano, ranged from 21 °C (in the night) to 35 °C (in the day) with an average value of 28.5 °C; while the ambient temperature was in the range of 14 °C to 43 °C and an average temperature of 33.2 °C ([14]).

Cost benefit of IAMS

These economic advantages of IAMS over conventional silos were observed. The conventional silos require frequency of application of pesticides, turning of grains to prevent caking and high cost of labour. A cylinder of 50 kg N_2 gas used in storage of Ife brown cowpea in a 45-ton capacity IAMS at commercial level in NSPRI Ibadan, Oyo State cost N7014 and was used between 8 and 15 weeks. All indices of economic analysis adopted showed that the technology is economically viable for storage of grains with a return per unit of investment of 0.44 when utilized for storage of wheat for a period of 48 months in NSPRI Headquarters, Ilorin, Kwara State ([20,21,23]).The cost effectiveness has revealed that any investment in the facility is capable of huge economic return within short period of the investment.

Utilization of IAMS

The benefits of the technology coupled with the economic return on the storage structure have prompted the adoption of the technology. The beauty of the technology is that it could be used for storage at all levels (ranging from domestic storage to commercial/industrial grain storage). These are some of the factors that aided the decision of the management of Landmark University Farm to put up a battery of two units of 250 tonnes capacity of the structure for safe keeping of grains for production of feeds for the livestock arm of its commercial farm located in Omu-Aran, Kwara State. Aside from this, a number of individual grain farmers/handlers in the Northern part of the country have committed themselves to the adoption of the technology because of the huge benefits attached to it. In fact, this was referred to as a sustainable and reliable investment opportunity for retirees ([22]). The government of Nigeria through NSPRI was able to construct and install some units of 5 tonnes capacity IAMS for the benefit of stakeholders in the grain sector of agriculture as intervention and a means of popularizing the technology among the grain farmers and marketers. Four units of the silos were installed at Dawanu grain market (the largest grain market in West Africa) in Kano state of Nigeria.

One of the major factors responsible for the low adoption of the technology despite the enormous benefits attached to it, is the initial cost of construction and installation. Awareness has commenced

on the rentage of the facilities for storage of grains for benefit of those that have interest and confidence in it but lack the initial capital require to put up such facility. Another means been adopted to propagate the technology is through training. IAMS was the main storage structure recommended aside from PICS bag for storage of sorghum in the training organised and facilitated by International Crop Research for the Semi-Arid Tropics (ICRISAT) and NSPRI respectively in six (6) states of the federation. Another capacity building workshop was organized by NSPRI on principles and operations of IAMS for grain merchants and industrialists across Nigeria.

4. Discussion

The practical application of N2-CA in stored grain showed that the effect of N2-CA control pests and closely related to the nitrogen concentration and processing time. The efficacy of nitrogen controlled atmosphere is closely related to the pest species, nitrogen concentration, grain temperature and exposure time. Only pure nitrogen eliminated those fungi, preserved grain and oil quality ([15]). Construction of new IAMS will engage fabricators and thereby creating more job opportunities and wealth for the people in the sector. The previous researches carried out by different researchers on different grains at different time and different locations within Nigeria have shown that the principle of operation of the silo is key to its functionality and efficiency. Irrespective of the capacity of the silo, once the principle is strictly adhered to, the efficiency and effectiveness of the structure in handling grains is guaranteed. Capacities of the silo range from 100 kg to thousands of tons. Construction of new IAMS will engage fabricators and thereby creating more job opportunities and wealth for the people in the sector.

Essentially, the adoption of any storage structure for grains is to protect the grains against insect pests attack. IAMS has proved its efficiency in dealing with stored products insects. The technology has potential to attack insect at its every developmental stages. The cost effectiveness has revealed that any investment in the facility is capable of huge economic return within short period of the investment.

One of the major factors responsible for the low adoption of the technology despite the enormous benefits attached to it, is the initial cost of construction and installation. Awareness has commenced on the rentage of the facilities for storage of grains for benefit of those that have interest and confidence in it but lack the initial capital required to put up such facility. Another means being adopted to promote the technology is through capacity building training. IAMS was the main storage structure recommended aside from PICS bag for storage of sorghum in the training organised and facilitated by International Crop Research for the Semi-Arid Tropics (ICRISAT) and NSPRI respectively in six (6) states of the federation. Another capacity building workshop was organized by NSPRI on principles and operations of IAMS for grain merchants and industrialists across Nigeria in October, 2017.

In conclusion, the recent achievement of the technology is that its utilization has been taken up by entrepreneurs, marketers and universities for grain storage in Nigeria due to the success of application, operating cost and increased awareness for availability of grains for food safety, grain quality and nutrition. Investment in this technology has economic benefits to the stakeholders in particular and the country. The technology is an advanced environmental friendly, and construction and operating cost and application is feasible all the agro-ecological zones of Nigeria. Apart from providing a green environment for the preservation of grains, it has the capacity to create jobs for those that will be involved in the management of the structure. IAMS application will encourage farmers to produce more grains as there is a technology that is effective and efficient for grain storage. The cumulative success recorded on different grains stored in IAMS is an evidence research input by NSPRI to ensure food safety and quality thereby meeting MDGs in food security. Finally, there is opportunity for collaborative research work to further strengthen the present achievement.

Acknowledgement

We thank the Executive Director of NSPRI Prof. Olufemi Peters for sustaining the IAMS technology of his predecessors and most importantly on the recent utilization by some relevant stakeholders. We thank all past and present NSPRI Staff who through their doggedness researched on this IAMS. We thank the lead and presenting author for self-sponsorship to this conference. The 3rd co-author is appreciated for writing the manuscript which was reviewed. Finally, the interest of the Executive Director permission to the lead author to attend and make oral presentation by participating in the 12th International Working Conference on Stored Products Protection, 7 -11 October, 2018, Berlin, Germany is acknowledged.

Abstract

The merchant grain beetle (MGB), *Oryzaephilus mercator* (Fauvel), the cigarette beetle (CB) *Lasioderma serricorne* (F.) and the rice weevil, *Sitophilus oryzae* (L.) cause significant damage to stored grain, grain-based products, and other durable commodities. Ozone, a highly oxidative toxic gas, has the potent to kill insects, meantime degrades rapidly to oxygen, making it a potential alternative to phosphine, a fumigant to which insects are developing resistance. The adults of MGB and CB were exposed to ozone concentrations of 100 - 400 ppm at 50 ppm increments for one hour and at 100 ppm for 1-6 h. Adults of rice weevil buried at 5, 15 or 25 cm depths within a wheat mass placed in 10 cm diameter 30 cm high PVC pipes were exposed to ozone concentration of 200 ppm for six hours and then at 12-h increments up to 60 h. Adult survival was recorded at 0, 24, and 48 h post-treatment. Significantly fewer MGB or CB adults survived when exposed to higher ozone concentrations or when exposed to ozone in the absence of food. RW adult mortality at 5 cm depth were significantly higher than that of 15 or 25 cm depths. This paper further discusses about mortality of MGB, CB and RW adults at different exposure periods at various ozone concentrations and effect of ozone on wheat germination.

Keywords: Fumigants, germination, ozone, stored product insects, wheat

Introduction

The ban of methyl bromide, the most effective fumigant for the control of many stored product insect pests, has necessitated the search for other potential alternative management methods. One of the potential alternatives is ozone (O_3), a highly oxidative, environmentally safe gas that degrade into molecular oxygen (O_2) within 20-50 minutes. Ozone is formed by the excitation of molecular oxygen, into atomic oxygen (O), and then combination of three atomic oxygen to form ozone. The use of ozone against stored product insect pests has gained tremendous attention over the past decade (Mahroof el al., 2018).

There have been few studies (Hasan et al., 2012) on the effect of ozone on the merchant grain beetle, *Oryzaephilus mercator* (Fauvel), the cigarette beetle, *Lasioderma serricorne* (F.) and the rice weevil, *Sitophilus oryzae* (L.). Published studies did not investigate the effect of ozone when externally feeding insects are treated in the presence or absence of food. Therefore, the study described here was conducted using adults of *O. mercator*, *L. serricorne* and *S. oryzae* exposed to different concentrations of ozone for different durations. The objectives of this study were to evaluate the relative susceptibility of adults to different ozone concentrations, determining concentration-mortality and time-mortality relationships and to determine germination quality of wheat treated using ozone.

Materials and Methods

A bench-top ozone generating equipment that produces ozone in the range of 0-8000 ppm was used in the experiment. Detailed descriptions of the Ozone generator were provided in Mahroof et al. (2018).

Exposure of *O. mercator* and *L. serricorne* to different concentrations of ozone

Adults of *O. mercator* and *L. serricorne* were exposed to ozone concentrations beginning 100 ppm and then at 50 ppm increments up to 400 ppm for one hour. Ten jars with 20 adults were used for

ozone treatment and 10 jars served as control. Five of the either treatment or control jars had 10 g diet mix and the other five were without food. Insects were treated either in the presence or absence of diet to determine the effect of ozone, if any. For each concentration tested, each treatment was replicated five times. Each experiment for any particular concentration was repeated for a total of three times. Adults were observed for mortality soon after treatment (0). Then, adults were placed in an incubator at 28 °C and 65% RH and observed again at 1 and 2 days after treatment (DAT).

Exposure of *S. oryzae* to 200 ppm ozone concentration for different durations

The effect of 200 ppm ozone concentration on adult *S. oryzae* adults at different depths within a column of wheat mass was tested using PVC pipes. A nylon pouch containing 20 adults was placed at the 5, 15 and 25 cm depths from the top of the PVC pipe filled with wheat. Three of the pipes were exposed to ozone by placing them in the ozone chamber set at 200 ppm for 12, 24, or 36 h. The remaining three pipes served as control. Adults were observed for mortality immediately after ozone exposure (0 DAT). Then, adults were provided with wheat kernels and placed in an incubator at 28 °C and 65% RH and observed again at 1 and 2 DAT.

Germination test

Wheat kernels exposed at 200-ppm of ozone for 12-60 h with an increment of 12 h were germinated in a Petri dish and germination percentage was compared with untreated wheat kernels. Seeds layered on a wet paper towel placed in the Petri dish were maintained in an environmental growth chamber at 28°C, 65% RH and 18:6 D: L photoperiodism for 10 days to record germination.

Data analyses

For experiments exposing the adults of *O. mercator* and *L. serricorne* to different concentrations of ozone, the corrected mortality data were fitted to a complementary log-log (CLL) regression model to estimate the concentration required to kill 50% (LC_{50}) and 99% (LC_{99}) of insects exposed to ozone (SAS Institute 2013). In the CLL model, the concentration was transformed to $\log_{10}$ scale. The goodness-of-fit of the model to the data was compared using a χ^2 statistic (SAS Institute 2013). For *S. oryzae*, we determined the differences between treated and corresponding control for each depth. The means were separated using Tukey's Honest Significant Difference (HSD). ANOVA was considered significant if $P < 0.05$ (PROC GLM, SAS Institute, 2013). Results from germination tests were summarized in a graph and represented as mean % germination at 5, 15 and 25 cm depths.

Results and discussion

Exposure of *O. mercator* and *L. serricorne* to different concentrations of ozone

The Probit estimates from the mortality response of adult *O. mercator* exposed to different ozone concentrations are summarized in Tab. 1. The results showed that susceptibility for adults varied to ozone when they were treated with or without diet. When adults were treated with diet, they were more tolerant to ozone than without diet. In *L. serricorne*, when diet were provided, similar to *O. mercator* adults were more tolerant than when diet was absent (Tab. 1). The χ^2 values were significant for the concentration-mortality regression models, an indication that the responses to ozone by the *O. mercator* and *L. serricorne* adults were heterogeneous whether they were treated with or without food. In height of heterogeneous response, the CLL model estimated a very high LC_{50} and LC_{99} values that did not yield any fiducial limits for O. Mercator adults, those were treated with food.

Tab. 1: Relative toxicity of ozone to adults of *O. mercator* and *L. serricorne* determined through concentration-mortality bioassays

Stage	Treatment type	Total # of insects	Intercept ± SE	Slope ± SE	LC_{50} (95% FL) (ppm) [a]	LC_{99} (95% FL) (ppm) [a]	χ^2 (df) [b]

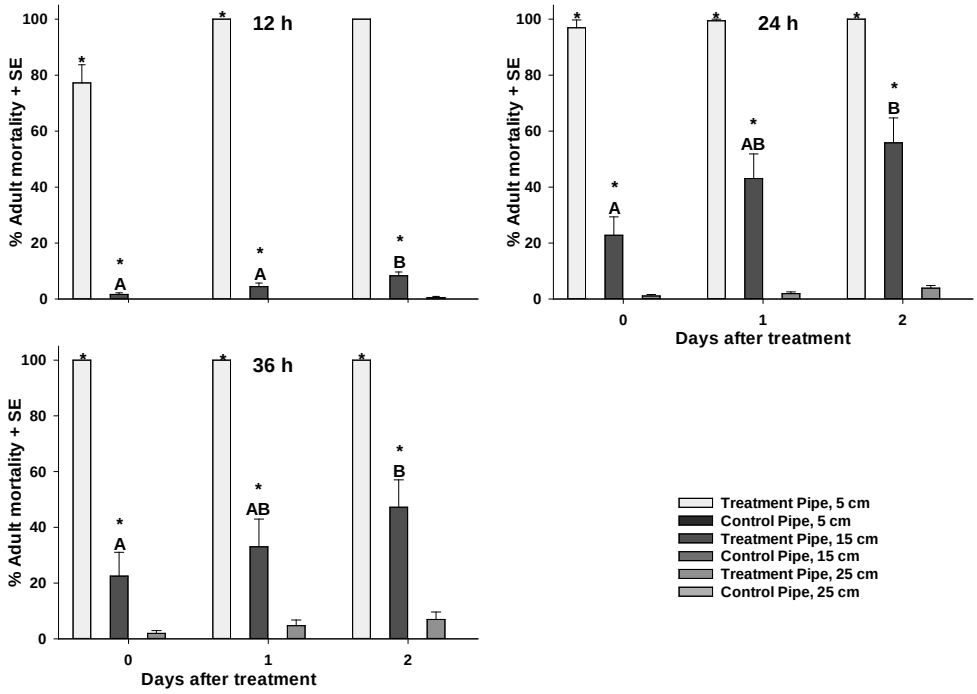

Fig. 1: Mean % mortality ± SE of adult *S. oryzae* exposed to 200 ppm of ozone for 12, 24 and 36 hours at 5, 15 and 25 cm depths in a wheat column.

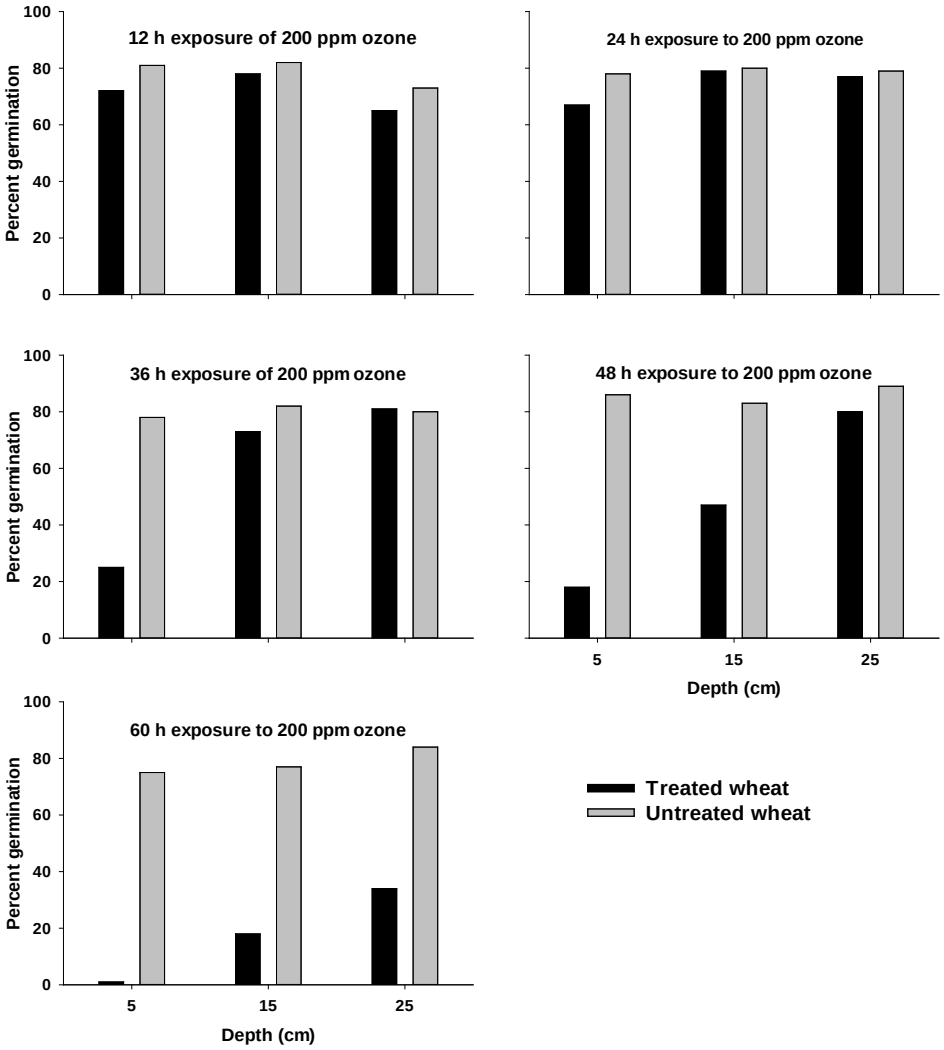

Fig. 2: Percentage germination of wheat seeds exposed to 200 ppm of ozone for 12-60 h at an increment of 12 h. Seeds were collected from 5, 15 and 25 cm depths in a wheat column.

Exposure of *S. oryzae* to 200 ppm ozone concentration for different durations

The percentage mortality of *S. oryzae* adults when exposed to 200 ppm for different durations, is presented in Fig. 1. Higher mortality was recorded at the 5 cm depths for each of the durations investigated. The longer the exposure period, the higher the mortality recorded. Exposure durations of 12 h or higher resulted in 100% mortality at the 5 cm depths by 2 DAT. At 24 h exposure duration, there were significant higher adult mortality at the 15 cm depth compared to control, soon after treatment, or at 1 and 2 DAT ($P < 0.001$). However, at the deepest depth, at 25 cm, there was no significant difference among days and between a treatment and its corresponding control for three durations tested ($P > 0.05$).

Based on our data, the highest concentration of ozone tested, 400 ppm, could not result in 100% mortality for both *O. mercator* and *L. serricorne*. Complete mortality in adult *L. serricorne* was achieved with 24 ppm after 48 h exposure, and shorter exposure periods required significantly

higher ozone concentrations to elicit similar effects (Hassan et al., 2012). Longer exposure durations and or higher concentrations will also be required to be able to control *S. oryzae* adults placed at the 25 cm depth of the PVC pipes. Ozone adsorption in grain layer depends on factors such as the ozone concentration supplied to the layer, ozone degradation rate, and the exposure duration to ozone (Tojanowska, 1991). Hence, longer exposure periods and or higher ozone concentrations may be required to control *S. oryzae* adults placed in deeper depths of a wheat column.

Germinations tests

Wheat germination was not adversely affected when seeds were exposed to 200 ppm up to 24 hours (Fig. 2). However, percentage germination was reduced, when compared to control germination at 5 cm depth, beyond the 36 hour-exposure to ozone at 200 ppm. Germination of wheat seeds considerably decreased when wheat was exposed to 60 hours at depths of 15 or 25 cm. Seeds collected and germinated from the 5 cm depth at 60 hours of exposure had germination closer to 0%. To our knowledge this is the first experiment to report effect of ozone on germination of wheat seeds in relation to insect mortality. It is clear with this study, that prolonged exposure of grain to ozone may adversely affect the germ quality. If grain is stored for seeding and cultivation purposes, or extracting germ for commercial uses, care must be taken if ozone treatment is an option for stored insect management.

Update on ProFume® gas fumigant (sulfuryl fluoride) use for post-harvest pest control

Barbara Nead-Nylander[1], Ellen Thoms[2]

[1]Douglas Products and Packaging Co., LLC; baneadnylander@douglasproducts.com

DOI 10.5073/jka.2018.463.127

Keywords: Sulfuryl fluoride, ProFume, *Cryptolestes pusillus*, *Sitophilus zeamais*

ProFume® gas fumigant (99.8% sulfuryl fluoride), first registered in 2003, is a broad spectrum, non-ozone depleting fumigant for the control of rodent, insect and other invertebrate pests. It is used to treat a wide range of stored products and structures which transport, store, and process commodities and is currently registered in 22 countries. Sulfuryl fluoride is not cross-resistant with phosphine and has been documented to effectively control quarantine pests, including the pinewood nematode and brown marmorated stinkbug.

Continued reduction of methyl bromide availability for non-quarantine fumigations coupled with the emergence of phosphine tolerant or resistant populations has led to increased interest in registration of sulfuryl fluoride in several tropical and sub-tropical countries. As part of the registration effort additional efficacy data has been developed to support the use in these countries. hile found in temperate zones, both Flat grain beetle (*Cryptolestes pusillus* (Schönherr)) and Maize Weevil (*Sitophilus zeamais* (Motschulsky)) are more problematic in tropical environments. As

sulfuryl fluoride was developed mainly for use in temperate zone countries, limited efficacy data has been developed for these pests. In 2018, laboratory studies were conducted in California by the Dried Fruit and Tree Nut Association (DFA, Fresno, CA, USA) to determine the dosage required for control of all life stages of these pests. The results of this study coupled with earlier work may allow for inclusion in the Fumiguide® program.

The Fumiguide program is required for use with ProFume to calculate dosage and dose requirements. The program allows users to tailor applications based on job specific parameters to best meet customer needs for cost and time. The new Fumiguide includes improvements in the underlying algorithms, additional functionality for fumigators and the ability to easily add new pests.

Since the purchase of sulfuryl fluoride from The Dow Chemical Company in 2015, Douglas Products has continued to expand product use through new country registrations, expanded efficacy data and development of an updated Fumiguide program. This presentation provides updates on registrations for ProFume, details efficacy work for two insect species of interest in tropical regions, and reviews the updated Fumiguide program, a required tool for dose and dosage determination.

Nitric oxide as a new fumigant for postharvest pest control

Yong-Biao Liu [1]*, Xiangbing Yang [2]

[1] USDA-ARS, Crop Improvement and Protection Unit, 1636 E. Alisal St., Salinas, CA 93905 USA

DOI 10.5073/jka.2018.463.128

Abstract

Nitric oxide (NO) is a new fumigant for postharvest pest control. It is effective against all pests tested to date, including external and internal pests of fresh and stored product insects, and mites. Efficacious treatment time ranges from 2 h to 72 h, and NO concentrations range from 0.1% to 5%, depending on species and life stages of the pests.

Nitric oxide fumigation must be conducted under ultralow oxygen conditions because NO reacts with O_2 spontaneously to produce nitrogen dioxide (NO_2), which is toxic to perishable fresh products. Fresh product fumigation must, therefore, also be terminated by flushing with N_2 to dilute NO at the end of fumigation to avoid damage to delicate products by NO_2. Nitric oxide fumigation was safe in small-scale tests to postharvest quality of all fresh commodities when terminated with N_2 flush. In addition, NO fumigation resulted in better postharvest quality of strawberries and apples as compared with controls, indicating its beneficial effects on postharvest quality of fresh products.

Twenty fresh fruit and vegetables and 10 stored products were fumigated with NO to determine residue levels of nitrate and nitrite. When terminated properly with N2 flush, NO fumigation does not increase nitrate or nitrite levels in fumigated products. NO fumigation was demonstrated to be effective against all pests, safe to fresh products, and has no toxic residues and, therefore, has the potential to be a practical alternative to methyl bromide fumigation for postharvest pest control on both fresh and stored products.

Keywords: Nitric oxide, fumigation, quarantine treatment, residue, postharvest quality.

Introduction

There is a severe lack of safe and effective alternative treatments for postharvest pest and disease management after phasing out of methyl bromide. The current main alternatives, including phosphine and sulfuryl fluoride, have difficulties in meeting the need for postharvest pest control on stored products or fresh commodities. Phosphine fumigation typically has long treatment time and is not effective against some pests due to tolerance or resistance (Hole *et al*., 1976; Benhalima *et al*., 2004). Sulfuryl fluoride is not effective against insect eggs (Bell *et al*., 1998) and therefore has limited efficacy in addition to its phytotoxicity to fresh products (Aung *et al*., 2001). Nitric oxide (NO) is a newly discovered fumigant for postharvest pest control and has high efficacy against insects

and mites and no toxic residues (Liu, 2013, 2015). It was also demonstrated to be safe to fresh commodities and enhance postharvest quality of fresh commodities (Liu, 2015, 2016, Liu *et al*., 2016). Therefore, NO may have potential to be a practical alternative fumigant for postharvest pest control on both fresh and stored products.

Nitric oxide is a chemical produced naturally in fossil fuel combustion and lightning and commercially as an intermediate in fertilizer production. Since the discovery of NO as a cell messenger molecule in 1980s, NO has been studied extensively and was found to play diverse roles in physiological and biochemical processes in organisms (Lamattina *et al*., 2003). Nitric oxide has also been used in medical fields to treat certain respiratory and cardio vascular conditions (Roberts *et al*., 1993; Ricciardolo *et al*., 2004) and was also found to be an inhibitor of ethylene biosynthesis in plants and can be used to enhance postharvest quality and prolongs shelf-life of fresh fruit and vegetables (Wills *et al*., 2000; Soegiarto and Wills, 2004; Manjunatha *et al*., 2012; Saadatian *et al*., 2012).

As a new fumigant, NO is effective against a wide variety of pests (Liu, 2013, 2015, 2017; Liu and Yang, 2016; Liu *et al*., 2016). Nitric oxide fumigation is also safe to fresh products (Liu, 2016, 2017, Liu et al. 2016). In fact, NO fumigated strawberries and apples have better postharvest quality as compared with untreated controls (Liu, 2016; Liu *et al*., 2016). Nitric oxide fumigation also has no toxic residues on fumigated fresh products (Yang and Liu, 2017). In this paper, NO fumigation past research was reviewed and discussed, and new data on efficacy and residues were also presented and discussed.

Procedures of nitric oxide fumigation

Nitric oxide fumigation must be conducted under ultralow oxygen (ULO) conditions. This is due to the nature of spontaneous reaction between NO and oxygen (O_2) to produce nitrogen dioxide (NO_2). The reaction not only consumes NO, but also produces NO_2 which can cause injuries to sensitive fresh products at high concentrations. Therefore, ULO needs to be established in a fumigation chamber by flushing with nitrogen (N_2) to reduce O_2 concentration to a minimum level. The fumigation chamber also needs to be sealed airtight to prevent O_2 leaking into the chamber. For stored product fumigation, carbon dioxide (CO_2) can also be used to flush the fumigation chamber as CO_2 is unlikely to affect stored products. At the end of fumigation, especially for fresh products, the fumigation chamber also needs to be flushed with N_2 to dilute NO before opening the chamber to prevent the reaction between NO and O_2 and production of NO_2.

Nitric oxide fumigation procedures have been published in a video article (Liu *et al*., 2017) and also described previously (Liu, 2013, 2015; Liu and Yang, 2016; Liu, 2017). Nitric oxide fumigation starts by establishing ULO conditions in an airtight fumigation chamber with a N_2 flush. Greasing with petroleum jelly often is required to achieve an airtight seal of a fumigation chamber. Tubing with low permeability or non-permeable to O_2, such as nylon tubing, should be used. Oxygen analyzers with zirconia sensors are recommended for their high sensitivities and longevity. To have high efficiency in establishing ULO conditions, the fumigation chamber can be flushed with N_2 at a high flow rate at the beginning and then reduce the flow rate when O_2 is close to a desired level. The ULO levels for NO fumigation can vary depending on NO concentrations and products. Higher ULO levels will consume NO and therefore reduce effective NO levels for pest control. Some fresh products are also sensitive to high NO_2 levels. We used $\leq$30 ppm O_2 in all of our small scale NO fumigation tests.

The length of time to achieve a desired ULO level may vary greatly depending on the type of products to be fumigated and the quantities of the products. Large fruit such as apples can take long time to establish ULO conditions as they contain large volume of air inside. Many fresh products are packed in perforated plastic bags or wraps with very limited air exchanges capabilities and therefore limit efficiency of N_2 flush in establishing ULO conditions. Vacuum may also be used to increase the efficiency in establishing ULO conditions.

Nitric oxide concentration, fumigation time, and temperature will depend on pest species and products. For packaged fresh products, it is recommended to use lower NO concentration but longer treatment time, because N_2 flush is needed to dilute NO at the end of fumigation and lower NO concentrations are easier to be diluted than higher concentrations. The level of dilution may also change depending on sensitivity of fresh products to NO_2. For fumigations of leafy vegetables and delicate fruits, it is preferably that NO be diluted to 100 ppm or lower before opening the chamber to ensure safety to products.

Currently there is no suitable analyzer to monitor NO concentrations in NO fumigations. The high concentration NO sensors in commercial flue gas monitors typically have a maximum concentration limit of 5000 ppm. Because of its reactive nature with O_2, NO cannot be quantified using a gas chromatograph. Therefore, NO concentrations in small chamber fumigations were calculated based on NO gas volumes used and the chamber volumes. For large fumigations, a flue gas monitor with a high concentration NO sensor can be used in conjunction with a dilution device to monitor NO concentrations in NO fumigations. The dilution device we made and used consisted of four equal length micro-tubes with one tube for sample gas and the other three for nitrogen. Under the condition of equal air pressure in the fumigation chamber and nitrogen in a foil bag, the air sample can be diluted four times and, thereby, a fumigation with 2% NO can be monitored using the monitor with a 5000 ppm NO sensor. However, a custom built NO analyzer with suitable maximum NO level for NO fumigation is possible from certain vendors.

Efficacy of nitric oxide fumigation

Over 10 species of insects and mites have been tested with NO fumigation. Nitric oxide fumigation is effective against all pest species tested to date at different life stages (Table 1) (Liu, 2013, 2015; Liu and Yang, 2016). However, there are considerable variations among species and life stages in susceptibility to NO fumigation. Nitric oxide fumigation is particularly effective against small external soft-body insects on fresh products. Western flower thrips (*Frankliniella occidentalis* (Pergande)), lettuce aphid (*Nasonovia ribisnigri* (Mosley)), and longtailed mealybug (*Pseudococcus longispinus* (Targioni Tozzetti) can be controlled in a few hours with 1-2% NO at a low temperature of 2°C (Liu, 2013).

Nitric oxide fumigation is also effective against internal feeding insects. Spotted wing drosophila (*Drosophila suzukii* (Matsumura)) larvae in infested cherries were controlled in 8 h with 2.5% NO fumigation. For codling moth (*Cydia pomonella* (L.)) larvae in infested apples, NO fumigation treatments of 24 h at 5% concentration at 2°C resulted in 100% larval mortality (Liu *et al*., 2016). Nitric oxide fumigation at 1-2% concentrations takes 24 h to 72 h at 15-25°C to control stored product insects such as Indianmeal moth (*Plodia interpunctella* (Hubner)), confused flour beetle (*Tribolium confusum* (Jacquelin du Val)), and rice weevil (*Sitophilus oryzae* (Linnaeus)). The treatment time is shorter for mobile stages than for pupa and egg stages (Liu, 2013, 2015; Liu and Yang, 2016). Bulb mites (*Rhizoglyphus spp*.) on infested peanuts were also controlled with 2% NO in 24 h at 20°C (Liu, 2017) (Table 1).

The efficacy of NO fumigation increases with concentration, time, and temperature. Concentration x Time (C×T) products correlate well with mortality and can be used to determine NO fumigation treatments. Effect of temperature on efficacy of NO fumigation is lower as compared with concentration and time (Liu, 2013).

Safety of nitric oxide fumigation to product quality

Safety of NO fumigation to product quality includes possible injuries to fresh products and likely residues in fumigated products. In small scale tests, NO fumigation is safe to all fresh products tested to date including lettuce, broccoli, cucumber, pepper, tomato, strawberries, apple, pear, orange, and lemon when terminated with N_2 flush as there are not significant differences between the treatment and the control (Table 2) (Liu, 2016). When NO fumigation is terminated by directly

opening the fumigation chamber to ambient air without flushing with N_2, NO reacts with O_2 to produce NO_2 in the fumigation chamber and results in stains on delicate fresh products including leafy vegetables, broccoli, squash, and peach. Stains also occur to some apples (Liu, 2016).

Tab. 1 Summary of nitric oxide fumigation treatments that had 100% control of different pest species at specified life stages*

Species	Life stage	NO (%)	Time (h)	Temp (°C)	Note
Western flower thrips	larva, adult	0.2	8	2	on lettuce leaves
		2	2	2	
Lettuce aphid	nymph, adult	0.2	12	2	on lettuce leaves
		0.5	9	2	
		1	3	2	
Long-tailed mealybug	nymph, adult	2	2	2	on grape leaves
Confused flour beetle	larva, pupa	0.5	24	20	on flour diet
	adult	0.5	8	20	
	egg	2	24	10

Bulb mites	larva, adult	2	24	20	on peanuts

* Reprint from Liu and Yang (2016).

For some fresh products, properly conducted NO fumigation not only is safe to product quality but also help to extend storage/shelf-life. Nitric oxide fumigations for control of western flower thrips results in better postharvest quality of strawberries with significantly firmer and brighter, richer color as compared with the control one week after treatment (Liu, 2016). Nitric oxide fumigation for control of codling moth larvae in apples also results in better apple quality as compared control four weeks after fumigation (Liu *et al*., 2016).

Residues of nitric oxide fumigation

Nitric oxide fumigation can result in nitrate (NO^{3-}) and nitrite (NO^{2-}) as residues as NO reacts with O_2 to produce NO_2 which can be further converted to nitrate and nitrite. However, both nitrate and nitrite occur in varying quantities in fresh and stored agricultural products. Twenty fresh products and 10 stored products have tested for residues. For most fresh products, NO fumigation does not lead to significantly higher nitrate or nitrite if the treatment is terminated properly with N_2 flush (Yang and Liu, 2017). For the 10 stored products, there were also no significant increases in nitrate or nitrite in fumigated stored products as compared with the controls (Yang and Liu, unpublished). When NO fumigation is terminated without N2 flush, there are significant increases in nitrate and sometime also nitrite levels in fumigated fresh and stored products (Yang and Liu, 2017, unpublished).

Nitrogen dioxide release rates and nitrate and nitrite levels were evaluated for different treatments from five selected fresh products and five selected stored products at 24 h after NO fumigation. This study showed considerable differences between fresh and stored products and among different fresh products, as well as among different stored products (Tab 3). Apples from both NO-N_2 (NO fumigation terminated with N_2 flush) and NO-Air (NO fumigation terminated without N_2 flush) treatments had similar significantly higher NO_2 release rates as compared with the control. Lettuce from the NO-Air treatment, however, had a NO_2 release rate which was about 1000 times as those of the NO-N_2 treatment and the control. For other fresh products: asparagus, broccoli and strawberries, NO-Air treatments had significantly higher NO_2 release rates as compared with NO-N_2

and controls. Higher retention of NO_2 on the fresh products led to corresponding higher levels of nitrate and nitrite in the products (Yang and Liu, 2017).

* Reprint from Liu (2017). All products from the treatments and the control were stored at 2°C for 14 days before being scored for postharvest quality. The visual quality was scored for marketability using the 1 (extremely poor) to 9 (excellent) scale for lettuce (Kader *et al*., 1973) with 3, 5, and 7 representing poor, fair with major defects, and good with minor defects (Liu, 2016).

For stored products, NO_2 release rates were much lower as compared with the fresh products. The variations among the three treatments were also much smaller as compared with the three treatments for the fresh products (Table 3). However, for the most products, NO-Air treatment still had significantly higher NO_2 release rate as compared with NO-N_2 treatment and the control. Nitrate and nitrite levels also varied among the three treatments in consistence with the NO_2 release rate variations. Higher NO_2 release rates corresponded with higher nitrate and nitrite levels for all of the stored products (Table 3).

Discussions

Nitric oxide fumigation is effective against all pests tested to date, is safe to fresh product quality and leaves no toxic residues in fumigated products when terminated properly. Over 10 tested pest species have been effectively controlled and they represent different taxonomical groups, both external and internal feeders, both fresh and stored product pests, and different life stages. The efficacy data suggest that NO fumigation is likely effective against all insect pests and mites. Because of large variation in susceptibility to NO fumigation among different species and life stages, different pests will likely need different combinations of NO concentration and treatment time at certain temperatures to achieve effective control. CxT products can be used to determine appropriate NO fumigation treatments because they correspond well with mortality for individual species.

Nitric oxide has advantages in efficacy in comparison with other methyl bromide alternatives, including phosphine, sulfuryl fluoride, and ethyl formate. Phosphine is the major methyl bromide alternative fumigant for both fresh and stored product pests. However, phosphine fumigation is not effective against some pests due to tolerance or resistance. In general, phosphine fumigation

also has long treatment times which may extend over 10 days to achieve effective control of some pests (Hole *et al*., 1976). Although recently developed oxygenated phosphine fumigation has significantly increased efficacy of phosphine fumigation against phosphine tolerant insects (Liu, 2011; Liu *et al*., 2013), the prospect of commercial application is still unclear. Sulfuryl fluoride is not effective against insect eggs (Bell *et al*., 1998) and is also phytotoxic to fresh products (Aung *et al*., 2001). Therefore, it has limited effectiveness against postharvest pests. Ethyl formate has high absorbing rates in fresh products and also has phytotoxicity on fresh products (Stewart and Mon, 1984; Zoffoli *et al*., 2013). In contrast, NO is effective against all pests and all life stages and has high efficacy against small external pests on fresh products with short treatment times and very low absorbance in fresh products.

Tab. 3 Nitrogen dioxide (NO_2) release rate and nitrate (NO^{3-}) and nitrite (NO^{2-}) contents in selected fresh and stored products at 24 h after nitric oxide fumigation*

*Fresh products: apple, asparagus, broccoli, lettuce, and strawberries were fumigated with 5, 3, 3, 2, and 2.5% NO respectively for 16h at 2°C. Stored products were fumigated with 3% NO for 24 h at 20°C. Treatments NO-Air and NO-N_2 refer to nitric oxide fumigation that was terminated by flush with air and N_2 respectively. For each product, the values in each column followed by different letters were significantly different based on Tuckey HSD multiple range tests at $P \leqslant 0.05$ (SAS Institute, 2012). Data on fresh products are from a previous article (Liu and Yang, 2016).

In small scale fumigation tests, NO fumigation is safe to fresh products if it is terminated properly with N_2 flush to dilute NO prior to open the fumigation chamber to ambient air. These results are encouraging and need to be demonstrated in large scale trials. Commercial fresh products often are sealed in plastic packing materials such as perforated wraps and bags with very limited air exchange ability and then packed in cartons and crated on pallets. All of these restrict air exchange and

increase difficulty in establishing ULO conditions for NO fumigation and diluting NO at the end of fumigation.

For delicate fresh fruits and vegetables, the additional benefits of NO fumigation for pest control on postharvest quality can have significant economic impact as it increases shelf-life and enable wider distribution of the products. Fumigation of flower bulbs for controlling bulb mites with or without N_2 flush to dilute NO also did not have any effects on their germination or growth, indicating NO fumigation was safe to propagating plant materials (Liu, 2017).

Some harvested fresh products are treated with chemical agents to maintain proper storage life. For example, diphenylamine (DPA), a plant growth regulator, is used to control storage scald of apples in USA. Nitric oxide, however, is an inhibitor of ethylene biosynthesis (Manjunatha *et al*., 2010) and can also help to maintain postharvest storage life (Wills *et al*., 2000; Soegiarto and Wills, 2004; Manjunatha *et al*., 2012; Saadatian *et al*., 2012; Liu *et al.,* 2016). It is possible that NO fumigation for postharvest pest control can also reduce or replace the usage of chemical agents such as DPA for postharvest storage of fresh fruit. This potentially bring additional benefits of NO fumigation and enhance food safety.

Nitric oxide fumigation does not leave toxic residues on fumigated products. When NO fumigation is not terminated properly by directly opening the fumigation chamber to ambient air without prior N_2 flush, the fumigation will likely cause significant increases in nitrate levels and sometimes also nitrite levels in fresh products. However, nitrate and nitrite are nutrients and they exist in both fresh and stored products at various levels (Santamaria, 2006; Hord *et al*., 2009) and the increases after NO fumigation are also well within their normal ranges in prospective products.

Nitrogen dioxide has a boiling point of about 21°C and high solubility in water. This is likely the main reason for higher NO_2 release rate 24 h after fumigation on fresh products than on stored products. Fresh products were fumigated at 2°C and stored products were fumigated at 20°C. At the end of fumigation, NO_2 from oxidation of NO will more likely to stay on fresh products because of the low ambient temperature and high relative humidity than on stored products. Retaining of NO_2 not only cause increases in nitrate and nitrite contents, also affect management of fumigated products due to increased health risks related to workers' exposures to released NO_2 from fumigated products. So, even the increases in nitrate and nitrite from NO fumigation are acceptable, it is preferably to terminate NO fumigation with N_2 flush to avoid prolonged emission of NO_2 from fumigated products, especially for fresh products since NO_2 at high levels can also cause injuries to delicate fresh products (Liu, 2016).

Due to the reactive nature of NO with O_2, NO fumigation, however, must be conducted under ULO conditions in airtight fumigation chambers. Therefore, NO fumigation requires complex and strict procedures and efforts are needed to develop protocols for commercial applications of NO fumigation. The complex fumigation procedures also add costs to NO fumigation. These costs include initial capital expenses on N_2 generation equipment and fumigation chambers and operation related costs including electricity, equipment maintenance, and NO supply. Nitrogen generation equipment is widely available commercially. Electricity cost varies depending on locations. Nitric oxide gas is also available commercially. Previous analysis suggests that NO fumigation is technically feasible and cost effective (Liu, 2015).

Nitric oxide has been studied extensively over past three decades since it was found to be a ubiquitous cell messenger. However, as a newly discovered fumigant, the mode of action of NO for pest control is still unknown. In addition, NO is known to be toxic to humans. Therefore, even NO is produced naturally by almost all organisms, it still needs to be registered as a chemical pesticide in USA in order to be used for postharvest pest control. Nitric oxide will also need regulatory approval in other countries in order to be used commercially for postharvest pest control. Participation of industry will be critical for eventual registration and commercial use of NO for postharvest pest control.

There have been extensive efforts to find alternative treatments for postharvest pest control since the start of global phase out of methyl bromide production. However, progresses are very limited and there is a severe lack of safe and effective alternative fumigants to meet the demand for postharvest pest management. Nitric oxide fumigation has high efficacy against a wide variety of pests, no toxic residues on fumigated products, and can be used on both fresh and stored products. In addition, NO fumigation has potential to extend storage life of fresh products. All these advantages of NO should far offset the disadvantages of complex and strict fumigation procedures and associated costs on acquisition and operation of N_2 generation equipment. More efforts are needed in several fronts in order to speed up the commercial applications of NO fumigation. They include research to develop effective and safe treatments for various pests on a variety of products, developmental efforts for suitable and reliable systems and protocols for commercial scale NO fumigation, including techniques to reduce emission of NO into atmosphere and registration efforts from industries to attain regulatory approval from respective countries for commercial applications.

Abstract

The presented paper provides preliminary results on the fumigation potential of two preparations: Bluefume (HCN - hydrogen cyanide) and EDN®. (Ethane-dinitrile). Their biological efficacy was tested on Granary weevil (*Sitophilus granarius*; Curculionidae; Coleoptera) as a primary stored product pest in the Czech Republic. In fumigation chamber, we tested temporal survival of various *S. granarius* strains following exposure of a dose of 9 $g.m^{-3}$ HCN (Bluefume). We compared differential sensitivity of one laboratory (i.e. sensitive) CRI-strain and 9 field strains collected from the Czech stores and mills. The HCN Ct products required to kill the tested *S. granarius* strains ranged from CTp= 30.5 $g.m^{-3}.h^{-1}$ to CTp= 51.7 g.m3.h^{-1}. The efficacy of EDN (30 $g.m^{-3}$) on various developmental stages *S. granarius* was tested in a fumigation chamber. No live individual of *S. granarius* belonging to any life stage was recorded following 18 hours of EDN exposure.

Keywords: gas, ethane dinitrile, hydrogen cyanide, Granary weevil, Sitophilus granarius,

Introduction

Fumigation of stored product pests has become a real challenge for both farmers and pest control professionals (PCOs) in the last two decades. The reason is that broad-spectrum pesticide methyl bromide is no longer available and pest resistance to the remaining major fumigant phosphine is on the rapid increase (Nayak, et al., 2017). Therefore, the alternatives to methyl bromide or "resistance phosphine breakers" (e.g., Nayak et al., 2016) are urgently needed. However, there are only few candidate active ingredients available even at the worldwide scale (Ducom, 2006). Currently two of them (EDN and HCN) are produced in the Czech Republic (Lucebni zavody Draslovka Kolin a.s.).

HCN (Bluefume)

Various formulations of hydrogen cyanide (HCN) has previously been used for pesticide/biocide fumigation in several countries, including USA, South Korea, France, Germany, Czech Republic, and Switzerland (Rambeau et al., 2001). HCN as an active ingredient shows quick and high efficacy on structural pests infesting mills (Bond 1984, Rambeau et al. 2001, Aulicky et al., 2015a) and ships (Monro, et al., 1952). Aulicky et al., (2015a) demonstrated a higher activity of HCN on *Tribolium confusum* eggs than the one documented for phoshine during the commercial mill fumigations in Czechia (Aulicky et al., 2015b). HCN has been historically used for the fumigation of many dry

foodstuffs, grains, tobacco and seeds (Bond 1984, Emekci, 2010, Stejskal, et. al., 2014b). HCN also shows promising level of biocidal activity on package and structural wood infesting pests such as *Hylotrupes bajulus*, *Anoplophora glabripennis* and pine wood nematode, *Bursaphelenchus xylophilus* (Stejskal et al., 2014a, Douda et al., 2015). Recent works Zouhar et al., (2016) reported high nematicide potential of hydrogen cyanide against *Ditylenchus dipsaci* nematode present inside garlic seedlings.

EDN®

Ethane-dinitrile (EDN) is an ozone-friendly alternative to methyl bromide. Its advantages are good penetration characteristics, high efficacy and short application time (Ryan et al., 2006). The EDN® main use is aimed at limiting the risks of pests and disease spreading, within the agricultural and timber industry. It can be used to sterilize soil and control insects, diseases, nematodes, weeds and other parasites, before planting. It can also be used to fumigate harvested timber and logs. Its excellent penetration characteristics and high efficacy make EDN® a great solution for eliminating wood-boring insects in timber as well as pathogens and nematodes which present a direct biosecurity risk to many importing countries.

As apparent from the previous paragraphs, most of the recently published studies on both fumigants dealt mainly with wooden, soil or structural pests. However, there are only limited (Hooper et al., 2003) and/or outdated (Monro, et al. 1952, Lindgren, et al. 1954, Lindgren, Vincent 1965) information documenting the efficacy of ECN or EDN on stored product pests.

Therefore in the present work we evaluated the potential of two fumigantion preparations (Bluefume -HCN- hydrogen cyanide and EDN® -Ethane-dinitrile) regarding their biological efficacy on the primary stored product pest granary weevil (*Sitophilus granarius*).

Materials and Methods

Pest species

Granary weevil (*Sitophilus granarius*, Curculionidae; Coleoptera) was selected as a model species, since it is a major primary pests in the Czech Republic stores (Stejskal et al., 2014b; Stejskal et al. 2015). Both field (for HCN testing) and laboratory (for EDN or HCN testing) strains of *S. granarius* were included in the study.

HCN (Bluefume)

The efficacy of HCN on various strains of *S. granarius* was tested. In the tests, the efficacy of BLUEFUME (with the active substance HCN) at the initial dose of 9 g. m^{-3} (0.75%) of HCN on *S. granarius* adults was estimated. Testing was carried out in a small fumigation chamber of 650 litres (for detailed description of methods see Stejskal et al., 2014a). In total, 10 strains (one laboratory and 9 field strains) were included in the experiments. The following HCN exposure times were used: 15; 45; 60; 90; 180; 240; 300; 360; 420; 480; 540; 600 and 660 minutes. The reason for using short exposure times and a reduced dose of HCN was to divide the mortality of the tested individuals over a wider time span.

EDN®

The efficacy of EDN on various stages of *S. granarius* was tested. The tested EDN dose was 30 $g.m^{-3}$ and the exposure time was 18 hours. The tests were carried out in a 650-liter fumigation chamber (Stejskal et al., 2014a). The individual stages of development of the *S. granarius* were separately placed (in grain mass of winter wheat) in plastic containers with a diameter of 50 mm and a height of 70 mm. A hole of 40 mm diameter was formed in the lid and bottom of the plastic container, which was overlaid with a breathable fabric (miralon). Biological samples with grain containing

different stages of *S. granarius* were exposed in separate plastic containers. Adults aged 7-14 days were inserted into grain mass in the test vial one day before trial.

Eggs of *S. granarius* were ovtained by exposing adult females to grain mass for 3-4 days before trial. For the testing of pupae, the infested grains were used 42-48 days after exposure to *S. granarius* females. The biological efficacy of EDN on various stages was evaluated after removal and ventilation of samples in the laboratory. In adults, the efficacy was assesed visually, directly on the basis of their knockdown and mortality. In pupae, larvae, and eggs, however, the EDN efficacy was evaluated indirectly: according to adult emergence from the exposed grain-infested samples.

Results and Discussion

HCN (Bluefume)

Figure 1 shows comparison of the HCN sensitivity of one laboratory strain with 9 field strains of *S. granarius* (collected from the Czech stores and mills). The maximum time required to kill all of the tested 10 *S. granarius* strains was 660 minutes. The Ct products - required to kill the tested 10 *S. granarius* strains - ranged from CTp= 30.5 $g.m^{-3}. h^{-1}$ to CTp= 51,7 $g.m^{-3}. h^{-1}$.

Monro, et al. (1952), were the first who published a comparison of the efficacy of HCN and methyl bromide as fumigants for the treatment of stored product pests in empty ships. Later Lindgren, et al. (1954) compared the laboratory efficiency of 10 fumigants to selected types of food and warehouse pests. Their work showed the high efficiency of HCN in 8 tested species. Grain weevil (*S.granarius*) and Rice weevil (*S. oryzae*) were less tolerant to HCN than other pests including *Tribolium confusum, Acathoscelides obtectus, Oryzaephilus surinamensis* and *Rhizopertha dominica*. However, Ct products were not established in their work. The first study, which documented the HCN Ct products required to kill *S. granarius*, was the work of the French researchers Rambeau et. al. (2001). They claimed that *S. granarius* was more tolerant to HCN than to methylbromide (CH_3Br). The Ct product and mortality of *S. granarius* for HCN was 36 $g.m^{-3}$ for LD_{90}, and 15.7 $g.m^{-3}$ for CH_3Br. Rambeau et al. (2001) did not use HCN formulations in the form of liquid or liquid soaked in porous matter - a formulation that uses BLUEFUME but worked with HCN released from cyanide salts.

EDN®

Table 1 shows that the exposure of *S. granarius* by EDN fumigant at a dose of 30 $g.m^{-3}$ led to 100% mortality in all of the tested pest stages. According to Ducom (2006) EDN was much more toxic than methyl bromide and killed most of the pests very quickly. However, S*itophilus* sp. was an exeception, since a very long exposure of 5 days was required to achieve complete mortality of the egg stage. However, our laboratory experiments suggested that 100% mortality can be reached after 18 hours in all stages for the EDN dose of 30 $g.m^{-3}$. This preliminary result show good potential of EDN to be used to combat infestations from storage pests and it is therefore, desirable to continue with further validation tests against other pest species.

Tab. 1 The efficacy of EDN on various stages of *Sitophilus granarius* (dose: 30 g/m3, exposure time: 18 hours) in a fumigation chamber.

	Mortality (%)		Larval emergence (ks)	
Developmental stage	Treated	Control	Treated	Control
Adults	100	3,6	n	n
Larvae	n	n	0	483,4
Pupae	n	n	0	651,6
Eggs	n	n	0	2,8

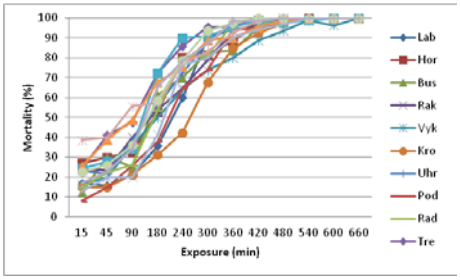

Fig. 1 Mortality of 10 strains (9 field and 1 laboratory) of *Sitophilus granarius* after HCN exposure in a dose of 9 $g.m^{-3}$ in a fumigation chamber.

Abstract

The benefits and deficiencies of several methods of analysis for PPO and PXH, including the aqueous extraction used in ASTA method 23.1 and the MTBE extraction method previously reported by the authors, will be discussed. Novel methods utilizing dynamic headspace extraction and solid phase microextraction (SPME) will also be reported with particular emphasis on preventing artefactual effects. Preliminary experiments have found that dynamic headspace sampling can lower detection limits by up to 3 orders of magnitude.

Keywords: Propylene Oxide, Fumigation, Sterilent, Headspace-SPME, Pesticide Degradants.

Introduction

The importance of propylene oxide (PPO) treatments for stored product protection has only increased in recent years, especially as the implementation of FSMA in the US puts pressure on tree nut producers to pasteurize their product. In the search for post-harvest methyl bromide replacements; PPO/SF blends, with PPO overcoming the ovicidal deficiencies of sulfuryl fluoride, have been shown to be effective against several stored product pests.

With the increasing variety in PPO treatments across commodity types and a "deharmonized" global MRLs comes an increasing need for the quick and accurate quantification of PPO residues. Analysis is complicated by the ease with which PPO will undergo nucleophilic reaction with water to form propylene glycol, or with chloride and bromide to form propylene chloro and bromo- hydrin, which can artificially lower the detected PPO residue. Avoiding the formation of these halohadrins (PXH) is of particular importance as they face regulatory scrutiny as carcinogens.

Materials and Methods

Jimenez et. al. Method:

Almonds or walnuts are added to an explosion proof blender along with chilled, deionized water and MTBE and homogenized. 45mL of the homogenate is centrifuged and a 1 mL aliquot of the MTBE supernatant is transferred to a 2 mL amber glass vial for analysis. A 10x concentration (10 mL to 1 mL) of the MTBE supernatant could be performed to increase detection of PBH-1 and PBH-2. Analysis was performed via cool on-column injections in an Agilent 6890 gas chromatograph (GC) equipped with a 5973N mass spectrometer (MS).

Dynamic Headspace Extraction Method:

Three almonds or walnuts are chopped roughly, transferred into a 20 mL headspace vial and sealed. The vial is then incubated at 80C for 42 min in a Perkin-Elmer Turbomatrix dynamic headspace autosampler, and three cycles of pressurizing the vial to 15 psi and allowing it to vent through an adsorbent trap are performed prior to ballistically heating the trap and directing the sample flow into a Perkin-Elmer Clarus SQ8 GCMS.

SPME-Headspace Method:

An approx. 50g sample of almond or walnuts is cryogenically milled under liquid N2 and a 2g subsample is transferred to a 20 mL headspace vial and sealed. SPME extraction is performed with

a Carboxen / DVB / PDMS fiber at room temperature and 30min sorbtion time. Analysis is performed on an Agilent 7890B GC with a LECO Pegasus BT TOF-MS.

For each methods, % recovery and LODs were determined by spiking known amounts of each analyte onto the surface of a walnut or almond and extracting. The amount of side reaction (amount of PCH or PBH formed during extractioin and analysis) was determined by spiking PPO-treated nuts with d6-PPO and measuring the amount of deuterated PCH (PCD) and PBH (PBD) formed. The reaction kinetics between PPO and chloride / bromide will be examined by spiking PPO onto the surface of nuts or nut grounds and measuring the amount of PCH and PBH formed at varying reaction times and temperatures.

Results

Negative chemical ionization MS (NCIMS) was not found to improve analyte sensitivity for the target analytes when compared to electron impact MS (EIMS). GC-ECD (electron capture detection) demonstrated improved sensitivity for PBH-1 and PBH-2 in non-concentrated MTBE extracts (approx. 0.7 mg/kg compared to 50 mg/kg for EIMS). Ten-fold concentration of the MTBE extract yielded a 10x improvement in detection limits for PBH, but recoveries for PPO and PCH, respectively, dropped below 50% and ranged from 50 to 72%.

The use of dynamic headspace extraction demonstrated a great improvement in the simplicity, speed and sensitivity of analysis compared to MTBE extraction, with detection limits for PCH and PBH around 10 ng/g (ppb). The incubation temperature required for the sensitive detection of PBH, however, was shown to also cause further reaction of PPO into PCH and PBH. Results from the the use of a saturated KI solution to preemptively react with PPO will be reported.

Preliminary experiements show that SPME-Headspace extraction has been shown to have excellent sensitivity for each target analyte, able to detect as little as 1.5 ng of material, dissolved in 5 µL H_2O, and spiked into an empty 20 mL HS vial. Spiking approx. 20 µL of PPO into almond grounds and analyzing with SPME-headspace analysis has shown that PBH and PCH begin to form in as little as 20 min at room temperature.

Tab. 1 Limits of detection for each target analyte for the MTBE extract and dynamic headspace methods.

Compound	Matrix	LOQ - Solvent Extract	LOD - Head Space Trap
PPO	Almond	0.85 ug/g	0.54 ug/g
	Walnut	0.81 ug/g	0.08 ug/g
PCH-1	Almond	2.10 ug/g	10.0 ng/g
	Walnut	2.31 ug/g	12.1 ng/g
PCH-2	Almond	2.22 ug/g	N/A
	Walnut	1.95 ug/g	N/A
PBH-1	Almond	75.1 ng/g	6.01 ng/g
	Walnut	74.8 ng/g	19.0 ng/g
PBH-2	Almond	75.3 ng/g	4.92 ng/g
	Walnut	77.3 ng/g	N/A

Discussion

Preliminary experiments have demonstrated that while headspace sampling methods can significantly improve sensitivity for PPO, PCH and PBH, great care must be taken to avoid aretfactually raising PCH and PBH levels. The use of autosamplers (either dynamic headspace or L-PAL3 with SPME attachment) can greatly reduce injection to injection variability and reduce the number of person-hours required for analysis, but to fit walnuts or almonds into headspace vials they must be chopped or ground exposing further chloride or bromide to react with PPO. Future experiments using manual SPME sampling will allow the use of glassware that can accommodate whole nuts. The use of iodide, or other nucleophiles, to compete with chloride and bromide for the reaction with PPO will also be examined.

Monitoring of post-harvest fumigation with Gasmet Multikomponent FTIR gas detection systems

Frank Arnold

Ansyco GmbH, Ostring 4, 76131 Karlsruhe, frank.arnold@ansyco.de
DOI 10.5073/jka.2018.463.131

Keywords: Post-Harvest, Fumigation, Fourier Transform Infrared (FTIR), Fumigant, Library Search Tool

Fumigation business has changed dramatically after the Montreal protocol came into effect on January 1st 1989. Methyl Bromide had to be replaced in all its widespread application. A lot of fumigators having experience with Methyl Bromide are still mourning in regards of its outstanding fumigation performance. Today, almost 30 years after, we are having a big variety of different alternatives to Methyl bromide, developed by research institutes around the world.

Focusing on new gaseous alternatives to Methyl Bromide, FTIR technology is an extremely versatile detection principle, offering a widespread use in the fumigation industry.

Fourier transform infrared (FTIR) is a powerful gas measurement technology that offers true multicomponent capability. This technology that was originally used for challenging research applications has since proven to be very reliable and versatile and has become the industry standard in many challenging emissions monitoring applications.

Most gases absorb infrared light at some wavelengths in the infrared spectrum. The position and intensity of the absorptions are determined by the molecular structure of the gas and this means that each gas will have a unique absorption pattern. This unique pattern can be used like a fingerprint to identify and measure each gas in the sample.

An FTIR analyzer works by simultaneously scanning the entire infrared spectrum and then calculating the concentrations of each gas in the sample based on their characteristic absorptions. The fact that the entire infrared spectrum is scanned at once means that all the gases in the sample can be measured simultaneously. This allows for very quick multicomponent measurements and for compensation for any cross-interference.

As all gases are measured by scanning the same infrared spectrum, adding new compounds can be done easily in the software without requiring any changes to the hardware. The recorded spectra are also unaltered by the analysis performed on them and can therefore, always be re-analyzed at a later point. This allows for traceable data and facilitates for instance retrospectively checking the measurements for new gases.

All this makes FTIR the ideal solution for a variety of applications where multiple gases need to be measured quickly, accurately and reliably.

Working on approving, registering, developing or applying new fumigation procedures has become much more demanding than what experienced for Methyl Bromide. The need for an ideal gas detection device is enormous.

FTIR technology brings some outstanding advantages for the fumigation industry as listed below:

1. Detection of several different fumigants with the same instrument
2. No changes of sensors required for change in gases
3. Extremely easy and low cost calibration
4. Detection of complex gas mixtures

5. Due to the evidential detection of the target gas cross sensitivities are reduced to a minimum and can be evaluated and analysed even after the measurement.
6. Generating of ct-diagrams is a crucial part of the whole FTIR measurement.
7. Ready to measure new fumigants
8. High concentrations of fumigants during fumigations and low concentrations for clearance /entry permits can be measured with one instrument

A lot of gases can be detected, qualitative and quantitative

	Gas	Fumigation procedure	Clearance/ entry permit	LDL in N2
1.	Methyl Bromide	X		0,4 ppm
2.	Phosphine	X		0,2 ppm
3.	Sulfuryl Fluoride (Vikane®, Profume®)	X	X	0,03 ppm
4.	HCN	X	X	0,35 ppm
5.	EDN	X	X	0,9 ppm
6.	COS	X	X	0,004 ppm
7.	Ethyl Formate	X	X	0,1 ppm
8	Propylene Oxide	X	X	0,1 ppm
9.	Methyl Iodide	X	X	0,1 ppm
10.	Chloropricrin	X	X	0,08 ppm
11.	Formaldehyde	X		0,09 ppm
12.	Ethylene Oxide	X	X	0,2 ppm

A real big advantage is to detect several gases (up to 50) parallel. By using the entire spectrum between 850 and 4200 waves/cm.

Examples for parallel evaluations are:

1. HCN and CN2
2. SO2F2 and Chloropricrin

This options enables the user to check for interactions with the fumigated material, metabolisms and other tasks where more than one gas has to be evaluated.

Determination of safe storage moisture content of commercial maize (*Zea mays*) seeds during hermetic storage

Bernadette Abadía[1,*], Ricardo Bartosik[1,2]

[1] Researcher, National Institute of Agricultural Technology (INTA), Balcarce Research Station, Argentina
[2] Researcher, National Scientific and Technical Research Council (CONICET), Argentina
* Corresponding author: abadia.maria@inta.gob.ar
DOI 10.5073/jka.2018.463.132

Abstract

Germination declines during storage and meeting official standards (90% limit) can be challenging for the seed industry. Hermetic storage, through the establishment of self-modified atmospheres has shown to preserve germination in high-moisture maize seeds, but in the range of the low-moisture contents (m.c.) used by the seed industry, the relationship between hermetic storage and seed quality has not been fully studied. The aim of this work was to determine the safe storage m.c. of commercial maize seeds during hermetic storage considering both germination and microbiological aspects. Maize seeds with 95% initial germination were conditioned to m.c.s. between 11.5 and 14.5% and stored hermetically at 25ºC for 6 months. Germination, % oxygen, % infected grains, and colony forming units (CFU) were evaluated. Germination declined with increasing m.c.s, dropping to 50% at 14.5% m.c. Microflora respiration started to be detected at 13.5% m.c. and an anaerobic self-modified atmosphere was reached at 14.5% m.c. Despite the higher relative humidity, % infected grains and CFU count at 14.5% m.c. were lower than at 13.5%, probably due to the suppressive effect of the anaerobic atmosphere. In conclusion, 11.5% was a safe storage m.c. as it preserved germination above marketing requirements without microbiological risk. Hermetic storage was useful to generate self-modified atmospheres for m.c.s above 13.5%, but these self-modified atmospheres were not effective to protect germination. Further research on the effects

of controlled and self-modified atmospheres on the quality of different maize genotypes is needed to evaluate the benefit of hermetic storage of commercial seeds.

Keywords: seed germination, microbial activity, modified atmosphere, controlled atmosphere, respiration.

Introduction

Relative humidity and temperature are two major factors that must be controlled during seed storage to preserve germination (Krishnan et al., 2004; Kong et al., 2015; Mansouri-far et al., 2015). At an equilibrium relative humidity (e.r.h) above 75%, the seed associated microflora will develop rapidly during storage affecting seed quality (Pixton, 1967; Navarro and Donahaye, 2005). For most grains and oilseeds, a threshold of 70% e.r.h is used to determine the microbiological safe storage moisture content (Pixton, 1967; Giner and Gely, 2005). Also, degenerative reactions associated with seed ageing are hastened above 70% e.r.h. (Bewley et al., 2013). Because seed deterioration increases with temperature (Barzali et al., 2005), commercial maize seeds must be stored in refrigerated (5-10ºC) and controlled e.r.h chambers at the expense of high energetic costs (Robertson et al. 1984; Chiu et al. 2003; Sun et al. 2007; Abreu et al. 2013).

Besides e.r.h. and temperature, low oxygen concentrations during storage have shown to benefit germination in many species (Chiu et al., 2003). Low-oxygen concentrations limit the development of various aerobic genera of seed fungi (Hocking, 1990; Weinberg et al., 2008; Taniwaki et al., 2009; Marcos Valle, 2015) and also impair oxidative aging reactions (Chiu et al., 2003; Yeh et al., 2005; Groot et al., 2015). Exploring the potential of low-oxygen modified atmospheres as an alternative technology to refrigeration is of great interest for the seed industry, as it could help to save energy and reduce storage costs.

Low-oxygen atmospheres can be easily obtained storing seeds hermetically. During hermetic storage, the respiration of the seed associated microflora will consume the oxygen and release carbon dioxide originating a self-modified atmosphere (Navarro and Donahaye, 2005). Seed respiration starts to be detected above 90% relative humidity (Bewley et al. 2013), and thus it is not expected to occur in the range of low-moisture contents used in the seed industry.

Hermetic storage of high-moisture maize (above 14%) has proved to benefit germination compared to open-air storage (Moreno et al. 1988; Cardoso et al. 2016). However, in the range of the low-moisture contents used by the seed industry, the relationship between hermetic storage and maize seed quality has been less studied. The aim of the present work was to determine the safe storage moisture content (s.s.m.c.) of commercial maize seeds under hermetic storage considering not only microbiological risk but also germination decay. Therefore, the s.s.m.c. was defined as the maximum moisture content (m.c.) that preserves germination above 90% (official requirement in Argentina for maize seed marketing, SAGyP (1993) with no evidence of microbial activity after six months of storage at 25ºC.

Materials and methods

Maize samples preparation and experimental procedure

Maize seeds harvested in February 2016 (GLStack 4500, KWS) were divided into four batches and put into plastic bags for moisture conditioning to four target m.c.s. (11.5, 12.5, 13.5, and 14.5%). Calculated amounts of distilled water were poured into the bags and seeds were thoroughly mixed after wetting. The four bags were stored for 7 days at 4ºC with daily mixing of the seeds for moisture stabilization.

The maize of each batch was divided into three and placed in glass jars, each with a rubber septum on the lid for gas sampling. Maize samples were collected from the jars before closing the lid for initial measurements of germination, colony forming units (CFU), and infected grains. The sealed jars were stored at 25ºC for 6 months.

Analytical procedure

The germination percentages were determined following ISTA guidelines (ISTA, 2015). Briefly, three replicates of 50 seeds per jar were placed on extended wet paper towels, rolled, and introduced into plastic bags to be incubated at 25°C for 7 days. Results were expressed as percentages of normal seedlings.

The m.c. of the maize samples was determined by forced-air oven drying at 130ºC for 72 h according to ASAE (2003). Equilibrium relative humidity (e.r.h.) of the headspace was determined at 25ºC using relative humidity sensors (I-button, Hygrochrom, EEUU). Oxygen and carbon dioxide concentrations in the headspace were determined using a gas analyzer (CheckPoint, DanSensor, Denmark).

Microbiological analysis

Colony forming units (CFU) were determined by homogenizing 10g of maize seeds in 90 ml of peptone water, serial diluting 1ml in 9ml of the same diluent, and spreading 0.1ml aliquots on potato dextrose agar (PDA) plates. Plates were incubated at 28ºC for 5-7 days, when colonies were counted (Castro et al., 2002). Results were expressed as logCFU/g of maize.

Infected grains were determined by the direct plating technique. Fifty kernels were randomly sampled from each jar, and they were surface-disinfected in a 1% sodium hypochlorite solution for 2 min. The samples were plated on potato dextrose agar (PDA) plates (10 seeds by plate) under a sterile hood, and incubated at 28ºC for 5-7 days, when the percentage of fungi contaminated seeds was determined for each sample (Berardo et al., 2005).

Statistical analysis

Linear or Generalized Linear Models were fitted to the data after checking model´s assumptions by means of residual plots. The statistical analysis included analysis of variance and Tukey´s multiple comparisons test. The packages nlme (Pinheiro et al., 2017), lattice (Sarkar, 2008), and emmeans (Lenth, 2018) of the statistics software R version 3.4.3 were used.

Results

At the beginning of the hermetic storage period, the m.c.s. of the maize in the 11.5%, 12.5%, 13.5%, and 14.5% levels were (11.64±0.01)%, (12.68±0.06)%, (13.70±0.05)%, and (14.70±0.10)%, respectively. The corresponding initial e.r.h.s. were (63.0±1.6)%, (70.5±2.5)%, (75.2±2.7)%, and (77.2±4.2)%, respectively. M.c.s. showed a slight increment during the storage period, because of respiration activity. The final m.c.s. were (12.2±0.4)%, (13.7±0.2)%, (14.8±0.1)%, and (14.9±0.8)% and the corresponding final e.r.h.s. were (63.2±1.1)%, (72.3±0.1)%, (77.1±0.5)%, and (80.7±0.8)%.

Table 1 summarizes the germination percentages of the maize seeds at the beginning and after 6 months of hermetic storage. The initial germination percentage was higher than 95% in all the four seed lots conditioned to the different m.c.s. Final germination remained unchanged at 11.5% m.c. and started to decrease at 12.5% m.c., dropping by half at 14.5% m.c. However, due to variability in the data, no significant differences were found between final germination for 11.5, 12.5, and 13.5% m.c.s.

Tab. 1. Estimated marginal means ± model standard error of germination percentage under hermetic storage.

Time (months)	Moisture content (%)			
	11.5	12.5	13.5	14.5
0	95.7±2.9 Aa	97.7±2.9 Aa	97.0±2.9 Aa	99.0±2.9 Aa
6	94.0±2.9 Aa	83.7±2.9 Aa	81.3±2.9 Ba	48.0±2.9 Bb

Within each column, means followed by different upper case letters are significantly different; within each row means followed by different lower case letters are significantly different ($P<0.05$).

As a Linear Model was fitted to the germination data, the model standard error is the same for all groups.

Table 2 shows the concentration of oxygen within the sealed containers of maize seeds after 3 and 6 months of storage. At 11.5% m.c. oxygen remained constant during the whole storage period and similar to the normal atmospheric concentration, indicating there was no respiration at this m.c. At 12.5% m.c., a slight self-modification of the atmosphere occurred by 3 months, indicating the onset of respiration at this m.c. At 13.5% and 14.5% m.c.s., oxygen dropped markedly by 3 months revealing a more intense respiration. An anaerobic self-modified atmosphere was reached only at 14.5% m.c. The carbon dioxide concentration always remained below 21% (data not shown), suggesting that aerobic respiration prevailed in the range of m.c.s. studied.

Tab. 2. Estimated marginal means ± model standard error of oxygen concentration during hermetic storage of maize seeds. Normal atmospheric oxygen content: 20.9%

Time (months)	Moisture content (%)			
	11.5	12.5	13.5	14.5
3	20.0 ±0.2 Ac	19.4 ±0.4 Ab	1.3±1.1 Aa	0.0±0.1 Aa
6	20.1 ±0.2 Ac	18.3±0.4 Ab	2.6±1.1 Aa	0.5±0.1 Ba

Within each column, means followed by different upper case letters are significantly different; within each row means followed by different lower case letters are significantly different ($P<0.05$)

Tab. **3** shows the results of the microbiological analyses before and after 6 months of hermetic storage. The initial percentages of infected seeds were similar for the different m.c.s. After the storage period, the percentages of infected seeds were similar at 11.5% and 12.5% m.c.s., and remained on average below 40%. The final percentage of infected seeds increased abruptly at 13.5% m.c., where practically all the seeds were infected by molds. The percentage of infected seeds at 14.5% was near 60%, and was lower than at 13.5% m.c. despite the higher e.r.h. However, due to variability in the data, the differences were not significant.

The initial CFU counts were similar between the four m.c. level seeds (Tab. **3**). Only the seeds stored at 13.5% m.c. showed a significant increment in the CFU counts after the hermetic storage. There were no differences between the final CFU counts at 11.5%, 12.5%, and 14.5% m.c.s., which remained similar to the initial counts.

Tab. 3. Estimated marginal means ± model standard error of percentage of infected seeds (Inf) and CFU counts (expressed as log10CFU/g) in maize seeds under hermetic storage.

Time (months)	Moisture content (%)

Discussion

Low-oxygen atmospheres are a promising alternative to refrigeration for seed storage. This technology could help to reduce costs and is friendly with the environment (Weinberg et al., 2008). The availability of new plastic liners with oxygen barrier (Cardoso et al., 2016) and of portable gas analyzers that provide quick results makes it feasible to implement modified atmospheres in the commercial scale. Hermetic storage may serve as a practical, simple way for obtaining low-oxygen atmospheres.

The results of this work show that, under hermetic storage, maize seeds with up to 11.5% m.c. can be stored safely for six months at 25ºC (Tab.4). At this m.c., oxygen concentration and microbial indicators remained unchanged (Tab. **2.** Estimated marginal means ± model standard error of oxygen concentration during hermetic storage of maize seeds. Normal atmospheric oxygen content: 20.9%

Time (months)	Moisture content (%)			
	11.5	12.5	13.5	14.5

6	20.1 ±0.2 Ac	18.3±0.4 Ab	2.6±1.1 Aa	0.5±0.1 Ba

Within each column, means followed by different upper case letters are significantly different; within each row means followed by different lower case letters are significantly different ($P<0.05$)

Tab. **3** shows the results of the microbiological analyses before and after 6 months of hermetic storage. The initial percentages of infected seeds were similar for the different m.c.s. After the storage period, the percentages of infected seeds were similar at 11.5% and 12.5% m.c.s., and remained on average below 40%. The final percentage of infected seeds increased abruptly at 13.5% m.c., where practically all the seeds were infected by molds. The percentage of infected seeds at 14.5% was near 60%, and was lower than at 13.5% m.c. despite the higher e.r.h. However, due to variability in the data, the differences were not significant. andTab. **3**) indicating that there was no microbial activity. This result was expected due to the low e.r.h. (63.1% e.r.h. on average for the whole storage period). Final germination was 94%, higher than the official requirements for maize seed marketing (90%, Tab. **1**) and therefore 11.5% m.c. resulted a safe storage moisture content. Additionally, since the absence of microbiological activity was related to the low m.c. (oxygen was not a limiting factor), storing 11.5% m.c. corn seeds in non-hermetic conditions would have the same results.

At 12.5% m.c., the microbial activity was also undetectable what can be attributed to the still low e.r.h. (71.4% on average for the storage period). However, germination dropped to 84%. Hence, other mechanisms rather than microbial damage must have been involved in the germination loss observed at 12.5% m.c., i.e. intrinsic aging of the seed. Because it failed to meet the germination criterion, 12.5% m.c. was not a safe storage moisture content at least for the quite challenging temperature used in this work (25ºC).

Because no appreciable modification of the atmosphere occurred at 11.5 or 12.5% m.c., it is not expected to find differences in germination or microbial charge between hermetic and open-air storage at these m.c.s. In contrast, removing the oxygen from the beginning of storage at 12.5% m.c. by means of a controlled atmosphere could have an impact on final germination that remains to be studied.

At 13.5% m.c., final germination dropped to 81%. The higher e.r.h. (76.2% on average through the whole storage period) favored fungal growth. This was reflected in the oxygen depletion and the significant increase of infected grains and CFU counts. Because it failed to meet both the germination and microbiological criteria, 13.5% is not a safe storage moisture content (Tab.4).

It is noteworthy that, despite the higher e.r.h. and microbial charge, the final germination at 13.5% m.c. was similar to the observed at 12.5% m.c. The low-oxygen atmosphere at the higher m.c. might have prevented a larger germination loss. Indeed, the higher respiration rate consumed the available oxygen (less than 2% of oxygen by 3 months of storage, Tab. **2.** Estimated marginal means ± model standard error of oxygen concentration during hermetic storage of maize seeds. Normal atmospheric oxygen content: 20.9%

Time (months)	Moisture content (%)			
	11.5	12.5	13.5	14.5
3	20.0 ±0.2 Ac	19.4 ±0.4 Ab	1.3±1.1 Aa	0.0±0.1 Aa
6	20.1 ±0.2 Ac	18.3±0.4 Ab	2.6±1.1 Aa	0.5±0.1 Ba

Within each column, means followed by different upper case letters are significantly different; within each row means followed by different lower case letters are significantly different ($P<0.05$)

Tab. **3** shows the results of the microbiological analyses before and after 6 months of hermetic storage. The initial percentages of infected seeds were similar for the different m.c.s. The final percentage of infected seeds increased abruptly at 13.5% m.c., where practically all the seeds were infected by molds. The percentage of infected seeds at 14.5% was near 60%, and was lower than at 13.5% m.c. despite the higher e.r.h. However, due to variability in the data, the differences were not significant.), which became limiting for further fungal development. The results of this experiment agree with the findings of various authors who reported reduction of microbial activity in low-oxygen environments (Hocking 1990; Weinberg et al. 2008; Taniwaki et al. 2009; Marcos Valle 2015). The high percentage of infected grains and CFU counts at the end of storage at 13.5% m.c. could be, in effect, a picture of what happened before oxygen became limiting for the microflora. Intermediate measurements of oxygen and microbial indicators are needed to characterize the fungal development more precisely. The low-oxygen atmosphere might have also contributed to limit other intrinsic degenerative reactions in the seed, what remains to be evaluated. Despite final germination was similar at 13.5% and 12.5% m.c., the former is a more risky condition from the microbiological point of view. Any change in the storage conditions could rapidly impact germination.

14.5% m.c. resulted a high-risk condition for hermetic storage at 25ºC (Tab.4). Final germination dropped markedly to 50%. The high e.r.h. (79% on average through the whole storage period) enabled an intense respiration that generated an anaerobic atmosphere by 3 months of storage. Microbial indicators, however, were lower at 14.5% than at 13.5% m.c., probably because oxygen was consumed earlier at 14.5% m.c. and rapidly became limiting for microbial growth. At 14.5% m.c., indeed, the oxygen concentration reached 0%. Some authors report that fungal growth is completely inhibited only below 0.5-1% of oxygen (Taniwaki et al., 2009; Marcos Valle, 2015). The anaerobic atmosphere, nevertheless, was not effective to protect germination. Open-air versus hermetic storage experiments are needed at 13.5 and 14.5% m.c.s. to explore the benefits of storing the seeds in a low-oxygen atmosphere.

Finally, this research was carried out using a single corn hybrid. Since there is evidence that seed storability is affected by genotype (Friday et al., 1989; Marks and Stroshine, 1995), additional research including different hybrids should be conducted before drawing general conclusions.

Tab.4. Summary of safe storage moisture contents for maize seeds under hermetic storage.

	Moisture content (%)			
	11.5	12.5	13.5	14.5
Final germination >90%	Yes	No	No	No
Absence of microbial activity	Yes	Yes	No	No
Safe storage moisture content	Yes	No	No	No

Conclusions

The results of this work show that 11.5% m.c. is a safe m.c. for storing maize seeds hermetically for 6 months at 25ºC, because germination remains above 90% (official standard for maize seed) and the seed microflora is inactive. At 12.5% m.c. the microflora is still inactive but germination falls below the official standard. Hence, seeds should only be stored at 12.5% m.c. if they are not intended for marketing. Moisture contents of 13.5% m.c. and above are not compatible with safe seed storage because of microbiological activity and damage to germination.

At 11.5 and 12.5% m.c.s., the hermetic storage was not useful to generate low-oxygen self-modified atmospheres. In contrast, self-modified atmospheres were observed for m.c.s. of 13.5% and above (e.r.h. higher than 75%). The self-modified atmospheres, however, were not effective to protect germination.

Further research is needed on the potential of low-oxygen modified atmospheres for seed storage. In the future it would be important to study the effect of anaerobic environments on germination and microbial activity from the beginning of storage, by means of controlled atmospheres. It would also be important to expand the temperature range, to include seed aging indicators for a better understanding of the mechanisms of germination loss, and to extend the studies to other maize genotypes.

Abstract

$ECO_2FUME^®$ phosphine fumigant was used to fumigate milled rice in a commercial plastic bag (5 kg) and milled rice in a jumbo bag (1,000 kg) under gas-proof sheets to assess its performance against a mixed-age culture of *Sitophilus zeamais, Tribolium castaneum* and *Oryzaephilus surinamensis*. The trials were divided into 2 groups: 1) milled rice in a commercial plastic bag (packed rice) treated with a 50 g/m^3 $ECO_2FUME^®$ application rate (700 ppm phosphine) for 2 days with two bag stacks of 46 m^3 and 55 m^3 and for 3 days with two bag stacks of 50 m^3 each; and 2) milled rice in a jumbo bag (raw material rice) with stack size of 314 m^3 treated with a 35 g/m^3 $ECO_2FUME^®$ application rate (500 ppm phosphine) for 3 days and a stack size of 435 m^3 treated with 50 g/m^3 $ECO_2FUME^®$ application rate for 2 days. Gas sampling lines were installed in the stack to measure the phosphine concentrations during the fumigation period. The results of the fumigation trials showed that mixed-age cultures of the three insect species in packed rice stacks were completely controlled at 2 and 3 days when applied with an $ECO_2FUME^®$ application rate of 50 g/m^3, whereas most insects in untreated control cages remained alive. $ECO_2FUME^®$ was also 100% effective in raw material rice stacks with complete control of mixed-age cultures of the three insect species using 35 g/m^3 of $ECO_2FUME^®$ for 3 days and 50 g/m^3 of $ECO_2FUME^®$ for 2 days. Commercial tarp fumigation of milled rice with $ECO_2FUME^®$ can be fumigated successfully without "top up" with good sealing procedures. Gas monitoring at regular intervals throughout the whole fumigation period is part of best fumigation practice to ensure that the minimum recommended phosphine concentration is maintained for complete control of all stages of target insect pests.

Keywords: $ECO_2FUME^®$ phosphine fumigant, fumigation, stored-product insect pests, milled rice, commercial plastic bag (5 kg), jumbo bag (1,000 kg).

1. Introduction

One of the largest rice-producing countries in the world, Thailand has an estimated 1.06 million hectares of cultivated land. In 2016, Thailand exported 9.88 million tons of rice with a total value of 154,434 million Baht (Office of Agricultural Economics, 2016).

Milled rice is prone to damage due to insect infestation. When the grain has no protection, the insect population will build up rapidly. Therefore, the losses and damage to stored milled rice due to insect

pests are related to the storage duration. The percentage of loss is very difficult to determine as the figure varies from 1% to as high as 25%. In 1977, FAO reported that the loss of rice ranged from 8 to 14% (Champ and Dyte, 1967) within the post-harvest system in Thailand. Suprakarn (1985) reported that 70 species of beetles and moths had been recorded in association with grains and other agricultural products in Thailand. Fortunately, only a handful of these insects have caused major economic damages. The major insect pests adversely affecting stored rice in Thailand are *Sitophilus zeamais*, *Tribolium castaneum*, and *Oryzaephilus surinamensis,* among others. Considered as an individual factor, the number of insect pests is not significant to the health of the harvested rice; however, preventing contamination is imperative as these pests can impact the quality and weight losses of stored rice. If contamination via insects occurs in the exported product, the rice may be rejected and returned to the country of origin, negatively affecting the reputation and revenue of the grain producer and exporter. Future exporting issues can occur as a result.

$ECO_2FUME^®$ fumigant gas is a cylinderized formulation of 2% PH_3 and 98% CO_2 by weight. It is packaged in high pressure aluminum or steel cylinders with net content of 31 kg of PH_3/CO_2 mixture and an equivalent phosphine amount of 620 g (Tumambing et al., 2012). $ECO_2FUME^®$ was first registered and commercialized in Australia during the 1990s. It was then registered in the USA in 2000, and approved for a shorter fumigation time of 24 hours for 1,000 ppm phosphine concentration at 27 °C or higher temperature for susceptible insect species (Cavasin et al., 2001).

There are several advantages when applying $ECO_2FUME^®$. The dose of $ECO_2FUME^®$ phosphine fumigant applied to the commodity is rapid delivery, easy maintenance of the required dose during the fumigation period, shorter exposures and ease of application. $ECO_2FUME^®$ does not require the applicator to enter the fumigation space. The ready-to-use cylinders can be dispensed from outside of silos or structures being fumigated. This eliminates the need for entry into confined spaces to apply fumigants and solid waste disposal (Bonjour, 1998; Phillips, 1998).

The controlled application of fumigant gas resulting in less fumigant was introduced in stored product instead of the traditional solid formulation. It relies on the generation of a high initial phosphine concentration followed by a slow deterioration to ensure that the phosphine concentration - time product (CT) - will result in an effective fumigation. With $ECO_2FUME^®$ fumigant gas, the concentration can be easily controlled by the applicator to maintain an efficacious concentration and can be precisely measured by adding the required amount of gas when needed. Disposal of solid waste products from tablets is becoming more difficult every day. $ECO_2FUME^®$ fumigant gas eliminates the concern associated with deactivating unspent metal phosphide residue and disposal of the waste product (Cavasin et al., 2001).

The objective of this research is to study the application of $ECO_2FUME^®$ phosphine fumigant on milled rice in a packaged plastic bag and as a raw material in a jumbo bag for the control of major stored-product insect pests under commercial fumigation conditions of selected Thai rice companies.

2. Materials and Methods

Test insects and preparation of mixed-age cultures

Strains of *Sitophilus zeamais*, *Tribolium castaneum* and *Oryzaephilus surinamensis* were investigated. All insects used in this study were from the stored-product insect colonies maintained at the Post-harvest and Processing Research and Development Division Lab of the Thai Department of Agriculture (DOA). The mixed-age population was prepared by adding 50 young adults (2-3 week olds) of each strain of each of *S. zeamais*, *T. castaneum* and *O. surinamensis* into the cage of a glass bottle containing 200 g of culture medium and kept for 3 weeks. The culture medium was different for each species: brown rice for *S. zeamais*, rice bran for *T. castaneum* and grinded rice for *O. surinamensis*. Afterwards, all adults were removed and kept in the laboratory for 4 weeks at a temperature of 30 ± 2°C and relative humidity of 65 ± 5% before fumigation. All of the life stages were examined for their presence in the mixed-age culture glass bottle prior to fumigation. Before the

experiment was carried out, the test insects were transferred from glass bottles to the spun-bonded bags.

Fumigant

$ECO_2FUME^®$ phosphine fumigant is manufactured at Solvay's Niagara Falls, Canada, facility (known also by its associated legal entity name, Cytec Canada).

Fumigation of mixed-age culture

The experiment was conducted in a concrete warehouse of Patum Rice Mill and Granary Public Company Limited Group of Companies, located at Sikhiu district, Nakhon Ratchasima province, Thailand, in 2015. The trials were divided into 2 groups, as outlined below.

1Milled rice in a commercial plastic bag of 5 kg capacity (packed rice) was treated with a 50 g/m³ $ECO_2FUME^®$ application rate (700 ppm phosphine) for 2 days with 2 bag stacks of 46 m³ and 55 m³, and for 3 days with 2 bag stacks of 50 m³ each (Figure 1).

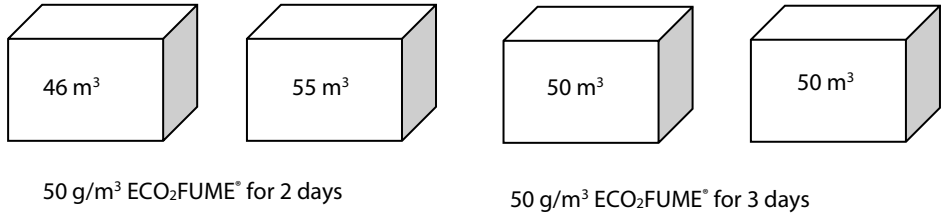

Fig. 1 Bag stack arrangement of milled rice in commercial 5-kg plastic bags

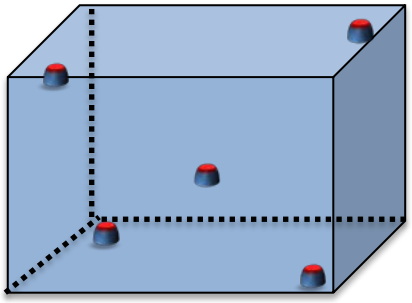
2) Milled rice in a jumbo bag of 1,000 kg capacity (raw material rice) and a stack size of 314 m³ was treated with a 35 g/m³ $ECO_2FUME^®$ application rate (500 ppm phosphine) for 3 days, and a stack size of 435 m³ was treated with 50 g/m³ $ECO_2FUME^®$ application rate (700 ppm phosphine) for 2 days (Figure 2).

Fig. 2 Bag stack arrangement of milled rice in 1,000 kg - jumbo bags

The raw material rice stacks and packed rice stacks were piled on the floor. Afterwards, 15 spun-bonded bags of test insects in a culture medium were placed in the stacks at 5 different locations: top (left and right), middle and bottom (left and right). Each spun-bonded bag of test insects contained a mixed-age culture of each insect species; *S. zeamais, T. castaneum* and *O. surinamensis*.

For the fumigation of both packed rice and raw material rice, the spun-bonded bags of mixed-age test insects in the culture medium were placed inside the bag (Figures 3 and 4).



Test insect locations in the jumbo bag stack

Fig. 3 Placement of test insects inside the jumbo bag stack

Fig. 4. Test insect placement inside the commercial 5-kg plastic bag.

The commercial 5-kg plastic bag of milled rice in the market of Thailand was punched 4 holes with diameter 1.0 mm. On the front and back of the bag, 2 holes were punched for each side. These holes allowed the air transfer which the bag could be stacked on the shelf during the distribution. Additionally, phosphine gas would penetrate into the plastic bag through these holes.

Two holes on the front of the plastic bag

Two holes on the back of the plastic bag

Fig. 5 Position of holes on the plastic bag

Gas sampling lines were installed at 3 locations in the rice stack (top, middle and bottom). Gas sampling lines were also installed inside the packed rice bag and the raw material bag to measure the phosphine concentration during the fumigation period.

Each milled rice stack with test insects was then covered with a clear polyvinyl chloride (PVC) sheet (0.2 mm thickness) as a fumigation enclosure to keep the phosphine gas inside the stack. The sheets were sealed to the concrete floor with sand snakes and masking tape.

The equivalent amount of phosphine from $ECO_2FUME^{®}$ was injected inside the tarp using a stainless steel quick-dispensing hose and gas injector with a gas flow rate of 6.8 kg/min. The exact amount of dispensed $ECO_2FUME^{®}$ was determined by the weight change of the cylinder on the top of a digital weighing scale accurate to 0.01 kg or 10 g.

Monitoring of gas concentration

Phosphine concentration was monitored at each of the following time intervals: 1) 1, 18, 24 and 42 hours for 2-day exposure time; 2) same as item 1 plus 48 and 66 hours for 3-day exposure time. The two phosphine target concentrations of 500 ppm and 700 ppm were maintained during the whole fumigation period. When the phosphine concentration fell below the target concentration, ECO2FUME® dosing was topped up to bring the concentration back to or above the target level. Phosphine concentration was monitored with calibrated SILOCHEK phosphine monitor (0 - 2000 ppm).

Fumigation was terminated at 2 and 3 day exposure times followed by aeration of the slightly opened enclosure until the phosphine concentration reached the threshold limit value (TLV) of 0.3 ppm or lower. The plastic cover sheets were completely removed afterwards.

Assessment of insect mortality

Effectiveness of $ECO_2FUME^®$ against the test insect was determined by mortality of the mixed-age culture. After fumigation, the spun-bonded bags that contained the test insects were retrieved from each stack. The mortality of adults from each experiment was recorded after the removal of the fumigation sheet cover. Dead and alive insects were separated and culture media were returned to the bottles and then kept in the laboratory at 30 ± 2°C and 65 ± 5% for 6 weeks and were observed weekly for any newly emerged adults. This period was sufficient for emergence of all insects in the treatment as well as the control. The occasional death from the control was corrected by Abbott's formula (Abbott, 1925).

Monitoring of temperature, relative humidity and moisture content

The temperature and relative humidity in the warehouse were monitored by a thermo-recorder every day during the fumigation period. The moisture contents of maize were measured before and after treatment by applying the samples to an SB 900 Steinlite moisture meter.

3. Results

The effectiveness of $ECO_2FUME^®$

The results of the fumigation on packed rice stacks shown in Table 1 demonstrated that mixed-age *Sitophilus zeamais, Tribolium castaneum* and *Oryzaephilus surinamensis* were completely controlled at 2 and 3 days when applied with an $ECO_2FUME^®$ application rate of 50 g/m^3 (700 ppm phosphine). No live insects were observed immediately after fumigation or 6 weeks later. Most insects in non-fumigated control cages remained alive. $ECO_2FUME^®$ was also 100% effective in raw material rice stacks, completely controlling the mixed-age cultures of the three insect species with concentrations of 35 g/m^3 (500 ppm phosphine) for 3 days and 50 g/m^3 (700 ppm phosphine) for 2 days (Table 2).

The concentration of phosphine

Fumigation on packed rice in stacks at 50 g/m^3 $ECO_2FUME^®$ (700 ppm) phosphine concentration was achieved at 2 and 3 days of exposure period times, as shown in Table 3. One hour after gas injection, the phosphine concentrations in the rice stacks were higher than 2,000 ppm, yet phosphine gas did not penetrate the plastic bag of packed rice. After fumigation for 18 hours, the phosphine concentration decreased but was still higher than the target concentration of 700 ppm in all rice stack fumigations. Phosphine concentration was monitored throughout the fumigation period. There were small reductions in phosphine concentrations, but all were still over the target concentration. The phosphine concentrations inside the plastic bag were nearly equal to the phosphine concentrations inside the fumigated stacks. This indicated that phosphine penetrated well into the plastic bag.

Phosphine concentrations on raw material rice fumigated with 35 g/m^3 $ECO_2FUME^®$ for 3 days and 50 g/m^3 $ECO_2FUME^®$ for 2 days from the rice stacks were shown in Table 3. The phosphine concentration of the fumigated raw material rice was quite similar to the fumigated packed rice stacks. After fumigation for an hour, the phosphine concentrations in raw material rice stacks were higher than 2,000 ppm. However, phosphine concentration could not be found inside the jumbo bag, indicating that there was no gas penetration yet.

After fumigation for 18 hours, the concentrations of phosphine decreased but were still well above the target concentration in the rice stacks. All phosphine concentrations were above the target concentrations of 500 and 700 ppm throughout the fumigation period. These results show that phosphine concentrations inside the jumbo bags were close to the concentrations of the fumigated stacks, indicating that phosphine could also penetrate well into the jumbo bag.

Monitoring of temperature, relative humidity and moisture content

The moisture content of maize was 11.8-13.5%. Temperature and relative humidity in the warehouse were 29.0-30.3ºC and 66.9-68.2%, respectively.

4. Discussion

The commercial fumigation trials of milled rice in 5 kg plastic bags and 1,000 kg jumbo bags using $ECO_2FUME^®$ showed complete control of all stages of the target major grain insects at selected rice mills in Thailand. Results were achieved using phosphine fumigation protocols of 35 g/m^3 $ECO_2FUME^®$ (500 ppm phosphine) for 3 days, and 50 g/m^3 $ECO_2FUME^®$ (700 ppm) for 2 days at a daily temperature fluctuation of 26 - 33°C.

The results showed that the amount of phosphine gas absorbed by milled rice is minimal. The good sealing of the stack also minimized the gas loss due to gas leaks, and the higher phosphine concentration achieved at the start of fumigation remained higher than the target phosphine concentration throughout the entire fumigation period. In this study, top up of $ECO_2FUME^®$ was unnecessary to maintain the target concentration. Hence, the commercial fumigation of milled rice during storage of both raw material rice and packed rice with $ECO_2FUME^®$ before distribution could be completed successfully without top up.

Despite the fact that the target phosphine concentration was maintained throughout the duration of the fumigation period, it is still necessary to monitor phosphine concentrations at regular intervals. If the phosphine concentration is not regularly monitored during the entire exposure period, there could be a risk of greater gas loss due to gas leak and gas sorption, which can render the fumigation ineffective.

Acknowledgements

I wish to express my sincere gratitude and appreciation first to Patum Rice Mill and Granary Public Company Limited Group of Companies and Ms. Jurairat Wongnam, IPM AGRO CO., Ltd. for supporting staff, place and commodities for the experiment. Finally, I would like to express my appreciation and gratitude to my colleagues for the invaluable support in the completion of my experiment.

Residual behaviour of phosphine in different commodities

Goetze Marie-Carolin[1*], Jakob Gerhard[1]

Detia Freyberg GmbH, Dr.-Werner-Freyberg-Str. 11, 69514 Laudenbach, Germany

Abstract

Phosphine is one of the most common active substances used in storage protection worldwide. As it is very efficient amongst a broad range of living organisms, it has become the favoured product after phasing out methyl bromide in 2010, as it can be used in many commodities.

In 2005, the regulation 396/2005 was enacted and came into force in 2008. With this, the European commission started to evaluate residues arising from the use of a pesticide and to set maximum residue levels (MRLs) for safe and regulated food trade.

To proof residue levels are below MRL and therefore far below concerning concentrations of phosphine in food or feed, residue studies are permanently conducted. In addition to support MRL settings, the intention of these trials is to determine withholding periods needed in storage protection, corresponding to PHI (pre harvest interval) for field and glasshouse treatments.

Results of those studies show different levels and differences in decrease of residues after defined time periods. Thus, withholding periods for various commodities can differ. Residue trials with repeated exposure were conducted as well to determine possible additive effects.

Keywords: Phosphine, maximum residue level (MRL), withholding period

Regulatory background

To ensure safe and fair trading conditions among the EU member states and non-European countries, regulation 396/2005 came into force on 1st of September 2008. The major aim of this regulation was to set maximum residue levels (MRL) for pesticide residues in and on cereals, foodstuff of animal origin, and products of plant origin in one regulation only. This became necessary due to formerly separate regulations, inhibiting harmonization and complicating registration processes during plant protection authorization. Besides, the setting aims to avoid unacceptable risks posed by residues in treated commodities to humans and in animals feeding. MRLs are being reviewed and updated on a regular basis.

To evaluate a potential risk arising from treating goods with plant protection products (but also biocides), manufacturer of active contents and products composing those actives destined for plant protection uses are obliged to characterize the residual behavior of the product inside each targeted commodity. One important basis to set an MRL for a commodity or a group of commodities is provided by residue trials.

Behaviour of phosphine

There are many forms of phosphine (PH_3) emitting products, such as compacts, bags and plates. The reaction is based on the very simple reaction of the metal phosphide with humidity and air.

During fumigation with metal phosphide based formulations, the small molecule phosphine is being formed as a reactive intermediate. As it has many advantageous properties, the possibilities of use are various. One of these is the excellent capability of the gas to penetrate inside the commodity, facilitating all stages of stored product pests to be effectively eliminated.

As the commodities vary highly in nutrient composition, structure, and size, the phosphine molecules show very different binding behaviours and elimination times inside the goods.

It has become clear that these characteristics are essential during evaluating MRLs and play a crucial role in setting withholding periods after fumigation.

Materials and Methods

To represent a possible worst-case scenarios, different storage goods from commodity groups defined as in COMMISSION REGULATION (EU) 2016/1785 (2016) are chosen to be fumigated with different metal phosphide formulations containing magnesium or aluminium phosphide. All trials are conducted following GLP principles set be OECD.

In the present study, 20 kg of different storage goods were placed in 4 different airtight containers. After exposing the test items to 5 g PH_3/m^3 (Degesch Magtoxin) and 5.5 g PH_3/m^3 (Degesch Plate) for 5 days, and to 10 g PH_3/m^3 (Phostoxin Tablet and Detia Gas-Ex-B) for 14 days, samples were taken in intervals to determine residues. The longest withholding period was 28 day after aeration. To ensure negative control levels, residue analysis were conducted prior to fumigation.

The dosage and exposure time represented the highest registered doses and exposure times in the EU.

Commodities tested were:

cereals

tobacco

flour (wheat)

coffee beans

cocao beans

dried fruit (apricot)

dried vegetable (leak)

legumes (lentils)

expeller (oilseed rape press cake)

oilseed (flaxseed)

hay

herbs (dried, marjoram)

malt (dried)

nuts (hazelnut)

pistachios

coriander

medical plants (blossoms, chamomille)

liquorice

spices (leaf, laurel leaves)

black tea

potato starch

The treated commodities were sampled and stored deep frozen until analysis, which was conducted within 24 hours after sampling.

Results

No residues were detected in any of the control samples prior to fumigation.

For all tested commodities, the residue analysis directly after the end of aeration showed values below 0.05 mg/kg, except for hazelnuts and pistachios. For the two products, Degesch Plate and Detia Gas-Ex-B, residues after right aeration were increased in hazelnuts and pistachios. For Degesch Plate treatments, the residues in hazelnuts and pistachios were below 0.05 mg/kg after 14 days, while for Detia Gas-Ex-B, pistachios achieved values below 0.05 mg/kg after 7 days and hazelnuts after 21 days.

Discussion

The trials show a different behavior of storage goods regarding elimination of phosphine. Especially, high fat containing representatives of the group of tree nuts show a slower removal of the gas. Therefore, the withholding periods after aeration are increased.

As analytical methods have become significantly more accurate, residue trials were and are necessary to determine MRLs. Withholding periods are therefore a necessary and important indication for food and feed industry to be regarded on behalf of safe and fair trading or processing of the goods after fumigation.

Abstract

Stored product beetles that are resistant to the fumigant phosphine (hydrogen phosphide) have been reported for more than 50 years in many places worldwide. The high levels of phosphine resistance in lesser grain borer *Rhyzopertha dominica* (F.) have been noted from several countries including Bangladesh. This study was designed to evaluate the status of resistance to phosphine in Bangladeshi *R. dominica* and to verify the possible comparison among other phosphine resistant strains from tropical countries *viz.* Burkina Faso and Malaysia. The data reported and summarized here showed varied levels of resistance compared to the laboratory phosphine susceptible strain (*RDLAB*). *Rhyzopertha dominica* strains originating from Bangladesh (*RDBGD*) and Burkina Faso (*RDBKF*) exhibited higher levels of resistance to phosphine compared to the Malaysian strains (*RDMAL*). Analysis of dose–response data indicated that the *RDBGD* and *RDBKF* strains were the most resistant to phosphine under different exposure periods. At LC_{50}, these two strains were more than 80-fold more resistant at all exposures compared to the susceptible strain. Results also revealed that *RDBGD* and *RDBKF* strains required a relatively high concentration of 334.94 and 240.081 mg L^{-1} for 99% mortality. The mean survival time (MST) for the phosphine resistant and susceptible also varied significantly. The maximum MST was recorded for *RDBGD* and *RDBKF* strains. The present findings further confirmed that the Bangladeshi originated *R. dominica* strain contained higher resistance to phosphine compared to strains from other countries. This study could be useful in developing management strategies to prevent stored grain from being infested by resistant strains of *R. dominica* in tropical countries.

Keywords: phosphine, resistance, grain borer, tropical countries

Introduction

Tropical environments provide most favourable conditions for insect growth and multiplication in the ideal medium of food stored by humans. Some insects begin infestation in the field and continue attack in storage. In tropical developing countries, especially in humid zones, pest infestation in stored food is inevitable due to lack of proper management. Fumigation with phosphine (hydrogen phosphide, PH3) is the preferred means of controlling pests in many countries of the tropics.

The first global survey of phosphine resistance was conducted during the 1970s by Champ and Dyte (1976) who used a discriminating dose bioassay on adult insects (FAO 1975) and documented the occurrence of phosphine resistance in several key stored grain pest species across many countries. However, further studies indicate a substantial increase in phosphine resistance in stored product pests worldwide including Australia (Nayak et al. 2013), India (Kaur et al. 2015), Brazil (Lorini et al. 2007), and Malaysia (Rahim et al. 2004).

Phosphine resistance has been detected in most of the major species of stored product insects including *Rhyzopertha dominica*, *Tribolium spp., Sitophilus spp.*, *Oryzaephilus surinamensis* and *Cryptolestes* spp. (Taylor, 1986). This appears to be due to the increased selection pressure in some countries (Halliday *et al,* 1983; Friendship *et al.,* 1986). The distribution of phosphine resistance is not known in detail but it is likely that resistance to phosphine is not an unusual phenomenon in most countries in which the fumigant has been used. The reported incidence of phosphine resistance is particularly high in the lesser grain borer *R.dominica* (F.) and two species of *Tribolium* (Champ and Dyte, 1976; Taylor, 1986). It has also been noticed that some of the strains of *R. dominica* collected from the field showed very high levels of resistance to phosphine (Mills, 1983). However,

fumigation failures have been reported from Bangladesh that were caused, in part, by high levels of phosphine resistance in *R.dominica* (Mills, 1983, Tylor *et al.* 1983). Potential replacement fumigants lack the versatility possessed by phosphine. The indiscriminate uses of phosphine fumigation may lead to the increase of risk in control failures. The aim of the present investigation was to examine the relative phosphine toxicity relationship between concentration and time exposure to phosphine resistant and susceptible strains of *R.dominica* originating from the tropical countries of Bangladesh, Malaysia and Burkina Faso.

Materials and Methods

Insects

Phosphine susceptible laboratory strain RDLAB and phosphine resistant strains RDBGD, RDBCF and RDMAL of the lesser grain borer *Rhyzopertha dominica*, originated from a population sampled in Bangladesh, Burkina Faso and Malaysia respectively, were used in this study. The frequency of phosphine-resistant adults in samples from *R. dominica* field populations was determined by earlier using the Food and Agriculture Organization Method No. 16 (FAO, 1975) (Reichmuth, 1983; Mills 1983; Rahim and Sulaiman, 1999). All these strains had been cultured for many decades at the Federal Research Centre for Cultivated Plants – Julius Kühn-Institut, Berlin, Germany (Table 1). They were reared on whole wheat and dried cassava in a controlled temperature room set at 25°C, 16L: 8D h photoperiod and 75% RH.

Fumigation Procedure

Production of phosphine

Pure (100%) phosphine was generated from magnesium phosphide granules (*Degesch Co*., Frankfurt am Main) reacting to water ($Mg_3P_2 + 6H_2O = 3Mg(OH)_2 + 2PH_3$) (Hasan and Reichmuth, 2004). The method provides a convenient source of phosphine for dosing purposes over a period of time, depending on the rate of removal.

Table 1: Culturing details and specification of reference and phosphine-resistant strains of *R.dominica*.

Strains	Origin of strains	Collection & Test year	# adults to seed culture	Adult wt. (mg) Mean ± SE*	Original Culture maintained
RDLAB (S)	Germany	1978	150	1.45 ± 0.02	BBA Inst., Berlin
RDBGD(R)	Bangladesh	1982	150	1.42 ± 0.02	CSL,UK
RDBCF (R)	Burkina Faso	1993	150	1.25 ± 0.02	BBA Inst., Berlin
RDMAL (R)	Malaysia	1993	150	1.31 ± 0.01	BBA Inst., Berlin

S- Susceptible; R- Resistant; * mean of four replicates each having 50 insects.

Fumigation Test

Newly emerged (8-10 day-old) mixed-sex adults of *R. dominica* were selected for phosphine fumigation. The fumigation was carried out in cylindrical steel gauze cages (5.0 x 1.5 cm) containing a small quantity of diet (0.5 g). Treatments of phosphine consisted of three replicates containing 25 insects each. An untreated reference sample was kept for each type.

Glass Dressel flasks (2.5 l) were used as fumigation chambers. The flasks were connected to each other with a gas-tight PVC tube. A small electric pump was set up to recirculate the gas evenly throughout the apparatus. A silicon rubber septum fitted in the narrow tube, protruding from the gas reservoir, was used to inject and withdraw a phosphine sample with a gas-tight Hamilton syringe. An equal volume of air was withdrawn from the flask before injecting the respective concentration of phosphine. The sealed Dressel flasks contained saturated sodium chloride solution to achieve about 75% RH by the end of exposure period. The time of injection was recorded and the pump was operated to distribute the gas evenly. The concentration of phosphine in each of the flasks was assessed at the beginning and end of the fumigation period using quantitative gas chromatography (Hasan and Reichmuth, 2004). The glass flasks containing the experimental insects

were then disconnected without losing any gas and immediately transferred to the CT-room conditioned at 25°C, where they were kept throughout the exposure periods.

Post-fumigation

The adults *R. dominica* were fumigated at 25°C at a range concentrations of phosphine, 0 (control), 0.25, 0.50, 1.0, 2.0, 3.0, 4.0, 5.0 and 6.0 mg/l and exposure periods of 4.0, 5.0, 6.0 7.0 and 8h. The Exposure periods for each test was designed to encompass the dose-response range ensuring, where possible, that a 100% kill was achieved at the maximum dose. At the end of desired fumigation periods, the insect cages were removed from the fumigation chambers and kept in small petri dishes containing food media for assessment of mortality. The mortality of adult *R. dominica* was recorded each day after exposure to phosphine until complete mortality occurred.

Data processing

The LCs and LTs were estimated from a Probit regression analysis using PROC PROBIT from SAS version 9 (SAS 2002). Comparison among populations for differences in their level of resistance were made after computing resistant ratios based on the LC_{50} value for the population of interest divided by the LC_{50} of the laboratory-susceptible strain, referred to as the RR_{50}.

Mean Survival Times (MST): The mean survival time (MST) for adult *R. dominica* strains exposed to phosphine was calculated following the model developed by Cheng and Ducoff (1989):

$MST = 1/n \Sigma(t \times Yt)$

Where, n = number of beetles in the group, t = hour t, and Yt = number of beetles that died at hour t.

Results

The effect of phosphine on the mortality of resistant adult *R. dominica* originating from tropical countries varied significantly ($P < 0.001$). Results of dose–mortality studies with three phosphine resistant populations of *R. dominica* and susceptible laboratory strain are reported in Tables 2 and 3. The results indicated clearly that the adults *R. dominica* originated from Burkino Faso and Bangladesh required higher concentration of phosphine at the mortality level of LC_{50} when compared with resistant RDMAL strain from Malaysia. The strain RDBCF was 152-fold more resistant than the susceptible strain RDLAB when exposed for 5 h to phosphine (Fig. 5). However, the strains RDBCF and RDBGD showed more or less similar resistance as the RDLAB strain when exposed to 6, 7 and 8 h exposures at LC_{50} level (Table 2 & Fig. 5). The RR_{50} for the RDMAL strain gradually decreased as the exposure levels increased (Fig. 5). This pattern of relative resistance was also reflected in the LC_{99} values (Table 2). At the LT_{50}, adult *R. dominica* exhibited several fold resistance to phosphine compared to the susceptible strain particularly at lower exposure levels (Table 2). The strains RDBGD and RDBCF showed more resistance to phosphine compared to RDMAL strain at the exposure up to 2h exposure at LT_{50} level, but they exhibited more or less similar trends of resistance at higher exposures levels of 6 to 8 h (Table 2). However, this trend did not follow at the mortality level of LT_{99} at which the RDBCF and RDBGD strains showed higher resistance to phosphine compared to strain RDMAL. Table 3 shows, the higher level of resistance in RDBCF and RDBGD at lower concentration of 0.25 and 0.50 mg/l. Moreover, the strain RDBGD required 193.32 h for 99% mortality at concentration 3 mg/l. The present findings show that the estimated fiducial limits for LT_{50} and LT_{99} values were narrow and overlapping for all the phosphine resistant strains tested, indicating a good fit of the data in the linear regression model (Table3).

The mean survival time (MST) for the phosphine resistant and susceptible strains of *R. dominica* varied significantly ($P < 0.001$). The $F_{(df\ 7,39;\ F_{crit\ 2.36})}$ values for phosphine concentration for the strains RDBGD, RDBCF, RDMAL and RDLAB were 43.72, 40.91, 10.17 and 5.12 respectively. The maximum MST was recorded for *RDBGD* and *RDBKF* strains in all concentrations (Figs. 1 & 2) while the minimum was in susceptible strains RDLAB (Fig. 4). Figure 4 shows that the MST for RDLAB strains was below

to the range of 3 day in all concentrations and exposures except 0.50 mg/l at 4 h exposure. The strains RDBCF and RDBGD exhibited higher fold of resistance in terms lethal time at lower phosphine concentrations ranging from 0.25 to 2.0 mg/l compared to strain RDMAL (Fig. 6). However, the RDMAL showed higher fold of resistance compared to RDBGD strain at concentration ranging from 4.0 to 6.0 mg/l.

Table 2: Probit analysis for the mortality responses of phosphine susceptible and resistant adult *R. dominica* after different exposure periods to varying concentrations of phosphine at 25°C.

Discussion

Our results revealed that the response of the adults of phosphine resistant and susceptible strains of *R. dominica* to phosphine fumigation varied significantly (P<0.001). All the phosphine resistant strains exhibited high levels of resistance compared to the susceptible strain. The strain RDBCF showed more resistance to phosphine compared to other resistant strains tested. Results also indicate that for resistant as well as susceptible strains, time of exposure to phosphine was more critical a factor for effective fumigation than concentration (Tables 1 & 2). The MST in all the resistance strains varied substantially. The MST values were found to be phosphine concentration dependent (Figs. 1-4) and it decreased as the concentration increased. The values of resistance ratio indicate that RDBGD and RDBCF strains were several folds higher resistant compared to the RDMAL

strain (Fig. 5). Phosphine resistance in lesser grain borer *R. domiica* has been reported from a number of countries and it is to be expected that this number will increase (Champ and Dyte, 1976; Mills, 1983; Taylor, 1986; Reichmuth, 1986; Price and Mills, 1988 Opit *et al.* 2012, Afful *et al,* 2018). Moreover, phosphine resistance has been detected in most of the other major species of stored product insects including *Tribolium* spp., *Sitophilus* spp., *Oryzaephilus surinamensis* and *Cryptolestes* spp. (Taylor, 1986). This appears to be due to the increased selection pressure in some countries (Halliday *et al*, 1983; Friendship *et al*., 1986). Our results confirm the findings of others who reported the geographic variation in phosphine resistance in *R. dominica* (Collins *et al*. 2000, Benhalima *et al.* 2004, Lorini *et al*. 2007, Cato *et al*. 2017 Auful *et al*, 2018).

The distribution of phosphine resistance is not known in details but it is likely that resistance to phosphine is not an unusual phenomenon in most countries in which the fumigant has been used. The reported incidence of phosphine resistance is particularly high in the lesser grain borer *R.dominica* (F.) and two species of *Tribolium* (Champ and Dyte, 1976; Taylor, 1986). It has also been noticed that some of the strains of *R. dominica* collected from the field showed very high levels of resistance to phosphine (Mills, 1983; Afful et al., 2018). Fumigation failures have been reported from Bangladesh that were likely caused by high levels of phosphine resistance in those populations of *R.dominica* (Tylor *et al.* 1983). Mills (1983) also reported that the susceptible individuals of *R.dominica* could be killed at 0.03 mg/l phosphine dose at 20 h exposure while a field strain from Bangladesh could survive as high as 1.45 mg/l of phosphine for 20 h, and 72 hr exposure to this dose was require to produce a complete kill of these insects. Rahim et al. (1999) reported the presence of phosphine rresistance in stored grain insects including *R. dominica* from nine of the 13 states in Malaysia. The molecular mechanisms of phosphine resistance in *R. dominica* as well as other stored product pests are multifaceted and it is still under investigations (Chaudhry, 2000, Jagadeesan *et al.* 2012, Schlipalius *et al*. 2012, Chen *et al.* 2015).

Phosphine fumigation has the advantages of needing relatively low dosages when compared with other fumigants, being cost-effective, and least effects on the quality of fumigated grains. Consequently, despite the drawbacks in the existing storage and fumigation practices in the tropical countries, phosphine fumigant has helped preservation of food grains economically and at the same time meeting consumer demands with regard to the quality of the food grain. It is possible that these resistant strains could be controlled in tropical countries using phosphine fumigation, if conducted properly. This study also suggests that proper resistance assessment techniques can help to determine occurrence of phosphine resistance in populations of *R. dominica* in the field level of tropical as well as developing countries.

Abstract

Sub-lethal dose application of phosphine (PH_3) that is mostly caused by leakage during fumigation has resulted in resistance in *Tribolium castaneum*, *Rhyzopertha dominica*, *Cryptolestes ferrugineus*, *Sitophilus oryzae*, and other stored-product insect pest species worldwide. However, PH_3 resistance in the saw-toothed grain beetle, *Oryzaephilus surinamensis,* has not been reported in any country. Additionally, the discriminating dose of PH_3 for eggs of *O. surinamensis* has not been estimated. In this study, the discriminating dose for eggs of the susceptible strain of *O. surinamensis* was estimated as 28.4 ppm applied for 3 d. Adults from 4 out of 14 field-collected populations showed detectable resistance to PH_3 whereas eggs in 9 out of 14 populations had detectable resistance. Resistance frequencies in both adults and eggs in Box BF, Box BR and OKWat populations were > 90%. Levels of resistance (LC_{99}) in these three populations were estimated using probit analysis. LC_{99} values for adults of Box BF, Box BR, and OKWat populations were 320.5, 290.7 and 263 ppm, respectively, whereas those in eggs from the same populations were 1055.9, 1030.7, and 564.5 ppm, respectively, over 3-d fumigation. Resistance levels of adults and eggs of the most resistant population, Box BF, were 24.3- and 43.6-fold, respectively, higher than those of the lab-susceptible strain. The resistance levels in eggs from these three populations were > 3-fold higher than that in adults and this shows eggs of *O. surinamensis* are more tolerant to PH_3 than adults. These results indicate that it may not be practical to use PH_3 to control Box BF and Box BR populations. Therefore, it is important to develop alternative pest management strategies for controlling highly PH_3-resistant populations of stored-product insect pests.

Keywords: almond storage, resistance management, fumigation, resistance level

1. Introduction

The Central Valley of California produces ~ 840,000 metric tons/year of almonds valued at ~ $6.5 billion, and this accounts for nearly all almond production in the United States (National Agricultural Statistics Service [NASS], 2017). Such almond production levels are associated with a high level of risk from stored product insect pest infestation. Postharvest fumigation using phosphine is usually the method of choice for disinfestation of most stored agricultural commodities such as almonds (Johnson et al., 2012).

Phosphine or hydrogen phosphide (PH_3) is the most widely used fumigant for stored product insect pest control in the world because it is relatively inexpensive, easy to apply, and nearly no residue is left in the treated commodity. Sub-lethal dose application of PH_3 that is mostly caused by leakage during fumigation has resulted in resistance in *Tribolium castaneum* (Herbst) (Coleoptera: Tenerionidae), *Rhyzopertha dominica* (F.) (Coleoptera: Bostrichidae), *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Laemophloeidae), *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae), and other stored-product pest species worldwide (Zettler and Cuperus, 1990; Zettler and Keever, 1994; Rajendran, 1999; Collins et al., 2001; Cao et al., 2003; Benhalima et al., 2004; Pimental et al., 2010; Lorini et al., 2007; Opit et al., 2012; Ahmad et al., 2013; Nayak et al., 2013; Jittanun and Chongrattanameteekul, 2014; Chen et al., 2015; Koçak et al., 2015; Sağlam et al., 2015; Gautam et al., 2016; Afful et al., 2017; Cato et al., 2017; Konemann et al., 2017).

There are currently no published studies on PH_3 resistance in saw-toothed grain beetle, *Oryzaephilus surinamensis* (Coleoptera: Silvanidae) in the United States and other countries worldwide despite PH_3 resistance having been reported in several species of storage pests including *T. castaneum*, *R. dominica*, *C. ferrugineus*, *S. oryzae* and other stored-product pest species globally. Therefore, the objectives of this study were to estimate the discriminating dose for eggs of a laboratory-susceptible strain of *O. surinamensis,* given that this information is lacking in literature, and to estimate the resistance frequencies of both adults and eggs of 14 *O. surinamensis* populations collected from almond storage and processing facilities in California and wheat storage facilities in Oklahoma. An additional objective was to estimate PH_3 resistance levels (LC_{99}) in adults and eggs of those populations found to have resistance frequencies ≥ 40%.

2. Materials and methods

Insects

A PH_3-susceptible laboratory strain (Susceptible *STGB*) of *O. surinamensis* maintained in culture since 1972 was obtained from the Center for Grain and Animal Health Research (CGAHR) of the USDA Agricultural Research Service, Manhattan, KS. Fourteen field-collected populations of *O. surinamensis* were used. Eleven out of 14 populations were collected from almond storage and processing facilities in the Central Valley of California during the period 2013–2016 whereas 3 populations were collected using probe traps from wheat storage bins in Oklahoma in 2015 and 2016. Each sample received from California was transferred to a glass jar, labeled, and kept in an incubator at 28 ± 1°C and 65 ± 5% RH for 2–3 weeks to allow for the immature stages to develop. Adult *O. surinamensis* were then transferred to laboratory diet comprising 95% oats and 5% Brewer's yeast (wt: wt) and kept in an incubator at the same conditions described above. Code names were given to different populations, for example "Box A *STGB*" representing an *O. surinamensis* population from facility "A"; the purpose of code names was to conceal identities of the facilities insects were obtained. Voucher specimens of 20 adult insects of each population preserved in 95% ethanol that were used in this study were deposited at K.C. Emerson Entomology Museum at Oklahoma State University under lot numbers: 163 (Box A *STGB*), 164 (Box BF *STGB*), 165 (Box BR *STGB*), 166 (Box Q *STGB*), 167 (Box S *STGB*), 168 (Box U3 *STGB*), 169 (Box W *STGB*), 170 (Box X *STGB*), 171 (Susceptible *STGB*), 192 (OKBur *STGB*). 193 (OKSti *STGB*), 194 (OKWat *STGB*), 195 (Box 16A), 196 (Box 16B) and 197 (Box 16C).

In the estimation of discriminating dose for eggs of the lab susceptible strain, resistance frequencies of both adults and eggs of 14 field-collected populations, resistance levels of both adults and eggs of three populations with resistance frequencies ≥ 40% (resistance frequencies were > 80%), procedures in FAO Method No. 16 (FAO, 1975), Opit et al. (2012), Gautum et al. (2016), and Konemann et al. (2017) were used and are briefly described below**.**

Estimation of discriminating dose

Experimental procedures to estimate the discriminating dose for eggs of *O. surinamensis* laboratory strain were similar to those described by Gautam et al. (2016) and Konemann et al. (2017). To obtain eggs for fumigation, 200–300 *O. surinamensis* adults were transferred from lab culture into a glass jar containing ~ 20-g mixture of oats and wheat flour. Three jars were set up. After 3 d, *O. surinamensis* eggs were harvested by sifting contents of jars using U.S. Standard #40 and #70 (0.42- and 0.297-mm openings, respectively) pair of sieves (Seedburo Equipment Company, Des Plaines, IL). Fifty 0- to 3-d-old eggs were placed on a transparent piece of double-sided sticky tape that was attached to a piece of black filter paper. Each sticky tape with eggs was then transferred to a glass vial. The glass vials with eggs were then placed in fumigation jars as described by Gautam et al. (2016). Based on preliminary experiments, concentrations of PH_3 required ranged from 2.5–38.2 ppm with seven dose points over a 72-h (3-day) fumigation period at 25°C. After the fumigation, vials were removed from jars and kept in an incubator maintained at 28 ± 1°C and 65 ± 5% RH. Eggs that hatched were counted 10 d post fumigation.

Resistance frequencies

Discriminating doses of 37.5 ppm of PH_3 for 20 h for adults and 28.4 ppm of PH_3 for 3 d for eggs, respectively, at 25°C were applied to estimate PH_3 resistance frequencies in these life stages of 14 field-collected populations of *O. surinamensis*. Preparation of egg samples from 14 field-collected populations was conducted as described above. For *O. surinamensis* adults, for the laboratory susceptible strain and each of the 14 field-collected populations, 50 adult insects of each population were selected randomly and placed in individual glass vials that contained 0.5 g of oats diet. Vials containing insects were then placed in each of three fumigation jars. Insects were also placed in three additional fumigation jars and prepared as previously described but fumigant was not added

to these jars which served as the controls. Mortality assessments for eggs and adults were conducted 10 d and 14 d post fumigation, respectively.

Levels of resistance

The susceptible *O. surinamensis* (Susceptible *STGB*) and three field-collected populations, Box BF, Box BR and OKWat were tested in dose-response assays to estimate their levels of resistance for both adults and eggs. Populations Box BF, Box BR and OKWat had resistance frequencies > 40%. Concentrations of PH_3 used for dose-response tests for the Susceptible *STGB* strain have previously been described above whereas those for adults of Box BF, Box BR and OKWat were 24.4–354.1, 24.4–354.1 and 30.0–366.1 ppm, respectively. For eggs, these concentrations were 28.4–449.2, 28.4–449.2 and 42.4–420.0 ppm, respectively. Experimental set-up and fumigation procedures were similar to those described in Opit et al. (2012), Gautam et al. (2016) and Konemann et al. (2017). Fumigation period was 3 d and mortality assessments for adults and eggs were conducted 5 d and 10 d post-fumigation, respectively.

PH_3 concentration analysis

The concentration of PH_3 gas in each fumigation jar was measured at the beginning and at the end of the respective exposure periods using a gas chromatograph coupled with a flame photometric detector (GC-FPD) (Model 8610C, SRI Instruments, Torrance, CA). The concentrations were established using a standard curve based on 50, 40, 30, 20, and 10 µl of 200 ppm PH_3. The areas under the peak in microvolts (µV) were recorded along with the volume of PH_3 injected. PH_3 volumes were regressed against measured peak areas to generate a linear regression equation that had a coefficient of determination (r^2) value between 0.96 and 0.99 in all cases. Thirty microliters gas samples from each fumigation jar were analyzed using the GC-FPD and quantified using the regression equation generated from the standard curve.

Data analysis

The experimental designs for determining discriminating doses were completely randomized designs with three replications. LC_{50} and LC_{99} values and their 95% confidence intervals (CIs) of both adults and eggs were estimated by probit analysis using PoloPlus (LeOra Software, Petaluma, CA) (LeOra Software, 2005). The discriminating dose of eggs was the upper limit of the 95% CI of the LC_{99} value at a given exposure period at 25°C. A ratio test to compare LCs was also conducted for eggs and adults of *O. surinamensis* (Robertson et al., 2007) to estimate the degree by which the field populations were more resistant to PH_3 than the susceptible laboratory strain. In order to ascertain that the value of the mean is within the limit at 95% probability, we calculated G-factor using the equation, $t^2\ V(b)/b^2$, where t = student's *t* test with error degrees of freedom, V(b) is the slope variance estimate given in the variance-covariance matrix, and b is the slope estimate. If a G-value is less than 0.5, it suggests that the value of the mean is within the limit at 95% probability.

3. Results and Discussion

Estimation of discriminating dose for eggs of *Oryzaephilus surinamensis*

Given that there was no previously published phosphine discriminating dose for eggs of *O. surinamensis*, we first estimated it in using a dose-response experiment and a laboratory susceptible strain of this species. PH_3 discriminating dose for eggs of *O. surinamensis* was estimated as 28.4 ppm over a 3-d fumigation period at 25°C (Table 1).

Tab. 1 Estimation of PH_3 discriminating dose for eggs of the laboratory susceptible strain of saw-toothed grain beetle, *Oryzaephilus surinamensis* (Susceptible *STGB*) based on 3-d fumigation at 25°C.

Population/Strain	N	Slope ± SE	LC_{50} (95% CI)	LC_{99} (95% CI)	X^2 (df) [H*]	G-factor
Susceptible *STGB*	1200	9.8 ± 0.6	14.0 (13.3 – 14.7)	24.2 (21.8 – 28.4)	59.4 (17) [3.5]	0.016

*Heterogeneity factor, chi-square value/ degrees of freedom (chi-square is significant < 0.05).

Resistance frequencies

Adults from 4 out of 14 populations showed detectable resistance to phosphine whereas eggs in 9 out of 14 populations had detectable resistance to phosphine. The resistance frequencies in both adults and eggs in "Box BF", "Box BR" and OKWat *STGB* populations were > 80% (Table 2). These results suggest that in some almond storage and processing facilities in California, populations of *O. surinamensis* with strong phosphine resistance co-exist with populations of *T. castaneum* with strong phosphine resistance (Gautam et al. 2016).

Tab. 2 Survival of adults from a laboratory susceptible strain (Susceptible STGB) and 14 field-collected populations of *Oryzaephilus surinamensis*. Data for adults are based on 20-hour exposure to a PH_3 discriminating dose of 37.5 ppm at 25°C and for eggs, a 3-day exposure to a discriminating dose of 28.4 ppm.

Life Stage	Population	Percentage survival			
		Rep. 1	Rep. 2	Rep. 3	Mean ± SE

	Susceptible *STGB*	0	0	0	0.0 ± 0.0

Levels of resistance

LC_{99} values for adults of Box BF", "Box BR" and OKWat *STGB* populations were 320.5, 290.7 and 264.1ppm over 3-d fumigation, respectively, whereas those in eggs of the same populations were

1055.9, 1030.7 and 564.5ppm, respectively (Tables 3 and 5). The resistance levels of adults and eggs in the population with the highest resistance, Box BF were 24.3 and 43.6-fold, respectively, higher than that in the lab-susceptible strain (Table 4 and 6). The resistance levels in eggs of these two populations were >3-fold higher than that in adults. These data show that eggs of *O. surinamensis* have much higher levels of resistance than adults; similar results were reported by Gautam et al. (2016) for *T. castaneum*, also collected from almond storage and processing facilities.

Tab. 3 Probit analyses of dose-response data for the susceptible and three phosphine-resistant populations of *Oryzaephilus surinamensis* adults. LC values are lethal concentrations of phosphine (ppm) over 3 d fumigation period at 25°C.

Population/ Strain	N	Slope ± SE	LC_{50} (95% CI)	LC_{99} (95% CI)	X^2 (df) [H*]	G-factor

4. Conclusions

Resistance frequencies in adults and eggs of 14 field-collected populations of *O. surinamensis* ranged between 0–100 for both stages but were highest in three populations, namely "Box BF", "Box BR" and OKWat *STGB*, where frequencies were > 80%. Resistance levels (based on LC_{99}) in adults of these 3 most resistant populations were 22.1-, 24.3- and 19.9-fold, respectively, higher than in the susceptible strain, whereas those in eggs were 43.6-, 42.6- and 23.3-fold higher than in the

susceptible strain. These results show that phosphine-resistant populations of *O. surinamensis* are found in both almond storage and processing facilities in California and in wheat storage facilities in Oklahoma. For the control of stored product insect pests, currently the almond industry in California recommends a dose is 500–1,000 ppm of PH_3 for a minimum of 3 d, but 5–7 d are highly recommended, at 20–30°C. Therefore, it may not be possible to use PH_3 to effectively control Box BF and Box BR populations given that the LC_{99} values of eggs of these populations are 1055.9 and 1030.7 ppm, respectively. These data highlight the importance of developing alternative pest management strategies for controlling highly PH_3-resistant populations of stored product insect pests.

DOI 10.5073/jka.2018.463.137

Abstract

The psocids from the genus *Liposcelis* are also named booklice, which are stored-product insect pests. Recently, apparent insecticide resistances have been observed in booklice. Here, we mainly focus on mechanisms of metabolic resistance associated with the three major enzymes, Cytochrome P450 monooxygenases (P450s), Estrases (ESTs), and Gluthione-S-transferases (GSTs) in booklice. We developed four comprehensive transcriptomic databases for four booklice, and a large number of detoxification genes potentially involved in insecticide resistance were identified. Totally, 49, 68, 94 and 82 P450 genes, 31, 37, 35 and 23 GST genes, 21, 19, 34 and 19 EST genes were identified for *L. bostrychophila*, *L. entomophila*, *L. tricolor* and *L. decolor*, respectively. The large number of P450s and GSTs implied that Liposcelis species could potentially develop high level of insecticide resistance. The mRNA expression levels of detoxification genes showed that these genes expressed at all tested stages, but exhibited stage-specific patterns, with the higher expression in adults and elder nymphs. Additionally, mRNA abundances of P450 genes were relatively more abundant in adult females than in adult males. The research on different strains showed that the resistance strain of both *L. bostrychophila* and *L. entomophila* had significantly higher mRNA expression and enzyme activity of the detoxification enzymes than the sensitive strain. The above data indicated that detoxification genes might be associated with metabolism insecticides in psocids.

"Remote Sensing, Predictable Storage of Agricultural Commodities and Advances in Hermetic Storage"

Abstract

Modified atmosphere hermetic storage, now used in over 115 countries for fumigant-free storage of dry commodities from coffee to rice and maize, has been available for almost three decades. This paper describes the progress in the field use of hermetic postharvest storage systems and of recent innovations in this technology which include the introduction of remote monitoring of temperature, humidity and O_2 or CO_2 levels in large, sealed hermetic containers. Also, introduced in 2018, is the Cocoon Lite™, a 2nd generation multi-tonne container with major improvements in the permeability, weight and cost of high performance, large hermetic storage systems. Early examples of the uses of these innovations and data obtained from their study is expected by year end. The GrainPro EcoWiSe™ is a remote sensing system that enables monitoring of temperature, moisture and oxygen/carbon dioxide levels, thus providing real-time data on the conditions of the stored commodity involved without manual intervention. One (or more) low-cost, remote, wireless sensors/transmitters placed inside sealed. Postharvest hermetic storage units can be read remotely on laptops or cellphones. Data collected and accumulated over time enables development of an "algorithm" for a stored commodity to define an alarm, where the user can be notified immediately of any unsafe humidity or oxygen storage conditions. A substantial advance in large hermetic storage containers known as Cocoons™ is the new Cocoon Lite, a 500:1 improvement in permeability to oxygen as well as a unit weight only 28% of existing Cocoons with the same capacity and a significantly lower cost. The paper also discusses prevention of the public health hazard of exponential growth of aflatoxin levels in conventional postharvest storage such as in rice, maize, and groundnuts; field data is provided on the control achieved through hermetic storage.

Keywords: hermetic, grain storage, aflatoxins, remote sensors, safe storage, seed storage

1. Brief overview of current hermetic storage use for postharvest storage

Over 25-years ago, we saw the first commercial introduction of fumigant-free, hermetic (airtight) postharvest storage for many types of grains and seeds. Where used, this resulted in drastically reduced, multi-month storage postharvest losses of the stored grains and other dry commodities. Hermetic storage to prevent both qualitative and quantitative postharvest losses for periods of one-year (or more) is now used in over 115 countries and takes many forms. Hermetic storage has the further proven benefit of arresting the exponential growth of aflatoxins, a major public health hazard for key commodities, especially in hot, humid climates.

In 2018, a new large multi-tonne storage unit, the Cocoon Lite was introduced to supplement the existing 5 to 1,000 tonne capacity Cocoon for indoor or outdoor use. The Cocoon Lite described further is much lighter, has 500 times lower O_2 permeability and is significantly less expensive than the standard Cocoon.

Various manual means have been used to verify the continued integrity of hermetically sealed postharvest storage of commodities, from sampling to taking measurements with an oxygen analyzer. With the 2018 introduction of remote sensing, continuous monitoring of the container environment is now possible. The capacities of currently available hermetic storage units in current commercial use, typically range from 15kg to as much as 1,000 tonnes.

A 2016 Fintrac/USAID study in Kenya concluded: "Hermetic technologies offer small-scale farming families effective, cost-efficient, insecticide-free methods for on-farm storage." (Fintrac 2016).

2. The principle of hermetic storage and its requirements

The goal of hermetic storage is to create a container sufficiently airtight to allow the total insect respiration rate of infesting insects plus, where applicable, that of the stored commodity itself, is to be greater than the rate of residual infiltration of oxygen through the ultra-low permeability hermetic container surface. To successfully accomplish this goal in small size, man-portable storage containers, a special, coextruded PE plus barrier layer with oxygen permeability of available models of between 1 to 50 cc/ m^2/day is used. In large containers of 1-tonne (or more) capacity, use of a PVC with oxygen permeability of less than 500 cc/m^2/day is typical. This approach, which uses 0.8mm thick modern plastic materials, also requires proper sealing (and unsealing) mechanisms to permit the loading and discharge of commodities.

Because of the larger ratio of volume to surface area, small containers such as man-portable bags need much lower permeability than large containers to reach the same equilibrium between respiration and infiltration of air, and therefore to achieve the same degree of oxygen depletion in the container.

Thus, the principle of successful use of hermetic storage is that insect respiration alone, plus any respiration of the commodity itself as well as microflora activity, can create a modified atmosphere and either approach (or reach) the unbreathable atmosphere levels of 3% oxygen. Somewhat higher oxygen levels can be successful in killing insects when synergistic carbon dioxide levels rise to 12 - 15% or above, primarily, through insects exhaling of CO_2.

In those few instances where insect respiration needs to be supplemented, or where rapid disinfestation is desired (or required), the natural insect respiration process can be supplemented by an adjuvant to reduce the time required to reach LT99. The typical adjuvant is carbon dioxide, or for smaller containers, a smaller commercial oxygen-absorbing sachet. In most instances, an initial dose of 80-90% CO_2 alone will kill the total insect population in approximately 10 days, provided that the final concentration of CO_2 remains > 35% (Navarro, et all, 2012).

3. Introduction of remote sensing

GrainPro EcoWiSe™ was introduced in the first half of 2018 as an alternative to manual measurement or observation of the content of a sealed, hermetic container. The remote sensing technology enables monitoring of temperature, moisture, and oxygen/carbon dioxide levels. Measurements are made wirelessly and information is displayed on a laptop or desktop computer capable of receiving wireless signals. Real-time data on the conditions of the stored commodity are produced without manual intervention.

Data collected and accumulated over time enables development of an "algorithm" for a stored commodity using an alarm setting, where the user and others, can be notified immediately of any preset unsafe humidity or oxygen storage conditions. If any of the preset values being monitored are exceeded, the alarm indicates that an out of control condition exists and requires immediate attention. The algorithm helps as well in predicting the "storability" of the commodity.

One (or more) low-cost, remote, wireless sensors/transmitters placed inside sealed, postharvest hermetic storage units can be read without opening the container and at distances up to 500 meters (and more with a repeater), the small electronic module (Figure 1) placed inside the sealed storage container broadcasts information through a nearby computer to the "cloud". A single, remote receiver communicates with one or more sensors/transmitters placed inside. The sensors weigh a fraction of a kilogram and are powered by a 5-year active battery, A single receiver can handle up to one hundred sensors.

Fig. 1 Wireless sensor/transmitter

Fig. 2 Cocoon Lite™ capacity 5-tonne, PE-based, weight 7.75 kg (Courtesy, GrainPro, 2017)

4. A new class of lightweight, multi-tonne hermetic container

2018 also marked the introduction of the Cocoon Lite, an innovating addition to the widely used, PVC-based hermetic Cocoon. Cocoon Lite is lighter and far more airtight than the Cocoon.

The Cocoon Lite (Figure 2) is composed of an improved, 205µ thick composite material consisting of a special formulation of polyethylene, a compound barrier layer, plus a white, opaque barrier layer, which also adds UV-resistance and strength against penetration by insects. It is designed for both indoor and outdoor use.

Although the 5-year rated life of the Cocoon Lite is significantly shorter than the 15-year life of the existing PVC-based Cocoon, advantages include significantly lower cost and a weight of only 20% of the equivalent size PVC Cocoon. Its permeability to O2 improved to <1 cc/m^2/day instead of the conventional Cocoon permeability of <500/cc/m^2/day. This shortens the time needed to reach an unbreathable atmosphere and low oxygen level.

Because it is much lighter, the Cocoon Lite is easier both the transport and install, and it better protects against the entry of outside humidity, with permeability to water vapor of <2g/m^2/day versus <8g/m^2/day for the PVC-based Cocoon.

First deliveries of the Cocoon Lite took place in the first half of 2018.

5. Hermetic storage for control of exponential aflatoxin growth in storage

The health consequences of high levels of aflatoxins (produced by *Aspergillus flavus* and *Aspergillus parasiticus*) are widely recognized as major health problems, particularly in hot, humid climates. The international community and many individual countries have set strict limits on acceptable levels of aflatoxin – most commonly 10-20 parts per billion (ppb), or even 5 ppb for direct human consumption. In practice these limits are often greatly exceeded or not being monitored at all, causing serious health effects by depressing the human immune system (Williams, et. al., 2004).

In humans, high aflatoxin levels contribute to many health problems ranging from cancer and susceptibility to HIV, to stunting growth among children. In African countries, Dr. Williams cites a sampling survey of several local markets which showed that 40% of the commodities tested had food aflatoxin levels exceeding the international standard of 10 to 20 ppb, putting an estimated 4.5 billion people in developing African countries at risk. (Williams, 2011).

A cross-sectional study conducted in Ghana (Dr. Williams, 2011) showed that the immune systems of recently HIV-infected people had above-median levels of aflatoxins and that "people with a high aflatoxin biomarker status in Gambia and Ghana were more likely to have active malaria." Small holder farmers were particularly affected: "A major area of neglect and opportunity is foods stored by small farmers for their own consumption. A very common consequence of quality control in markets is for farmers to retain, for their own use, grains that would reduce the price offered in the market place." Further Williams writes "studies of groundnuts in local storage facilities show a steady increase in (aflatoxin) contamination levels and these differences are observed in the cyclical variation in the biomarkers of rural African people." (Williams, 2011).

"Hermetic (i.e., airtight) storage devices arrest aflatoxin growth nearly entirely", according to a 2017 ACDI/VOCA brief, sponsored by the Bill and Melinda Gates Foundation. The report states "This has been substantiated through research in both real-world and controlled settings. Hermetic storage offers tangible hope in mitigating aflatoxin's blight." (AflaSTOP, 2017).

Figure 3 shows the relation between the growth of aflatoxin-producing molds and humidity. 80% relative humidity and above is common in many parts of Africa, South America and Asia.

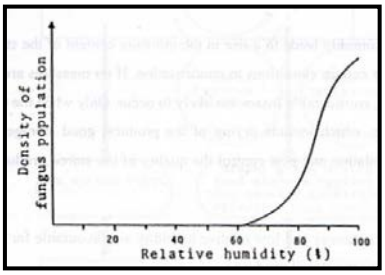

Fig. 3 Effect of relative humidity on mold/fungus density (Harrington, 1972)

Field study results from ICRISAT in Mali (Table 1), show how exponential growth of aflatoxins takes place within months. (Waliyar, et. al., 2013).

Tab. 1 Increased aflatoxin levels in groundnuts during conventional storage in farmers' fields in Mali.

Village In Mali	Aflatoxin content (ppb)		
	At harvest	1 month later in storage	2 months later in storage
Bamba	101.3	168.9	275.5
Gouak	61.4	118.0	174.7
Kolokani	119.2	352.6	400.0
Sido	53.7	93.6	166.2

Another 2013 study from Ruhira, Uganda, by Millennium Villages shows the growth of aflatoxins in conventional storage versus hermetic storage methods and illustrates the major suppression of aflatoxin growth when using hermetic storage versus alternative, conventional storage. (Figure 4), (private communication, 2013).

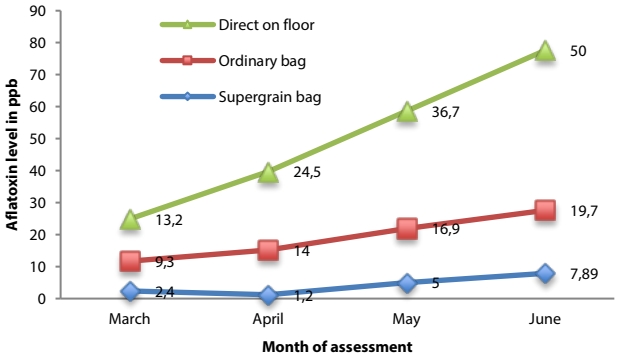

Fig. 4. Comparing aflatoxin concentration over one season in maize stored in conventional and hermetic methods. Millenium Village study in Ruhiira, Uganda (2013).

6. Hermetic storage performance in storing major commodities

Postharvest hermetic storage systems, in addition to contributing to public health through inhibiting aflatoxin growth, dramatically reduce quantitative postharvest losses from insects, rodents and molds. In grains, such as maize conventionally stored for many months, total postharvest losses including storage can (and often) exceed 25%. (Zorya, et. al., 2011).

Field performance of postharvest, hermetic storage systems and the large-scale applicability of Ultra Hermetic storage to preserve dry grains for up to a year, have been studied for several commodities that include: maize, wheat, rice, seeds, coffee, cocoa and ground nuts.

These studies generally have documented reduction of losses using hermetic storage in hot, humid climates to less than 1% per year for up to 1-year. For some commodities, such as coffee and cocoa, the primary goal is preserving premium quality for up to a year without use of refrigeration, pesticide, or fumigants. Examples of results for a few of these key commodities are shown in the following sections, including ground nuts where the injection of CO_2 or oxygen absorbers as an accelerant has been found important.

6.1 Hermetic maize storage

Babban Gona, an integrated contract farming model project, involving 20,000 small farmers in Northern Nigeria, provide farmers with seeds, fertilizer, technical support, financing and take-out in aggregation centers catering especially to quality buyers for high quality/low aflatoxin uses including baby food. Babban Gona features their low aflatoxin levels in its maize. (Figure 6). They report a doubling of farmer yields for maize.

Fig. 5 Storing maize in 150 MT Cocoon at Babban Gona Aggregation Center in northern Nigeria, emphasizing low aflatoxin in their maize (courtesy, Babban Gona, 2017).

According to Babban Gona's records in Oct 2017, the maize losses out of 26,000 tons of the 2016 harvest were an average of 0.003% (about 7 bags out of 250,000 bags stored in 170 Cocoons with 1,500 bags each). (Private communication, Donna Etiebet, Babban Gona, 2018)

A report by Kukom Edoh Ognakossan in Togo compared maize storage in woven polypropylene versus hermetic storage for 150-days with populations of Prostephanus truncates and Sitophilus zeamais. Losses from Sitophilus zeamais were less than 0.5% in hermetic storage versus 19.2% in woven polypropylene. For P. truncates losses in hermetic storage were 6% in hermetic storage versus 27.1% in woven polypropylene. (Ognakossan, I.E., et al, 2013).

6.2 Hermetic rice & rice seed studies

Extensive postharvest studies of hermetic storage of rice and rice seeds (paddy) at IRRI (International Rice Research Institute, Los Banos, Philippines) (Villers and Gummert, 2009), and at PhilRice (Philippines) (Sabio, et. al., 2006)) have shown that rice seeds stored hermetically without fumigants, can be stored for up to a year with negligible loss rates, while maintaining germination rates and vigor. Results are comparable to refrigerated or air conditioned storage. Rice seed, as see in Table 2, can be stored hermetically for six months with germination levels equivalent to air-conditioning or cold room storage without the energy cost or capital investment (Villers, et al., 2006)

In a field study by IRRI, they reported that "in Cambodia, the germination for hermetically stored seeds was 90% after 6 months and 63% after 12 months. In comparison, seed stored in traditional systems had germination of 51% and 8%, respectively" (Villers and Gummert, 2009)

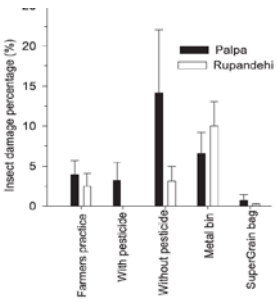

Fig. 7 Insect damage after 6 months in wheat seed versus storage method, Nepal (Devkota et. al., 2017)

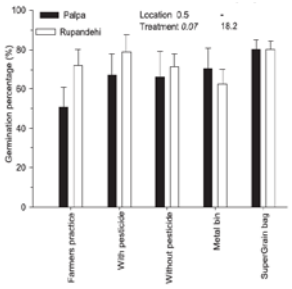

Fig. 8 Comparison of germination rates, wheat seeds in Nepal (Devkota et. al. 2017)

6.3 Hermetic wheat seed storage

An article published in the Journal of Stored Product Research (Devkota, et al, 2017) describes a joint 2017 IRRI and CIMMYT study conducted in Nepal of wheat seed storage measuring quantitative germination performance, insect damage and seed vigor. (Devkota, M., 2017)

The study demonstrated that wheat seed stored in hermetic SuperGrainbags (SGBs®) maintained a lower moisture content, and produced higher seed germination and seed vigor with less insect damage than other storage methods evaluated in the study (Figure 7). It also demonstrated that maintaining wheat seed storage quality is more challenging using traditional storage methods in the Nepalese hills, which have higher rainfall and lower temperature than in the Terai Plains. According to the authors, "the higher germination percentage and lower insect infestation under SGB storage was attributed to maintaining low seed moisture during storage. It is known that every 1% increase in seed moisture content reduces the seed shelf-life by half (Harrington, 1972).

Shown in Figure 7 and Figure 8 from their study showing data on insect damage and germination %, respectively from their study.

Tab. 2 Mean % germination rate of Mestizo 1 hybrid paddy (unmilled) seeds stored using different storage technologies. (Sabio, G.C., et al, 2006)

	Storage time after harvest (months)			
Storage method	**0**	**3**	**6**	**9**
Hermetic	96.2	96.5	93.3	86.2
Cold Room	96.8	97.6	93.0	89.6
Air-conditioned	94.3	94.8	88.1	85.8
Control (unprotected)	92.9	92.9	76.4	74.7

Tab. 3 Mean percent adult insect density1 per kg sample of Mestizo 1 hybrid paddy seeds stored under different storage technologies and durations. (Sabio, G.C., et al, 2006)

Months	Open Storage	Air-Conditioning	Cold Room	Hermetic (5 tons)

6	114	3.0	0	0.4
9	54	3.4	0	0.4
12	27	9.0	0	2.2

6.4 Green coffee storage

In the case of coffee, hermetic bags typically sized 15kg to 69 kg capacity, have become the defacto standard worldwide for the specialty coffee sector.

In 2012, Dr. Flavio Borem's Brazil study concluded "The coffee beans stored in the hermetically sealed packaging predominantly had desirable flavors such as chocolate, vanilla, citrus and red fruits. Conversely, the coffee stored in the jute sacks had predominately undesirable odors such as papery and jute." Also, "The lowest losses were observed when coffee was stored with artificial atmosphere. After 12-months, no differences were observed between vacuum and GrainPro bags." (Borem et. al., 2013)

Variations on hermetic storage of green coffee beans have been studied, including another study in Brazil by Dr. Borem that found a small, but not statistically significant, improvement can be obtained by injecting CO_2 during hermetic storage. (See Table 4). As to vacuum storage, in a different study, Dr. Flavio Borem writes: "This result confirm the thesis that it is possible to maintain coffee quality equal to the quality of vacuum-packed coffee, up to now considered by most coffee importers as the best storage system for specialty coffees". (Borem, 2016).

Tab. 4 Quantitative Value for Coffee Quality after 12-months of storage.
Mean values of the overall score of the coffee beans after 12-months of storage.

Big-bag (one-tonne hermetic)	Position	Score
With CO2	Upper	80.00a
With CO2	Middle	80.80a
Without CO2	Upper	78.09a
Without CO2	Middle	78.06a
Other treatments:		
GrainPro (SuperGrainbag, no CO2)	GrainPro	78.98a
Jute sack alone	Jute sack	73.03b

6.5 Hermetic cocoa bean protection

According to a Ghana Cocoa Board report "Experiments were conducted in the year 2008 in Tema, at the research department of the Ghana Cocoa Board with 150 tonne GrainPro Cocoons (for stacked bags of cocoa beans), SuperGrainbags (for 69 kg bags of cocoa), and TranSafeliners™ (gas-tight liner for shipping containers), all showing that the low oxygen/high carbon dioxide atmosphere was able to eliminate the insect population completely in less than two weeks…In conclusion, storing cocoa beans in hermetically-sealed structures inhibits activity of insect pest and mold development; consequently, the FFA deriving from microflora development was inhibited. Most possible that the toxicogenic mycotoxins are also inhibited…" (Jonfia-Essien et al, 2010)

6.6 Special requirements for safe storage of groundnuts

CO_2 injection is currently used in a number of countries for expelling air in order to achieve a faster suppression of mold growth than achieved through respiration alone, which, in the special case of groundnuts, can take 30 days or more to reach 3% oxygen. See table 5.

Tab. 5 Shows the effect of interventions on aflatoxin levels (ppb) in groundnuts for Drobonso Village, Ashanti Region, Ghana, 2014/2015 major season (Appaw, 2016).

	Field (Harvesting Stage)	Storage Stage + (Poly sac vs Hermetic Bag)	
Practice	**Aflatoxin level**	**Aflatoxin level**	**% Reduction**
Farmer (conventional)	Not detected	6.61 – 438.79 (133.22 average)	
Improved (hermetic)	Not detected	0.88 – 31.36 (10.89 average)	86 – 99 (95% average)

7. Comparative cost effectiveness data on hermetic storage

Three different examples of cost analysis each for a different commodity, are shown in Table 6, Figure 10, and Figure 11.

The cost effectiveness of utilizing hermetic storage of rice seed versus alternatives was studied at PhilRice in the Philippines, with results as shown below in Table 6. (Sabio et. al., 2006)

Tab. 6. Cost comparison (Philippines) using four storage methods for preserving Mestizo 1 hybrid paddy seeds (all values in US dollars; $1 = 50 Philippine pesos).

	3 months' storage				6 months' storage			
Costs	**Control**	**Hermetic**	**Cold room**	**Air-conditioned**	**Control**	**Hermetic**	**Cold room**	**Air-conditioned**
Investment	82,250	1,744	12,820	16,230	82,250	1,744	12,820	16,230
Operating expenses	24,991	504	3,548	3,820	31,086	504	4,196	3,950
Per bag	2.50	2.52	3.55	2.55	3.11	2.52	4.2	2.63

8. Range of Hermetic Systems currently in use

The need for hermetic storage varies, in size and form, and in loading/unloading requirements, and thus a variety of such systems are marketed. These range from the traditional Cocoon™, the new Cocoon Lite™ and 1-tonne GrainSafes™ to the light, man-portable 15kg to 90kg SuperGrainbags® (SGBs).

The same material is used in the TranSafeliner™ (TSL), also in Figure 12, which applies the hermetic principle to lining for standard 20- or 40-foot shipping containers. TSLs are used in the coffee, cocoa and spice businesses to prevent deterioration of their high value commodities in intercontinental shipments.

At the other end of the range, 69kg, man-portable storage containers such as the 50 kg cost SuperGrainbag Farm (0.078mm), made of PE with a thinner barrier layer and a higher permeability up to 50cc/m2/day, demonstrate satisfactory performance for storage of non-premium commodities, such as maize or rice crops.

Fig. 12 Examples of different sizes of hermetic storage on-farm and coop storage, ranging from SuperGrainbag liners of 15 – 69 kg and GrainSafes of 1-tonne and Cocoons of 5- to 300-tonnes. (Courtesy of GrainPro, Inc.)

9. Conclusion

More than 25-years ago, the hermetic, postharvest storage once used by the ancients in very large airtight jars sealed with beeswax, was revived in a modern form and became available commercially. Hermetic storage from 15 kg to 1,000 ton capacity is now used within 115 countries worldwide, generally with no more than 1% quantitative losses per year, and highly effective maintenance of quality, including prevention of exponential growth of aflatoxins. Recently, the introduction of remote sensing can largely eliminate the danger of unobserved accidental damage to a hermetic container that leaves a stored commodity unprotected. Also, recently introduced, is the 2nd generation large hermetic container, which has a 500:1 improvement on oxygen permeability and a weight reduction of 75%. The hermetic storage industry continues to grow and provides a variety of products and performance characteristics as specialized needs are addressed.

DOI 10.5073/jka.2018.463.139

Abstract

In the developing-country context of Nepal, farmers often incur in seed losses of 15-30% due to improper storage. To evaluate the efficacy and costs of modern storage alternatives, experimental trials were set up among ten farmers each in two contrasting ecologies, i.e. Palpa (hills) and Rupandehi (terai plains) districts of Nepal in 2013. Several wheat seed storage options were contrasted including farmer practices (FP) such as reused fertilizer bags, polythene bags, household metal containers, and mud bins. Modern storage methods that were evaluated included plastic bags (with and without pesticide), metal bins, and hermetic 'SuperGrainbag' (SGB). Seed quality and losses were assessed after six months of storage (May-October) with parameters such as grain moisture content, insect damage, seed germination, and seedling vigor. The overall quality of seed with FPs was lower in the hills than in the terai plains. Among the treatments, SGBs were more effective in maintaining acceptable seed moisture levels, controlling insect damage (<1%), preserving germination (>90% lab, >65% field), and promoting seedling vigor. Metal bins and plastic bags without pesticide had higher insect damage (7-15%) compared to FP and plastic bags with pesticide (2-5%). In terms of storage costs, SGBs were comparable with the farmers' storage methods ($5-6 per 100 kg seed storage). Our findings demonstrate that SGBs are better at maintaining seed quality and more economical than not only FP but also the other modern storage methods evaluated in this study across different production ecological regions in Nepal.

Keywords: SuperGrain bag, seed quality, germination, insect infestation, seed moisture.

Introduction

As a versatile crop, wheat is an essential part of the diet and food trade in many parts of the world (Uthayakumaran and Wrigley, 2010). In Nepal, wheat is the third most important cereal after rice and maize in terms of area and production. Moreover, it is widely adopted across the country with cultivation ranging from 50 to 4000 m in elevation. It shares 16% of the total calorie and 20% of the total protein supplied from plant products in diets of both the hills and plains in Nepal (CBS, 2015). The plains share 55% of the wheat area and contribute 62% to the total production, compared to 45% and 38%, respectively, by the hills (NARC, 2017).

Good quality seed is considered as the most basic and cheapest, yet most critical input for enhancing productivity (Rana, 1997). However, in Nepal, the seed replacement rate for wheat is only 13% (GoN, 2013). Only 15-20% of the total quantity of wheat seed required for planting is supplied by seed producing agencies that have proper storage structures (warehouses) with moderate cooling and periodic drying facilities. The majority of the seed is exchanged among farmers and stored at room temperature in various kinds of storage materials such as plastic or fertilizer bags, and small to medium sized metal bins, with or without pesticides (FGD, 2013). Seeds, being hygroscopic in nature, are prone to changes in moisture content in response to weather, which

ultimately affects their quality during storage (Ellis and Roberts, 1980). High temperature, seed moisture content and relative humidity during storage as well as poor on-farm storage facilities are the key reasons that lead to insect and mold infestation. Insect and pest damage are effectively responsible for most of the decline in quantity, quality, and germination potential of stored seed (Olakojo and Akinlosotu, 2004). In Nepal, grain storage losses due to insect-pests, rodents and mold range from 15-30% annually (K.C., 1992). Thus, knowledge on proper seed and grain storage methods is important to minimize these storage losses (Kibar, 2015).

The use of hermetically sealed bags such as SuperGrain bags (SGB) (GrainPro, 2017) and Purdue Improved Crop Storage (PICS) bags have been reported as alternative storage options to maintain quality of stored seeds and grain for many crops in Africa and South Asia (Afzal et al., 2017; Baoua et al., 2012; De Groote et al., 2013; Murdock et al., 2012; Mutungi et al., 2014; Vales et al., 2014). Hermetic storage refers to a modified atmosphere of low oxygen and high carbon dioxide (CO_2) content created by respiration of living organisms such as insects. It is designed to protect stored agricultural commodities such as seeds, cereal grain, pulses, and coffee (Baributsa et al., 2014; Chigoverah and Mvumi, 2016; Navarro, 2006; Villers et al., 2010).

In Nepal, the storage season for wheat seed (May-October) is wet and humid, with >90% of the annual rainfall occurring during this period. Thus, preventing post-harvest losses while maintaining seed quality is a major challenge for small holder farmers in both the hills and plains. There is a need for economically feasible, less labor intensive, safe (no use of chemicals) and convenient (easy to transport) storage technology that would benefit farmers and reduce losses. The present study was therefore conducted to evaluate the performance of alternative storage devices in maintaining seed quality of wheat as well as being economically competitive with farmers' traditional storage practices in climatically and geographically distinct areas.

Materials and methods

Experimental sites

The experiments were conducted at two sites, Palpa (Madiphat) and Rupandehi (Basantapur and Dhagdahi), selected based on different ecology and climatic conditions. Madiphat lies in the mid-hills of Palpa at an altitude of 800 m, and has a cool but humid climate with annual rainfall of 1513 mm and temperature of 20.5°C on average. Rupandehi lies in central terai plains at an altitude of 99 m, and has a hot and humid climate with annual rainfall of 1762 mm and temperature of 25°C on average. In both areas, over 85% of the total annual rainfall occurs in the four months of June-September (Fig.1) (MoSTE, 2014).

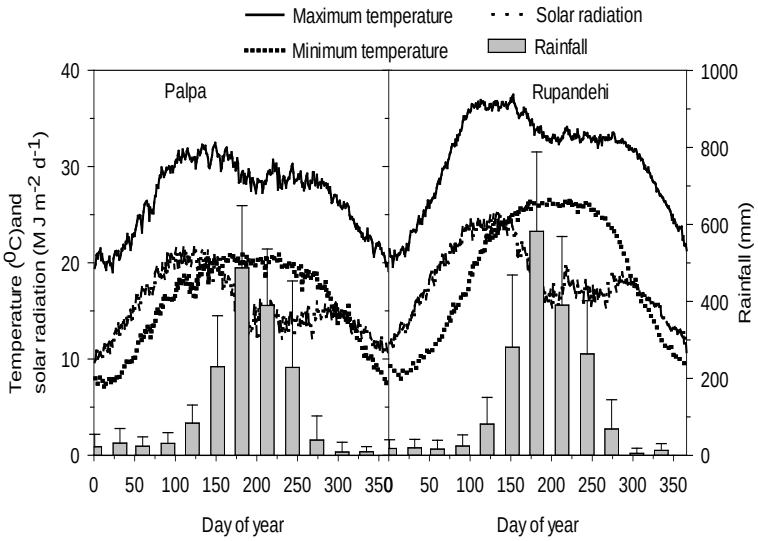

Fig. 1 Daily maximum and minimum temperature, solar radiation and the monthly total rainfall in Madiphat, Palpa and in Rupandehi. Data from long term average from 1987-2013 in Palpa and from 1977-2013 in Rupandehi. The vertical bars are the standard deviation. Source: (MoSTE 2014).

Experimental details and treatments

A participatory experiment was established in ten different wheat cultivating farmers' storage houses each in Rupandehi (terai plains) and Palpa (hills) in 2013. Five types of storage materials were evaluated at each site, i.e. traditional farmers' practice (FP), plastic bag with pesticide (celphus: a common pesticide used for storage pests), plastic bag without pesticide, metal bin and SuperGrain bag (GrainPro, 2017). Individual farmers were considered as replications; hence, each treatment was replicated 10 times in both sites.

Wheat variety NL-297 was used for storage in all the treatments. Prior to storage, the seeds were dried down to at least 12% moisture and then cleaned by removing all the broken seeds and other inert material. The storage duration was six months (May-October), i.e., after wheat harvesting (April) to before wheat seeding (end of October). Twenty kg of seed was stored in each storage treatment except FP, where samples were taken from the farmer's storage method.

The metal bins were fabricated from gauge 24 galvanized metal sheets (0.51 mm) by locally trained tinsmiths and had a seed holding capacity of 30 kg. Plastic bags with dimensions of 80 cm (height) by 50 cm (width) and seed capacity of 50 kg were bought from the local market. Celphus was applied only once to the selected plastic bags at the beginning of the experiment. The SGBs were purchased from Mero Agro Pvt. Ltd. (Kathmandu, Nepal), a local product distributor of GrainPro, Inc. (Zambales, Philippines). These bags are manufactured using high density polyethylene that essentially reduces gas exchange from the stored product. After filling the bag with seed, the empty portion of the bag was squeezed to remove excess air. The opening was then closed by tightly twisting the free portion and sealing it with a special strap fastener provided with the bag. For air-tightness, the top of the bag was twisted twice, folded back and sealed with another fastener. As per recommendations, the SGBs were used as liner bags inside the polypropylene bags, which provide more support and ease in handling. The top of the outer bag was also fastened and sealed in the same manner.

Seed sampling and data collection

After six months of storage, all the treatments were taken out to an open space and the seed inside each was thoroughly mixed. From each storage treatment, two seed samples of ~500 g and ~200 g

were taken to inspect for insect damage and for evaluation of seed germination and vigor, respectively. The samples were kept in clean, labeled plastic bags and transported to the laboratory.

Seed moisture content: It was measured immediately after sampling using a grain moisture meter (GMK-303CF. GrainPro, Inc., Zambales, Philippines).

In the laboratory, a sub-sample of ~200 g was taken to count for insect damage, and their number and weight were recorded. Seeds with holes and cracks in them were considered infested by insects. The count and weigh method, which is the most common method to measure loss by insects and pests in storage (Adams and Schulten, 1978), was used for insect damage assessment.

Determination of seed germination and vigor

One hundred seeds were randomly drawn per household from each treatment for the lab germination test which was conducted at the National Seed Testing Laboratory in Bhairahawa. The seed samples were placed evenly in germination paper and rolled around in it; then, they were wetted with distilled water and placed in an incubator at 25° C for seven days. Moisture was maintained by misting with distilled water as needed.

For the field germination test, 100 randomly drawn seeds from each treatment were sown in line (one treatment per line) in a well-prepared field with sufficient soil moisture at the National Wheat Research Program (NWRP), Bhairahawa. Germination, expressed as a percentage, was indicated by appearance of sprouts for lab seeds and seedlings coming out from the soil for field seeds. The seed vigor represents a more sensitive parameter than the germination test and aims to classify seed with higher probability to perform well after sowing and/or during storage (Marcos Filho, 2015). It was assessed based on germination percentage and seedling length, as suggested by Abdul-Baki and Anderson (1973).

Cost estimation for storage treatments.

The total cost involved in each storage treatment was calculated for storing one quintal of wheat seed. It included the cost of storage material and labor used for drying and storage for each treatment. Further, to understand the farmers' current practice for wheat storage, focus group discussions (FGDs) with 15 farmers in each group were carried out in both Rupandehi (3 FGDs) and Palpa (2 FDGs).

Statistical analysis

Data collected for different parameters were analyzed for analysis of variance (ANOVA) of completely randomized block design, considering farmers as replications using GenStat Version 18. Most variables were not normally distributed (except seed moisture content). Prior to analysis, the variables were transformed to normality using the Johnson Transformation Function of Minitab. Differences in locations and individual treatment effect were analyzed using Fisher's Protected Least Significant Difference (LSD) and treatment differences were considered statistically significant at $p<0.05$. Graphical representations were made in Sigma Plot version.

Results

Current farmers practice of wheat seed storage

From the FGDs, it was found that 70-75 % farmers stored wheat seed in fertilizer bags with 2-3 times sun drying during storage, while about 15-20% farmers' stored seed in metal bin with pesticide in both Rupandehi and Palpa districts. Ten percent of farmers used other storage structures, for example, mud bin, plastic bin, or plastic containers. In FGD, it was reported that 10-90% insect damage (10-80 % in Rupandehi, 15-90% in Palpa) occurred under the farmers' current method of storage in both districts.

Seed moisture content

After six months of storage, seed moisture content increased significantly ($p < 0.001$) from the initial level (~12%) in all treatments, with greater increment in Palpa (12.9-14.8 %) than in Rupandehi (9.3-13.1 %). In Palpa, a significant increase in seed moisture content was observed in plastic bags without pesticide (by 3%), followed by plastic bags with pesticide, metal bins and farmers' practice (by 2%), while that in SGB was <1%. In Rupandehi, the seed moisture content in SGBs and plastic bags with pesticide was unchanged, while it increased by 1% under metal bins and plastic bags with pesticide. Conversely, the moisture content dropped down to 9% under the farmers' storage practice, which could be attributed to frequent sun-drying, higher air temperature, and comparatively low rainfall (Fig. 6; Fig. 1).

Insect damage

Significant treatment effect (p=0.01) was observed in the insect damage levels in both the study sites. In Palpa, insect infestation was the highest in plastic bags without pesticide (14±3%), followed by metal bin storage (9±2%), plastic with pesticide (3.2%), FP (2.4%) and SGB (< 1%) at the end of the storage period. In Rupandehi, seed stored in metal bins had the highest level of damage (10±2%) followed by plastic bags without pesticide and farmers' method (3-4%), while plastic bags with pesticide and SGBs were found to have negligible damage. In both the locations, seed stored in SGBs showed negligible insect infestation (Fig. 2).

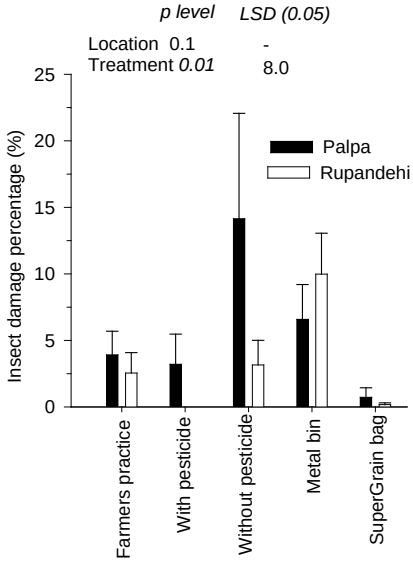

Fig 2. Variation in percent insect damage after six months storage under different treatments in Palpa and Rupandehi.

Seed germination and vigor

Seed obtained from all storage treatments in Palpa showed significantly lower (p=0.02) germination percentage than in Rupandehi, which is a similar trend to that of seed moisture content (Fig. 3A). A significant treatment effect was observed in both lab and field-tested germination percentage in both locations. In Palpa, seed from plastic bags without pesticide showed the lowest germination percentage (63% lab, 43% field), followed by metal bin storage (66.3% lab, 56% field), FP (69.3% lab, 53% field), plastic bags with pesticide (75.2% lab, 51.5% field) and SGBs (90% lab, 68% field) (Fig.3). In Rupandehi, the seed in metal bins showed the lowest germination percentage (67% lab, 50% field), followed by plastic bags without pesticide (81% lab, 54% field), FP (90% lab, 56% field) and

plastic bags with pesticide (89% lab, 65.4% field). The highest germination percentage was observed in SGB storage (92.8% lab, 69% field) as seen in Figure 3.

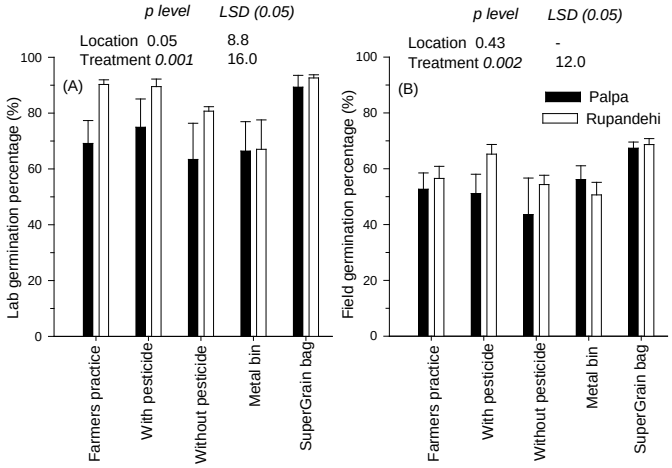

Fig. 3. Variation in laboratory and field germination percentage under different storage treatments in Palpa and Rupandehi.

Similarly, the vigor test resulted is comparable results as the lab germination test for all the storage treatments in the two locations. SGBs showed higher vigor percentage (~80%) than other treatments in both the locations. The seed from FP treatment in Palpa resulted in low vigor (~50%) while that for the other methods ranged from 60 to 70% (Fig. 4).

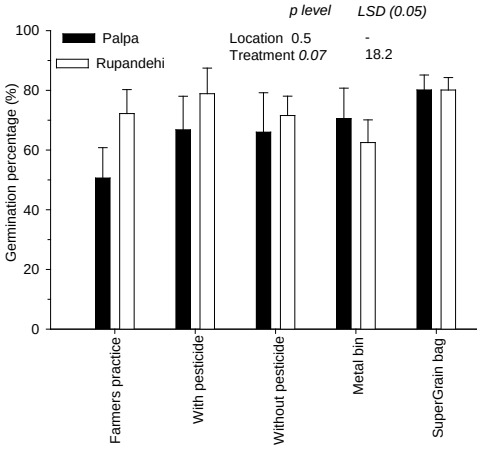

Fig. 4. Variation in seed vigor percentage under different storage method tested in Palpa and Rupandehi.

Cost involved with different storage structures

The total cost to store per quintal of wheat seed under different methods involves the cost of material and labor used for sun-drying, and storage and fabrication (in case of metal bins) of the storage structure. In terms of individual costs, the initial investment with metal bins was significantly higher ($18 per 100 kg) than the other storage structures tested in this study (Fig. 5). The cost of SGBs and FP storage method was $6 and $5 per 100 kg, respectively, which is one-third of the cost of metal bins. Moreover, the plastic bags with and without pesticide cost less than half of the SGBs and farmers' traditional practice (Fig. 5).

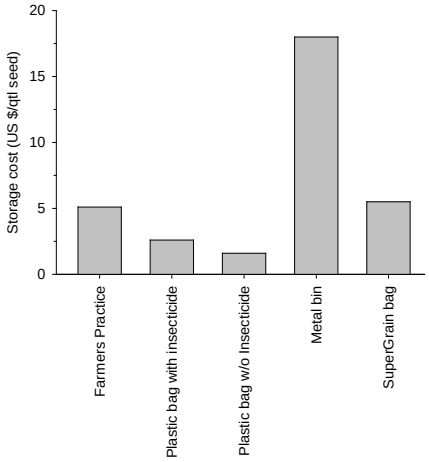

Fig. 5. Variation in cost involved ($/qtl. seed stored) for storing per quantal seed under different storage methods.

Discussion

In the six-month storage period, seed moisture content of all treatments increased. The increment was greater in hills compared to terai plains, which could be related to higher rainfall (Palpa: 2375 mm vs. Rupandehi: 1797 mm), more rainy days (Palpa: 85 days vs Rup: 70 days) and lower average temperature (Palpa: 23° C vs. Rup: 29° C) during storage period (Fig. 6). Interestingly, lower moisture and insect damage, and better germination percentage were observed under the farmers' method in terai plains. It suggests that farmers can maintain seed quality under ordinary storage structures to some extent in high temperature and low rainfall areas if they frequently check and dry their seed and grain during storage.

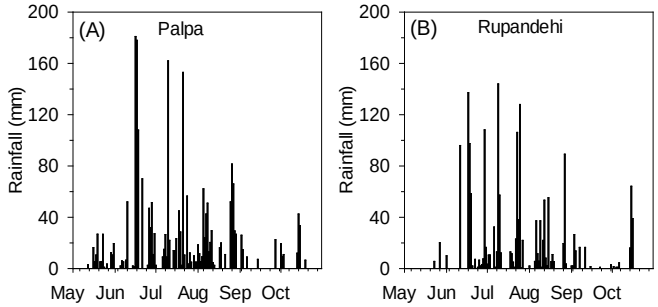

Fig. 6. Daily rainfall in Palpa (A) and in Rupandehi (B) during wheat seed storage period (1 of May to 31 October, 2013).

Seed stored in the SGBs maintained low moisture content with higher seed germination, seed vigor (Fig. 4) and less insect damage (Fig. 2) compared to other storage methods evaluated in both ecologies. It shows that maintaining wheat seed storage quality is more challenging under the ordinary storage method in the hills with higher rainfall and lower temperature than in the terai plains. Further, the higher germination percentage and lower insect infestation under SGB storage was mainly due to maintaining low seed moisture during storage. It is known that every 1 % increase in seed moisture content reduces the seed shelf-life by half (Harrington, 1972). This shows that the hermetic SGBs were mostly successful in preventing moisture migration during storage in both

ecologies, which was also observed in findings from previous work (Edoh Ognakossan et al., 2013; Navarro et al., 2002). In Kenya, Ndegwa et al. (2016) observed that after four months of storage, grain damage was 14% in farmers' storage methods and only 4% in hermetic bags. Baribusta et al. (2014) also found that airtightness of hermetic bags resulted in low oxygen and water vapor permeability, ultimately leading to low grain moisture variation during storage. However, some fluctuation in moisture content was observed in the SGBs, which can be attributed to the loss of air-tightness in storage containers as observed by Chigoverah and Mvumi (2016).

Increased seed moisture content in plastic bags without pesticide in Palpa can be directly linked to higher insect damage (Fig.2), since insects and pests thrive at high moisture conditions. Moreover, the germination percentage for the same was lower than other treatments which can also be ascribed to the higher insect damage. Rodent and insect damage to polypropylene bags has been found to be common in on-farm storage (Ndegwa et al., 2016). The use of a pesticide (celphus) in plastic bags was somewhat effective in reducing insect infestation and maintaining higher germination percentage compared to seed stored in plastic bags without the pesticide. Moreover, the effectiveness of pesticides in controlling insect infestation is well documented (Dales and Golob, 1997; De Groote et al., 2013; Golob et al., 1985). However, use of chemical pesticides in storage may be hazardous if the farmers do not take proper precautions in choosing pesticides and handling them. Again, pesticides may degrade rapidly in tropical climates because of the high temperatures and humidity (Vales et al., 2014).

Metal bins were not able to control insect infestation despite the large investment. The insect damage in the bins was higher compared to other treatments, even the farmers' method (Fig 2), which further led to lower germination (Fig. 3) and vigor of the stored seed (Fig. 4). One of the possible explanations is that the bins were not sufficiently air-tight and the hot and humid climate caused an increase in moisture and in the stress levels of the seed. Another likely reason is believed to be the fact that the bins were only filled up to ~15 kg when the total capacity was 20 kg, which might have left room for enough oxygen for insects to thrive. Hence, it is strongly advised that standardized procedures such as filling grain or seed up to the brim are followed, and artisan trainings are provided during metal bin fabrication to ensure airtightness of the containers. Chigoverah and Mvumi (2016) found that non-standardization of metal bin fabrication procedure, subjective air-tightness testing, and varying artisan experience may result in variable field performance of the technology. They observed loss of airtightness especially at joints near the inlet.

The cost involved for storing seed in SGB was comparable with the farmer's method (Fig. 5) and cheaper than the metal bin, which shows that it can be economical and potentially affordable to the small to medium farmers. For large-scale adoption of hermetic bags, farmers must know or be made aware of the technology, which leads to them expressing their demand for it. It would help if the farmers are in easy geographical reach to make the bags affordable in a sustainable way. Moreover, further communication, awareness programs, and trainings are recommended to inform extension workers and farmers on the importance of drying their seed and grain prior to storage as well as the benefits of hermetic storage. Ndegwa et al. (2016) reported that under basic price, hermetic bags become potentially profitable if they last for four seasons or more, when used for at least four months per season. Among the several hermetic storage bags available in the market, it is important to evaluate their efficiency and durability to maintain seed/grain quality and economics for storing different crops.

Abstract

India is the primary origin of the black gram that is majorly cultivated in the southern part of Asian countries. About 70% of world black gram production comes from India. Black gram is more prone to insect infestation and microorganisms resulting in deterioration of grain quality. These losses can be controlled by following appropriate storage method at farmer's level. Eco-friendly, safe storage methods are demanded by the customers due to food safety, quality and environmental issues. Hermetic storage is a safe storage method, suitable for long term storage without usage of chemical pesticides. It creates an air tight environment to rapidly exterminate insect development and suppresses micro floral activity. A study was conducted to identify the suitable, cost effective storage method for safe storage of black gram at the farm level. Hermetic bags were made by using different combinations of gunny, polypropylene & storezo bags for the safe storage of black gram. The properties of packaging materials viz., thickness, and water vapour transmission rate significantly affected the quality parameters of the black gram stored in various bags. Moisture content, thousand grain mass, bulk density, insect emergence, and germination percentage of black gram stored in various bags were studied over a storage period of 12 months. Black gram stored in polypropylene and gunny bags was infested with pulse beetle by the third month of the storage period. But black gram stored in bags with hermetic bag as inner layer was not infested up to 12 months and could retain the grain quality.

1. Introduction

India is the leading producer and consumer of pulses. The total pulse production in India significantly increased to 22.14 million tons during 2016-17 which is 2.89 million tons higher than the previous production of 19.25 million tons achieved during the year 2013-14 (Anonymous, 2018). About 70% of the total production is stored by the farmers. Due to insufficient and poor storage facilities, lack of knowledge in post harvest pulse management and storage, the risk of damage due to post harvest losses are huge up to 25-50% (Lal and Verma, 2007). During storage, pulse beetle (*Callosobruchus chinensis Linn*) attacks the pulse seeds and causes about 5-10% losses. The most important factors that cause grain deterioration are the interaction of temperature and moisture, which are the determining factors in accelerating or delaying the complex degradation reactions. In India, grains are generally stored in gunny bags which are inexpensive, reusable with good inherent toughness but high permeability and low resistance to insect and rodent attack results in frequent application of pesticides to prevent infestation (Maina et al., 2016). Consumer resistance against the use of chemical fumigants in stored products and international trade treaties increase the focus to find green and residue free technology. The main objective of the study is to develop an alternative ecofriendly safe storage method for controlling bruchid infestation in stored pulses. As there are no standard methods available for storing black gram at farmer's level, the present study was carried out to monitor the quality changes of black gram when stored under hermetic condition. Hermetic bags create modified atmospheres by increasing carbon dioxide concentration and decreasing oxygen due to the respiration metabolism of insects and aerobic microorganisms present in grains. Hermetic bags are less permeable, made up of a blend of polymers with LDPE (Low-density polyethylene) as inner liner which prevents the growth of microorganism and insect attack during long term storage. Hence, hermetic, gunny and polypropylene (PP) bags were used for the storage of black gram. Moisture content, thousand grain mass, bulk density, insect emergence, and germination percentage of black gram stored in various bags were studied over a storage period of 12 months.

2. Materials and Methods

Experiment was conducted at IIFPT, Thanjavur (Tamil Nadu) for the safe storage of black gram. The black gram variety ADT-5 was procured from National Pulse Research Centre, Vamban (Tamil Nadu) with an initial moisture content of 11.5% wet basis (w.b). The initial moisture content of the black gram was determined by hot air oven method at 135°C for 2 h. The aim of the study is to evaluate the performance of hermetic bags for the safe storage of black gram. Gunny, polypropylene, hermetic storezo bags (50 kg capacity) and their combinations were used for the storage of black gram (Table 1). Here, gunny bag was considered as control for the experimentation. Each treatment was replicated thrice and the experiment was conducted for a period of 12 months. Changes in grain quality parameters were analyzed at the beginning and at the end of the storage period. The following combination of bags was used for the study as given in Table 1.

Tab. 1 Treatment of bags chosen for experiment

Treatments
T_1 - Storezo+ Polypropylene
T_2 - Storezo+ Gunny
T_3 - Storezo+ Polypropylene+ Gunny
T_4 - Polypropylene+ Gunny
T_5 – Storezo
T_6 – Polypropylene
T_7 – Gunny

Properties of packaging materials

The thickness of the different packaging materials was determined using screw gauge. The water vapour transmission rate of the gunny, polypropylene and storezo hermetic bags was determined by the method followed by Othman et al. (2017) with slight modifications. A small cup was used to determine the water vapour transmission rate of the packaging material. The packaging material was initially made into circular shape that was slightly larger than the inner diameter of the cup. Then, the cup was placed on a horizontal platform. Known amount of anhydrous Calcium Chloride as a desiccant was placed inside the cup. Subsequently, the packaging materials were placed on top of the permeability cup (Talja et al. 2007). The cup was then covered and sealed with paraffin and weighed in order to calculate the initial weight. The weight of the cup was recorded every 24 hours for 3 days. The water vapour transmission rate (WVTR) was determined using equation 1:

$$WVTR = \frac{\Delta m}{\Delta t A} \quad \text{..... (1)}$$

Where Δm/Δt is the moisture gain weight per unit time (g/day), A is the exposed surface area of the film (m^2)

Moisture content

The moisture content of black gram was determined by Oven-drying method (AOAC, 2005; no.930.15); ground black gram was dried at 135°C for 2 h.

Thousand grain mass (M_{1000})

The thousand grain mass was measured by weighing 1000 whole grains in a properly calibrated electronic balance.

Bulk density

It is the ratio of mass of black gram to its total volume. A 250 ml graduated cylinder filled with black gram was tapped for the seeds to consolidate. The weight and volume occupied by the black gram were recorded and the bulk density was calculated using equation 2:

$$\rho_b = \frac{W_s}{V_s} \quad \text{..... (2)}$$

Where ρ_b is the Bulk density (kg m^{-3}), W_s is the Weight of the sample (kg), V_s is the Volume occupied by the black gram (m^3).

True density

The true density was determined using the liquid displacement method. Here, toluene was used as a displacement liquid instead of water to prevent absorption. 10 g of black gram were immersed in 50 ml of toluene in a 100 ml graduated cylinder. The amount of toluene displaced was recorded from the graduated scale of the cylinder. The ratio of the grain weight to the true volume of displaced toluene gives the true density of the black gram.

Porosity

The porosity of the bulk grain was determined from the true and bulk density of the grains using equation 3:

$$\varepsilon = \frac{\rho_t - \rho_b}{\rho_t} X\ 100 \quad \text{..... (3)}$$

Where ε is the porosity (%), ρ_b is the bulk density (kg m^{-3}) and ρ_t is the true density in (kg m^{-3}).

Germination percentage

Germination is a key index to test the seed viability of stored grains. One hundred seeds of black gram were soaked in distilled water for 24 h, put on a germination paper placed inside a Petri dish, and incubated at 25°C. The filter paper was moistened every day using fresh water to facilitate germination (Gupta et al. 2010). The ratio of the number of seeds germinated after seven days of incubation to the total number of seeds kept for germination were recorded as germination percentage.

3. Results

Properties of packaging materials

The thickness of the packaging materials is expressed in terms of microns as shown in the Table 2. The water vapour transmission rate (WVTR) is the rate of water vapour permeating through the packaging material. The WVTR is determined from the slope of the regression line of the sample weight versus time and the slope is then divided by the area of the film being exposed to the transmission (Equation 1). Table 3 shows that the least WVTR was observed in Storezo hermetic bags with 1.57 g/m^2 day, followed by polypropylene and gunny bags with 6.69 and 25.85 g/m^2 day, respectively.

Tab. 2 Packaging material properties

Properties	Storezo bags	PP bags	Gunny bags
Thickness (microns)	75.21±0.95	80.41±1.91	1346.67±27.22
Water vapor transmission rate (g/m^2 day)	1.57±0.56	6.69±1.65	25.85±2.12

Grain moisture content

Black gram moisture content when stored in different bags was determined and the variations in moisture content of black gram during storage are given in the Table 3. In T_7 (gunny) and T_6 (polypropylene) bags the moisture content was increased from the initial moisture content of 11.5% to 12.57% and 12.26%, respectively, because environmental factors such as temperature and relative humidity significantly affect the black gram stored in gunny and PP bags due to its higher permeability. There was no significant difference observed in the black gram moisture content

when stored in treatment T_3. Thus, the change in moisture content of stored black gram depends on the permeability of the bags used for the storage. From the study conducted in laboratory, it has been confirmed that the water vapor transmission rate of gunny bag was higher followed by polypropylene and storezo hermetic bags. Hence, less permeability in hermetic bags helps in the retention of the grain moisture content.

Thousand grain weight

The thousand grain weight of black gram stored in different bags varied from 43.22 to 41.93g. Black gram moisture content and infestation significantly affect the thousand grain mass because *Callosobruchus chinensis* feed on the endosperm portion of the black gram during infestation which results in a decrease in grain weight. The infested grains were sieved to separate grains from insects and grains dust. From the separated grains thousand grain mass was determined.

Bulk and true density

The bulk (ρ_b) and true (ρ_t) density of black gram stored in different bags are given in Table 3. The initial bulk density of black gram was 729 kg m^{-3}. After 12 months of storage period, it has been observed that maximum ρ_b was observed in the treatment T_3 with 697.42 kg m^{-3} followed by T_1 and T_5 with 688.69 and 687.54 kg m^{-3} respectively. The least bulk density was found in T_7 with 601.76 kg m^{-3}. The decrease in bulk density is due to emergence of insects from the stored black gram which results in weight loss. Thus, change in grain mass is directly proportional to bulk density.

The true density of initial black gram was recorded as1230.00 kg m^{-3}. At the end of storage period, true density decreased with the decrease in black gram moisture content. Similarly, in the infested treatments T_4, T_6 and T_7, the true density decreased to 1190.25, 1115.56 and 1108.00 kg m^{-3} respectively.

Porosity

The initial porosity of black gram was 40.73%. The porosity is inversely proportional to change in bulk density and true density of black gram. From Table 3, it has been observed that the maximum porosity was observed in the treatment T_7 with 45.69% followed by T_6 and T_4 with 44.86 and 43.80%, respectively. Hence, it is confirmed that the change in grain moisture content and insect infestation significantly affect the porosity.

Germination percentage

The initial germination percentage of black gram was 94.67%. There was significant difference ($P < 0.05$) between initial and final germination percentage of the black gram in all the treatments. After eight months of storage, the germination rate decreased in treatment T_7 followed by T_6 and T_4 with 77.67, 80.00 and 84.00 %, respectively. Maximum germination percentage was found in treatments T_3 and T_2 with 87.67% and 84.67%, respectively. Germination of black gram decreased with the increase in storage period. These changes may be due to variation in moisture content, moisture loss, and emergence of insect during storage. The germination percentage of black gram stored in PP (T_6) and gunny bags (T_7) decreased more due to emergence of insect from the stored commodity.

Insect emergence

Insect emergence from the black gram stored in various treatments was monitored regularly. *Callosobruchus chinensis* is a predominant internal feeder pest that infects pulses and affects the germination ability and nutritive value of the black gram seed during storage. No infestation was observed in the black gram stored in different treatments where hermetic bag is used as an inner layer, while black gram stored in gunny bag alone (T_7) starts to get infested from the third month of the storage period with 25.46% infestation at the end of the storage. Similarly, black gram stored with PP (T_6) and PP and gunny (T_4) got infested in the fourth and tenth month, with 19.87% and

5.16% of infestation respectively. Hence, black gram moisture content and packaging material permeability significantly affect the quality of the stored commodity.

Tab.3. Effect of different treatments of bag storage on black gram properties.

Treatments	Moisture content (w.b.%)	Thousand grains Mass (g)	Bulk density (kg m^{-3})	True density (kg m^{-3})	Porosity (%)	Germination (%)	Insect emergence (%)
Initial	11.50	43.22	729.00	1230.00	40.73	94.67	Nil
T_1	10.29	42.56	688.69	1205.00	42.85	83.67	Nil
T_2	10.55	42.83	685.12	1211.00	43.43	84.67	Nil
T_3	10.79	43.09	697.42	1224.00	43.02	87.67	Nil
T_4	11.62	42.26	668.89	1190.25	43.80	84.00	5.16
T_5	10.18	42.44	687.54	1194.48	42.44	82.33	Nil
T_6	12.26	41.97	620.66	1125.56	44.86	80.00	19.87
T_7	12.57	41.63	601.76	1108.00	45.69	77.67	25.46

4. Discussion

The *Callosobruchus chinensis* is one of the most serious pests infesting stored pulses in India. Saleem (1982) reported that *C. chinensis* causes serious damage to the pulses majorly in Bangladesh, India and many countries of the world. It causes greater damage to the pulses during storage which leads to heavy economic losses. The results coincide with the results of Mutungi et al. (2014), who report that grains stored in hermetic bags will prevent change in grain moisture content. Murdock et al. (2012) confirmed that triple layer hermetic bags are more effective in protecting grains from insect infestation. Munde (1999) reported that the increase in thousand grain mass is due to increase in moisture content for black gram. Theertha et al. (2014) found that the bulk density of black gram decreases with increase in moisture content. According to Pandiselvam et al. (2014), it is confirmed that there is a proportional relationship between grain moisture content and porosity. This might be due to increase in shape and size with respect to increase in moisture content.

Farmers in India use primitive gunny bags as a grain storage material. But within 3 months of storage period the quality of the grains gets deteriorated due to improper storage condition, which leads to insect infestation and fungal attack. To overcome these issues, the study was conducted by using storezo hermetic bag as an inner layer in multilayer bag for storage practice in godowns and at farmer's level. From the results it is evident that grain quality can be retained and insect infestation can be prevented by adopting hermetic storezo bag as an inner liner in multilayered bag storage.

Abstract

Hermetic storage of grains and oilseed has been proposed as a solution for reducing food losses in developing countries. However, to obtain full benefit of the hermetic storage it is required to achieve a low O_2 concentration (below 2%) or high CO_2 concentration (above 20%). The gas concentration inside the hermetic container is the result of the balance between the respiration and gas exchange rates with the outside (permeability and leakage). When the grain is dry, an insufficient modification in the internal atmosphere is achieved (exchange rate higher than respiration rate), allowing insect development and, hence, grain losses. This study focuses in creating an effective modified atmosphere during the hermetic storage of dry soybean using soaked grain as O_2 depletor. Three big bags with internal polyethylene liners of 70 µm thickness were filled with 590 kg of soybean (Glycine max, with 12.5% m.c.) and sealed. Gas concentration evolution was measured during 15 days (basal condition). Later, four plastic perforated bottles filled with of 4.3 kg of soaked soybean (44% m.c.) were inserted in each bag. The bags were re-sealed and gas concentration was measured during 45 days. Results indicated that the soaked soybean acted as an O_2 depletor, reducing the gas concentration to 1% in only 8 days, and maintained below 1% during 45 days. This research indicated that a small portion of soaked grain (0.4% dry matter (d.m.)) can be used to generate an effective modified atmosphere to prevent biological activity in the entire grain mass. This is a simple and inexpensive approach to reduce food losses under low cost hermetic storage.

Keywords: food losses; pest control; controlled atmosphere; respiration; gas leakage

Introduction

Hermetic storage of grains and oilseed has been proposed as a solution for reducing food losses in developing countries. However, to obtain full benefit of the hermetic storage it is required to achieve a low O_2 concentration (below 2%) or high CO_2 concentration (above 20%) (Navarro et al., 2012). The gas concentration inside the hermetic container is the result of the balance between the respiration and gas exchange rates with the outside (permeability and leakage). When the grain is dry, an insufficient modification in the internal atmosphere is achieved (exchange rate higher than respiration rate) (Abalone et al., 2011a, 2011b), allowing insect development and, hence, grain losses.

The use of liners with gas barrier is an alternative to improve the effect of hermetic storage systems, since the O_2 entrance and CO_2 losses are strongly reduced. This creates an internal atmosphere with a higher modification level than standard liners, with potential conservation benefits (Cardoso et al., 2016). However, liners with gas barrier are expensive and it might not be affordable for family storage systems. Additionally, small perforations in the liner (as small as 1 mm) could eliminate the

benefit of the barrier (Abalone et al., 2011a), preventing the conformation of an effective modified atmosphere.

Injecting CO_2 or N_2 to create an effective atmosphere from the beginning of storage is a widely used technique, usually known as controlled atmosphere (CA) (Navarro, 2012). Carpaneto et al. (2016) implemented CA treatments injecting CO_2 in flexible liners storage systems (silo bags), and concluded that airtightness level is critical to maintain a lethal gas concentration. The lethal atmosphere can be lost in a few days after injection due to gas leaks through small perforations and would fail to achieve insect mortality. A survey made in the field reported that the airtightness level of silo bags is quite variable, due to perforations in the liners from wild animal activity or problems in the sealing (Cardoso et al., 2012). Thus, placing storage systems made of flexible liners in the field might result in perforations that could compromise the effect of the CA treatment.

One alternative is to incorporate an O_2 depletor in a storage system made of a standard liner to speed up the conformation of a lethal atmosphere, even storing dry grains, and also consume the O_2 that is entering by permeability through the linear or through the small perforations. Thus, this study focuses in creating an effective modified atmosphere during the hermetic storage of dry soybean in a big bag using soaked grain as O_2 depletor.

Methodology

1800 kg of healthy and fresh soybean with 12.5% moisture content (m.c.) was bought from a local grain elevator in August 2017. Soaked soybean was obtained by sinking dry soybean seeds in distilled water for 60 minutes. After removing the superficial water with towel paper, the m.c. of the soaked soybean was determined by the oven method (15 g of soybean at 104°C during 72 hs) (ASAE, 2007).

Respiration soaked soybean was characterized. Samples of 50 g of soaked soybean were placed in glass jars of 225 ml, sealed were incubated in a temperature control chamber at 21.8 °C during 7 days. Jars were opened, ventilated for one hour, re-sealed and stored again in the temperature chamber. CO_2 and O_2 concentrations were measured every 1.5 hours until 6 hours with a portable gas analyzer (Checkpoint, Dansensor, Denmarck). Respiration rate in terms of O_2 consumption and CO_2 generation was computed according to the procedure described in Ochandio et al. (2017) (the respiration rate of dry soybean reported in this publication was used as reference).

Three big bags with internal polyethylene liners of 70 micrometers thickness and dimensions of 1.0 m x 1.0 m x 1.8 m were filled with 590 kg of 12.5% m.c. soybean, with a total exchange area for gas permeability of 4.07 m2. After filling, the big bags were thermo-sealed with portable sealing equipment, and airtightness was tested by a pressure decay test (PDT). The PDT consisted of generating a negative pressure inside the big bag of 1200 Pa with a vacuum pump (Dosivac, DV 95, Argentina) and measuring the time at which the pressure dropped to half the initial value (Navarro, 1998). Following this, hermeticity was restored and CO_2 was injected until an average concentration of 60% CO_2 was achieved. CO_2 and O_2 concentrations were measured once a day for 10 days and permeability of CO_2 and O_2 was calculated. Additionally, samples of plastic liners were sent to the Science and Technology Polymers Laboratory (PLAPIQUI, CONICET-UNS, Bahía Blanca, Argentina) for O_2 standard permeability analysis.

Later, the big bags were opened and internal atmosphere was allowed to equilibrate with ambient atmosphere, and big bags were sealed again. Gas concentration evolution was measured once a day for 15 days to obtain the basal O_2 and CO_2 concentration for dry soybeans. After this characterization, four plastic perforated bottles filled with 4.3 kg of soaked soybean (44% m.c.) were inserted in each bag (2.4 kg dry matter) (Figure 1). The soaked soybeans were placed inside plastic bottles to prevent the contact (and spoilage) with the dry soybean. Additionally, the bottle was perforated to allow the free gas exchange between the inside and outside. The bags were re-sealed and gas concentration measured during several days of storage with a portable gas analyzer.

Figure 1. Plastic bottle perforated and filled with soaked soybean.

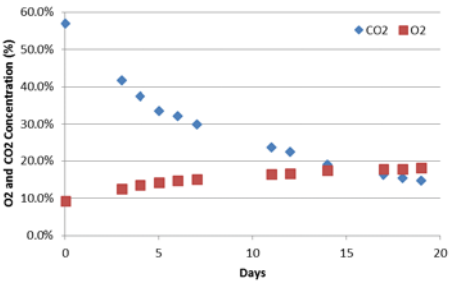

Figure 2. O_2 and CO_2 evolution inside a big-bag injected with CO_2 until 60% of concentration.

Results

Soybean respiration

The respiration rate of soaked soybean in comparison to dry soybean was about five thousand times greater in terms of O_2 consumption and eleven thousand times greater in terms of CO_2 generation (Table 1).

Table 1. Respiration rates of dry and soaked soybean.

Soybean moisture content (w.b.)	Respiration rate (mg/(kg d.m. d))		Source
	O_2	CO_2	
Dry (12.5 %)	1.465	0.617	Ochandio et al. (2017)
Soaked (44 %)	7418	6947	This study

The total O_2 consumption and CO_2 generation of the 590 kg of soybean with 12.5% m.c. (516 kg d.m.), were 1321 cc/day and 202 cc/day, respectively; and for the 4.3 kg of soaked soybean with 44% m.c. (2.4 kg d.m.) were 26870 cc/day and 9148 cc/day, respectively. This implies that the contribution to O_2 consumption of the soaked soybean was 20 times greater than the contribution of the dry soybean, while the contribution to CO_2 generation of the soaked soybean was 45 times greater than the contribution of the dry soybean (Table 2).

Table 2. Daily O_2 consumption and CO_2 generation of the dry (516 kg d.m.) and soaked (2.4 kg d.m.) soybeans (cc/day).

Gas	Dry soybean (12.5% m.c.)		Soaked soybean (44% m.c.)		Total
	(cc/day)	% of total	(cc/day)	% of total	(cc/day)
O_2 consumption	1321	4.7	26810	95.3	28131
CO_2 generation	202	2.1	9148	97.9	9350

Pressure decay test and permeability of the big bags

Results of the PDT for the three big bags were higher than 5 minutes. According to Navarro (1998), an hermetic structure 95% full should have a PDT of 3 minutes to be suitable for CA treatments and 5 minutes for modified atmosphere storage. However, Carpaneto et al. (2016) speculated that the threshold set by Navarro (1998) might be too strict for flexible grain storage systems, since there is no head space and, theoretically, no leakage of gas occurs as result of pressure release. Nevertheless, the results of the PDT indicated that there were some small leakage, which should be considered to estimate the gas exchange between the inside and the outside of the big bag, besides the permeability through the plastic liner.

The effective permeability of the plastic liner (taking into consideration the permeability through the plastic liner plus the gas exchange occurred through small openings) was calculated. Figure 2 shows the O_2 and CO_2 evolution after injecting CO_2 gas in the big bag up to a concentration of 60% of CO_2 and 10% of O_2. The rate loss (cc/(m^2 d Δ[%])) was derived from this figure, and linear models

for O_2 and CO_2 effective permeability were obtained (Figure 3). The permeability to both gasses was similar, 6941.3 and 7545.2 cc /(m^2 day atm) for CO_2 and O_2, respectively. The result of the standard permeability test of the liner for O_2 (without perforations) was 1434 cc /(m^2 day atm), indicating the effect of small perforations on the effective permeability of the system, which could quintuplicate the permeability of the liner. Abalone et al. (2011a) studied the effect of perforation in the effective permeability of flexible plastic liners (silo bags) and concluded that perforations provide non-selective permeation of gases, d.m. and also caused a significant modification in the internal atmosphere (although the effective permeability value of liners with perforation was not reported).

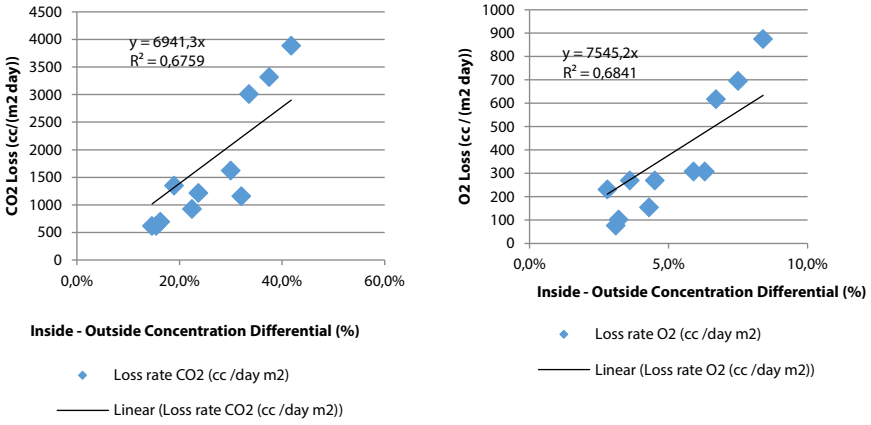

Figure 3. O_2 and CO_2 permeability rate (cc/(m^2 day). Note: the intercept of the linear model was set to cero.

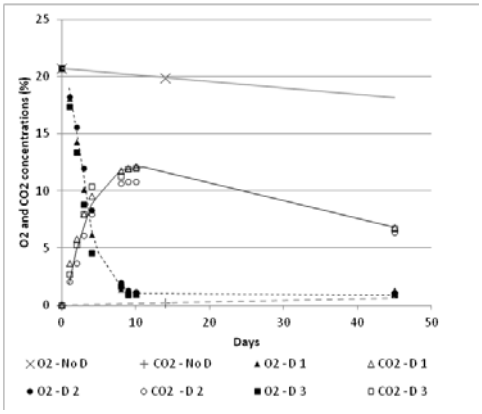

Figure 4. O_2 and CO_2 concentration inside the big bags with (D 1; D 2; D 3) and without (No D) O_2 depletor.

Figure 5. Plastic bottle with soaked and spoiled soybean after 45 days of storage.

Gas concentration inside the big bag with and without O2 depletor

Gasses concentration when dry soybean was stored in big bags did not change during 14 days of storage, being the O_2 and CO_2 concentrations of 19.9% and 0.2% respectively. This is because the respiration rate of dry soybean was low in comparison with the permeability of the big bag (Table 1). However, when the soaked grain was inserted inside the big bag, the respiration rate of the grain was high enough to create a substantial modification of the internal atmosphere (O_2 consumption and CO_2 generation increased from 20 to 45 times, respectively (Table 2)). The O_2 concentration dropped at a rate of 2.5 percentage points per day, reaching a concentration of 1% after 8 days and

maintaining such a low O_2 level until 45 days of storage, while the CO_2 concentration increased up to 12% at 8 days of storage and slowly decreased to 7% at 45 days (Figure 4).

After 45 days of storage the big bags were opened and the plastic bottles with the soaked and spoiled grain were removed. The grain inside the plastic bottles was completely spoiled, while the rest of the grain was without any visible damage (Figure 5). However, a strong smell to spoiled grain was detected and it was necessary to ventilate the grain to partially remove the odors.

Discussion

The key point to achieve an effective hermetic storage is to create an internal atmosphere with low O_2 concentration (below 2%) to prevent insect development and reduce microbial activity. For most insect species, 15 days of exposure to O_2 concentration below 2% would be enough to achieve 100% mortality.

Hermetic storage of dry products has some limitations due to the low respiration rate. In most cases, the respiration rate is about at the same magnitude order (or lower) than the permeability of the liners (or rigid hermetic structure), thus the system reach an equilibrium at a O_2 and CO_2 concentrations that is not effective for preventing insect or mold activity. Only if the insect or mold activity increases substantially, respiration rate surpass the permeability rate and an effective internal atmosphere is achieved. However, when this occurs, uncontrolled quality deterioration in the stored product is observed.

One possible solution for this problem is to incorporate liners with O_2 barrier, which extremely reduce the permeability to O_2 and allow achieving an effective atmosphere even when the respiration rate of the dry product is low. However, liners with O_2 barrier are not always available and also are more expensive, which prevent its use in low cost family storage systems. Additionally, regardless the permeability of the liner, there is gas exchange through small perforations or micro-failures in the sealing (most plastic liners are fragile and, during storage, wild and domestic animals can cause damage) substantially increasing the effective permeability of the liner. Thus, it is difficult to guarantee a low effective permeability during storage, even if O_2 barrier liners are used.

Other alternative to achieve an effective internal atmosphere is to incorporate O_2 depletor to consume the O_2 that is entering into the storage system. In this study, 2.4 kg (d.m.) of soaked soybean (44% m.c.) in 516 kg (d.m.) of dry soybean (12.5% m.c.) reduced the O_2 concentration to 1% in less than 10 days, and after 45 days of storage the O_2 concentration did not change. Such a low O_2 concentration is effective to control insects (Navarro et al., 2012) and would also reduce microbiological activity (Ochandio et al., 2017). The results of this study indicated that with a controlled loss of 0.46% of d.m. a safe storage condition can be achieved. However, even though the modification in the internal atmosphere was satisfactory, a strong smell to spoiled grain was detected after 45 days of storage inside the big bag. Using a chemical compound as O_2 depletor could be a better solution. In this case the chemical compound should react with the O_2 without generating toxic bi-products neither unpleasant odor. Taking as an example a big bag full with 590 kg of soybean, it would be required to consume 66080 cc of O_2 (86.45 g) to reach 0% concentration. Additionally, to maintain 0% concentration during 15 days it would be necessary to consume 6030 cc/day (7.9 g) extra of O_2 per day to compensate the permeability of the big bag. Thus, the O_2 depletor must be able to capture a total of 156530 cc (205 g) of CO_2 to reach and maintain 0% of O_2 during 15 days. If such chemical product is identified, effective hermetic storage of dry grains in big bags could be implemented using standard polyethylene liners.

Conclusions

The incorporation of 2.4 kg (d.m.) of soaked soybean in a big bag containing 590 kg of dry soybean (12.5% m.c.) reduced the O_2 concentration to 1% in less than 8 days. Additionally, the O_2 that permeated into the system was consumed by the soaked soybean at the same rate, maintaining the O_2 concentration below 1% after 45 days of storage.

A small portion of soaked grain (0.4% d.m.) could be used as O_2 depletor to create an effective modified atmosphere during storage of dry products in hermetic systems made of liners without O_2 barriers or with small perforations.

This is a simple and inexpensive approach to reduce food losses under low cost hermetic storage systems.

O_2 depletors made of chemical compounds could be investigated to obtain the same results as using soaked grain, but without generating unpleasant smell.

Abstract

Recently, a test was conducted in Italy for the evaluation of the biocidal efficacy of Nitrogen saturation (anoxic conditions). One application was carried out in a controlled atmosphere cell of a logistic center specialized in receiving, storing and shipping foodstuffs. The cell, circa 3682 m^3 volume, with capacity of 752 big bags of fresh shelled hazelnuts on 4 height levels was saturated with Nitrogen (99,9%) and maintained at 15-18°C for 21 days. Five test species of insects *Plodia interpunctella*, *Cadra cautella*, *Corcyra cephalonica*, *Tribolium confusum*, *Oryzaephilus surinamensis* were observed at different development stages (egg, larva, adult). The target species were sorted in special biotest and inserted in the big bags to simulate an infestation. At the end of the exposure period the biotests were collected and analyzed. The treatment resulted sufficient to achieve a total control on eggs of Lepidoptera test species only. This result confirmed and integrates the available information in literature that showed the need of a longer minimum exposure period for total control of common stored pest insects.

Keywords: stored pest insects, nitrogen, anoxic atmosphere, entomological biotest.

Introduction

As a result of the ban to use of the methyl bromide and the necessity to use control techniques with minimum impact on men and the environment, the attention was increased in treatments that do not involve the use of biocidal molecules (Navarro, 2006; Fields, *et al.,* 2002; Fleurat-lessard, 1990). In recent years new technologies have been developed to increase the efficiency and effectiveness of physical control methods such as modified atmospheres (Conyers and Bell, 2004). Modified or controlled anoxic atmospheres, including nitrogen, are among the most promising non-toxic alternatives for control of stored product insects and mites in many types of dry stored products (Aulicky *et al.,* 2016). The same authors also reported that ten days of exposure to a concentration of 99% N_2 led to 100% mortality of all adults of *Tribolium castaneum* (Herbst) and *Sitophilus granarius* (L.) at two different level in a metal silo bin. A study in grain at less than 12% moisture, 23°C with 98-100% N_2 concentration, showed that 28 days were needed to kill all the insect pests; while to reach the same insecticidal effect at 18°C the treatment lasted 105 days (Jian *et al.,* 2016).

The present work is aimed to providing data support to avoid phosphine in the process of stocking fresh hazelnuts, verifing that the biocidal effect of the exposure to 99.9% concentration of N_2 for 21 days at 15-18°C temperature is sufficient to ensure total control on the common pests of stored food, in particular of shelled hazelnuts, by evaluation on alive insects at different stages of development immersed within special probes, here named biotest, in 58 big bags that were homogeneously sorted in the cell space.

Materials and Methods

Insects

The insects used as test species were provided by Agroblu Laboratory of Applied Entomology (LEAA), where they were raised at 26 ± 2 °C, 70% RH and photoperiod light-darkness 16:8.

The test organisms used were typical insects infesting hazelnuts such as Plodia interpunctella (Hübner), Cadra cautella (Walker), Corcyra cephalonica (Stainton), Tribolium confusum (Jaqcquelin du Val) and Oryzaephilus surinamensis (Linnaeus) at different stages of development (egg, larva, adult).

Per each of the 58 test unit (big bag), one group of 7 Biotest was prepared and provided (table 1).

Tab. 1 Species, stages and substrates used for the test.

Insect	Stage	Quantity	Substrate
P. interpunctella	Eggs	50	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran
P. interpunctella	Larvae	10	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran
C. cautella	Eggs	50	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran
C. cautella	Larvae	10	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran
C. cephalonica	Eggs	50	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran
T. confusum	Mix population	20 eggs 5 larvae 5 adult	Semolino, brewer's yeast, bran
O. surinamensis	Mix population	20 eggs 5 larvae 5 adult	Honey, glycerin, white flour, semolino, yellow flour, oatmeal, sesame, bran

Substrates

Biotests containing adult insects were prepared with non-infested substrate normally used for breeding. In order to ensure the presence of all insects stages at the same time in biotest containing *Coleoptera,* 10 adults were transferred from the breeding to 10 grams of uninfested substrate 21 days before introduction in the big bags.

Insects were prepared in containers suitable for being inserted into big bags. At the same time, control biotests were prepared and transported with all the others but were kept away from the treatment in order to verify possible mortality during transport. An equal number of control biotest were left at LEAA at 26 ± 2 ° C; 70% HR; L: B = 16: 8.

Test site data

The site selected for the test was a logistic center with climatic cell. The cell has a controlled atmosphere permanent plant, capable of extracting oxygen and pumping nitrogen to reach 99.9% saturation of nitrogen at a chosen range of temperature (15-18°C). Such range of temperature was chosen to achieve a minimum pest development condition. This cell has 752 pallets capacity, sorted in 9 lines of 8 units, each replicated by 4 vertical levels (Fig. 1). The total dimension of the cell is 27.8 m length, 15.14 m width and 8.60 m height.

Fig. 1 The cell structure.

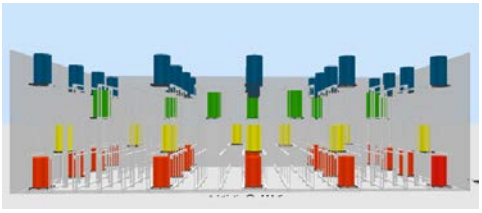

Fig. 2 The 58 big bags sorted in all cell levels from side 1

Test System and application

The test system is characterized by 58 fresh shelled hazelnuts big bags. Each big bag was considered as test unit and was sorted in a specific position in the cell to ensure homogeneus distribution in the cell at all 4 levels. (Fig. 2 and 3).

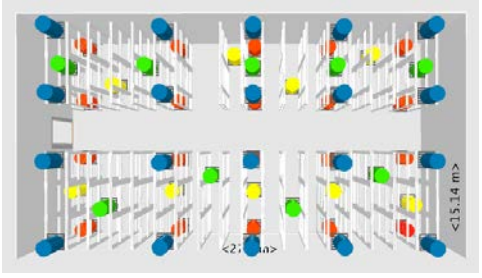

Fig. 3 The 58 big bags sorted in all cell levels from top

Fig. 4 Average temperature registered during the test in the treatment chamber

The test started when the N_2 saturation reached 99.9%. After 21 days of complete and constant N_2 saturation, the desaturation process started.

At the end of de desaturation process LEAA staff could remove all the biotests from the 58 big bags by pulling the relevant twines, then packing and transporting the biotests back to LEAA in the same day.

Table 2 shows the cronological details of the test.

Tab. 2 Test phases

Activities	Progress
Introduction of biotests	Day 1
Saturation process	Day 2
Complete saturation	Day 5
Desaturation process	Day 21
Complete oxygenation	Day 24
Biotest evaluation	Day 25-30

Evaluation method

All the evaluations of the biotests were performed at LEAA by the laboratory staff, through visual assessment, count and record of alive and dead individuals, within 5 days after the extraction.

The assessment was based on the observation of alive individuals. The assessment was recorded as "positive" at the first alive individual observed.

Climatic data and atmosphere monitoring

The internal temperature of the big bags during the trial were collected at least every 60 minutes by digital data loggers provided by the laboratory and immersed together with the biotests in 10 of the 58 test units. The graph (Fig. 4) below represents the mean temperature during the application period (average of ten big bags).

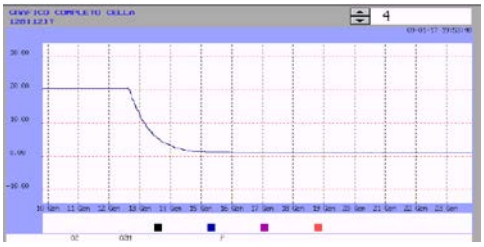

Fig. 5 Percentage of oxygen during the process

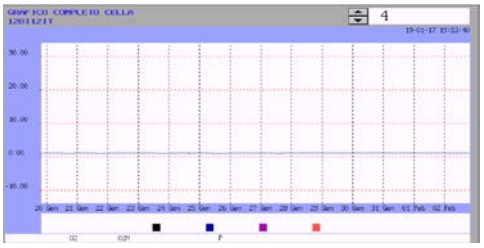

Fig. 6 Percentage of oxygen during the process

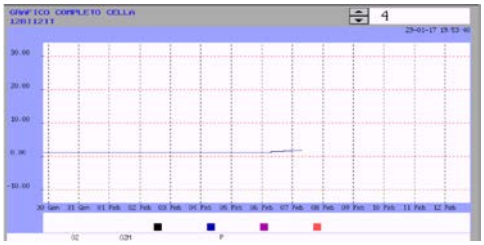

Fig. 7 Percentage of oxygen during the process

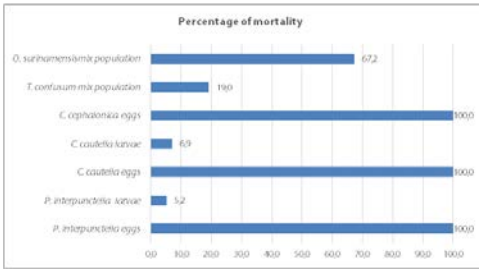

Fig. 8 Percentage of mortality of the different insect species and stages

During the application, the oxygen % in the cell was constantly monitored by a built-in oxygen meter. The data wasprovided by the storage company and reported in the figures 5, 6 and 7.

Results

The results elaborated with Abbott's formula showed that the high effect of the treatment was reached on the eggs of the lepidoptera species (100% mortality). On the Coleoptera species the mortality observed was 19.0% and 67.2% respectively for *T. confusum* and *O. surinamensis* (Fig. 8).

Tables 3 and 4 highlights the percentage of mortality and the number of biotest containing alive individuals in the treatment and the control experiment, respectively, corrected with the Abbott's folmula.

Tab. 3 Counts of positive biotest (with live insects) and mortality percentage in TREATED treatment for the different species and stages considered

Insect	Stage	Positive biotests (alive)	Mortality (%)
P. interpunctella	Eggs	0	100,0
P. interpunctella	Larvae	55	5,2
C. cautella	Eggs	0	100,0
C. cautella	Larvae	54	6,9
C. cephalonica	Eggs	0	100,0
T. confusum	Mix population	47	19,0
O. surinamensis	Mix population	19	67,2

Tab. 4 Counts of positive biotest (with live insects) and mortality percentage in UNTREATED treatment for the different species and stages considered

		TNT		LNT	
Insect	**Stage**	**Positive (alive) biotests**	**Mortality (%)**	**Positive (alive) biotests**	**Mortality (%)**
P. interpunctella	Eggs	2	0	2	0
P. interpunctella	Larvae	2	0	2	0
C. cautella	Eggs	2	0	2	0
C. cautella	Larvae	2	0	2	0
C. cephalonica	Eggs	2	0	2	0
T. confusum	Mix population	2	0	2	0
O. surinamensis	Mix population	2	0	2	0

*TNT=transfer untreated treatment - *LNT= Laboratory untreated treatment

Discussion

The test highlighted that an exposure to N_2 saturation at temperatures 15-18 °C for 21 days was not sufficient for a total control on mobile stages of all pests, while a total control of the *Lepidoptera* eggs, was observed. In fact no silk webs, feces or newborn larvae, even dead, were present in the biotests.

The population of *O. surinamensis* was the most susceptible to the treatment with 67.2% efficacy. The larvae of *P. interpunctella* were the least susceptible, 5.2% efficacy, similarly, the population of *C. cautella* with 6.7% efficacy. The treatment was barely effective on the population of *T. confusum*, with 19% efficacy.

Abstract

The lesser grain borer, *Rhyzopertha dominica* (Fabricius), is a pest of stored chickpeas in Mexico. The control of this pest is based largely on the application of pesticides, but this strategy has important limitations: there are few active compounds available, there is a high risk of development of resistance to them and the residues left in the chickpeas have harmful effects on consumer health and on the environment. For this reason, an alternative strategy to pesticides for the conservation of stored chickpea was evaluated with the use of modified atmospheres (MA). The effect of three different MAs (50%, 70% and 90% CO_2, in air) on the larval and pupal stages of *R. dominica* were evaluated. To obtain larvae and pupae of *R. dominica*, eggs were incubated for a variable period of time until reaching the desired stage: 9-15 days for 1st and 2nd larval instar and 35-39 days for pupae. Tests were carried out by placing chickpeas containing a total of 15 larvae or pupae plus 50 g of healthy chickpea in small ventilated boxes. These ventilated boxes were individually placed inside of plastic bags (30 x 21 cm, Cryovac BB4L µm). Bags were filled with desired MA before sealing, which were previously prepared in a gas mixer (Witt Km 100-3M/MEM). A control treatment without MA was also included. To verify the CO_2 and O_2 content inside the plastic bags a gas analyzer (OXYBABY®) was used and the gas levels were determined at the beginning and at the end of the treatment. Plastic bags were opened at different periods of exposure (larvae up to 5 days; pupae up to 10 days) and ventilated boxes were kept until adult emergence to assess mortality. Results show that increasing the concentration and exposure time of CO_2 increases the mortality rate of larvae and pupae of *R. dominica* (Fig. 1). The most resistant developmental stage was the pupae, with an LD_{90} of 241 h (50% CO_2) compared to the larval stage with an LD_{90} of 22 h (90% CO_2). The tolerance of the MA is greater in the pupal stage due to the reduction of respiration in this stage.

Keywords: *R. dominica*, pest, chickpea, alternative strategy, modified atmosphere.

This study was a part of a project granted by The Instituto Nacional de Investigación Agraría (INIA), with project number: RTA2014.00006-CO2-01.

CARVEX – Pressurized Pest Disinfection with CARBO Carbon Dioxide

Oliver Kik, Herbert Saal

CARVEX Verfahrenstechnologie für Lebensmittel und Pharma GmbH, Sprudelstraße 1, 53557 Bad Hönningen, Germany, Okik.hgn@carbo.de
DOI 10.5073/jka.2018.463.144

Abstract

Keywords: CARVEX, Carbon Dioxide, Pressure Fumigation, CARBO, Pest control.

Introduction

Pest control with insecticides and toxic gases have polluting effects on persons and the environment. However, CO_2 pressurized pest control is a real revolution. It does not present any hazard either to nature or to persons. Benefit from an innovative, efficient and future-capable process for optimized hygiene results!

The entrainment of pests right to the stage of final packaging is an enormous source of danger for manufacturers. If the reputation of a brand is damaged by infected products, confidence can be restored with difficulty only. Politicians and consumers demand appetizing and hygienic foodstuffs which are equally uncompromising. CARVEX assists in assuring compliance with strict legal general conditions and provides for brand confidence and consumer protection.

The employment of insecticides or toxic gases, such as methyl bromide, phosphine or hydrocyanic acid, is still usual. However, they leave residues and are problematic, also from the viewpoint of environmental protection and occupational safety. This is being increasingly criticized publicly by consumers and associations. The solutions from CARVEX are now convincing in many ways, where they provide for "clean" products while avoiding harmful residues. In this way, the justified demands of consumers are optimally fulfilled - as well as possible damage to image avoided as early as in the initial stages.

CARVEX offers you perfect solutions so that your products reach end customers in an optimum condition hygienically. The charged nature of the issue is highlighted for example in that almost all harvest herbs, as well as tea products, are infected by harmful insects as well as by their larvae or eggs. In this case also, as with all other possible areas of application, the processes from CARVEX enable the best utilization capability and value-added utility of your products.

Materials and Methods

Optimum pressurized pest control with carbo carbon dioxide

CARBO carbon dioxide has a side to it which is to a large extent unknown: Consumers hold natural products in high esteem where they provide a refreshing "sparkle" in mineral water, lemonade or beer. However, carbon dioxide because of its bacteriostatic and bactericide effects, is also increasingly used in the packaging of foodstuffs in inert gas. This tendency is increasing. The advantages are obvious: Complete disclaimer on the use of toxic gases. This follows the present Hazardous Material Ordinance (GefStoffV) which gives first priority to the health protection of persons.

Top hygiene without any losses in quality

With the proper selection of process parameters, the effects of CO_2 pressure processing on feedstock can be excluded. For example, a detailed study related to the CO_2 pressure processing of medication and herb teas indicates impressively that the amount of the material contents remains unchanged after pest control using the CARVEX process. Likewise, no negative impairments could be verified in the product quality of grain with the same processing method. As well as this, neither

the baking quality nor the germination characteristics were influenced in any way disadvantageously.

Three effects in perfect Interaction

In case of pressurized pest control, the exceptional effect of CO_2 results through the interaction of just three effects: Firstly, a forced dissolving of carbon dioxide in the bodily fluids of insects leads to an over-acidification of the cell fluid and hemoglobin, through which carbon dioxide is formed. In addition to this is the oxygen withdrawal effect and, a most important factor, the so-called pressure effect, which is also known to deep-sea divers as the bends.

The effect of pressure is particularly significant. Only the combination of CO2 and pressure allows the treatment to work well in a short period of exposure. For example, in the case of the dried fruit moth, treatment time increased from a few minutes at a pressure of 37 bars to 64 hours at a pressure of 3 bar

Neither a high nitrogen pressure, comparable with the pressurized CO2 process, nor high CO2 concentrations at atmospheric pressure, achieve the desired effect. To kill weevils using pressureless CO2 treatment an exposure time of around 28 days is required

Technical description

CARVEX systems are designed especially flexibly, where they are characterized by their quality as well as ease of operation and can also be re-equipped or retrofitted afterwards. In case of a large volume demand, the chamber number can be increased to three chambers, where the performance and cost-effectiveness are increased. Below on picture 1, you can see an example for a realized double chamber system.

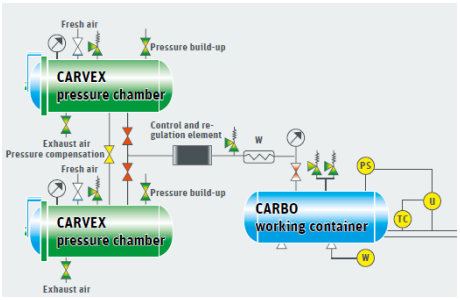
In addition, CARVEX offer different system lengths and diameters according to the area of application. With every system type, the number of pest control operations per shift is regulated by increasing pressure, which further increases throughput. Regardless of which solution you select, you can always choose whether the loading should be done manually, by lifting trolley or by roller conveyor.

The CO2 process for pressurized pest control works at ambient temperature above 15°C and pressures up to 30 bars. The material to be processed is inserted in bags in specially constructed pest disinfection chambers. After closure of the chamber, gaseous CO2 flows into the system until the required pressure has been reached. After the contact period, the pressure in the chamber is released and the material can be taken out.

The necessary CO2 is stored and refilled in a CARBO working container. The CO2 will be evaporated and tempered before entering in the chamber by heating. The pressure will be increased up to 30 bars by heating or by liquid pumping before heating.

The duration of the pressure treatment is varying depending on the chosen pressure (1-16 h), the product and the insect to be treated.

Picture 1: CARVEX Double Pressure Chamber



Picture 2: PID of a CARVEX Double Chamber

Results

CARVEX pressurized pest control with harmless CARBO carbon dioxide is based on experience which has been acquired over decades in inventory protection and pest control. Thus, not only are harmful insects, such as the grain weevil, the cigarette beetle, the rice-meal beetle, the meal beetle or the flour moth, rendered harmless within the shortest time, but also their larvae and eggs. Currently there has been positive experience with more than 30 different pests from different areas of inventory protection. The CARBO carbon dioxide is approved as plant production product in Germany and Austria.

Following effects have influence on the CARVEX process.

Packaging and product density

The type of packaging, as well as the existing product density, represent important factors in determining the contact period. For example, compressed goods such as bales, flour sacks or sealed bulk materials in big bags significantly increase the respective contact period. The reason is that it requires some time before the necessary concentration is reached in the package middle. A further influence factor on the contact period is the pest type to be expected, as well as their stage of development. For example, eggs and pupae are generally the most resistant.

The role of temperature

Increased temperatures effectively decrease the contact periods. For example, with pressure-free CO2 processing, the contact period of 28 days at 10°C for the death of the grain weevil is shortened to only a few hours at 40°C. Of course, the temperatures
cannot be increased at will because this would lead to a decrease in the product qualities. On the other hand, the influence of the temperature is reduced with increasing pressure, which is why it is always recommended to implement the processing based on optimum parameters.

Optimum co2 concentration

The CARVEX process achieves optimum effectiveness with an atmosphere which includes at least 90% CO2. The CO2 content is of particular relevance in case of pressure-free application.

The pressure-effect

As a result of the interaction of CO2 and pressure, the CARVEX systems achieve an exceptional effect while at the same time providing for short processing times. Thus, in comparison with a system which works pressure-free, the processing time of the Indian meal moth at an adjusted pressure of approx. 30 bars is decreased from approx. 240 hours to only ½ an hour. The advantage of the pressurized pest control can be demonstrated even more efficiently in the example of the grain weevil. While conventional, pressure-free gas flushing takes approx. 28 days, only a few hours are required in a CARVEX system in order to achieve the same result.

Discussion

Acknowledgement

I wish to thank Herbert Saal for his assistance and his treasure trove of experience.

Abstract

Experiments carried out to find the fumigant toxicity of three essential oils and their combinations from *Murraya koenigii*, *Citrus reticulata*, *Curcuma longa* on population buildup of *Sitophilus oryzae*, *Rhyzopertha dominica*, *Tribolium castaneum* in stored wheat at different days of infestation. The oil of *M. koenigii*, *C. reticulata* at 0.2% and *M. koenigii*+*C. reticulata*, *M. koenigii*+*C. longa* at 0.1% each were found highly effective against *S. oryzae* fumigated after 5, 10, 15 and 20 days. The oil of *M. koenigii* and *C. reticulata* at 0.2% *M. koenigii*+*C. reticulata*, *M. koenigii*+*C. longa*, *C. reticulata*+*C. longa* at 0.1% each and *M. koenigii*+*C. reticulata*+*C. longa* at 0.07% each were found highly effective against *R. dominica* fumigated after 5, 10, 15 and 20 days. Only *M. koenigii* at 0.2% was found highly effective against *T. castaneum* fumigated after 5, 10, 15 and 20 day. The fumigation of grain with *M. koenigii* at 0.2% completely suppress the infestation and weight loss when it was fumigated after 5, 10, 15 and 20 days while very low infestation and weight loss was observed in grain treated with *M. koenigii* +*C. reticulata* at 0.1% each and not affect the organoleptic properties and germination of wheat.

Key words: Fumigant toxicity, essential oils, Sitophilus oryzae, Rhyzopertha dominica, Tribolium castaneum

Introduction

Stored commodities are infested by more than 600 species of beetles, 70 species of moths and about 355 species of mites causing quantitative and qualitative losses at different storage level (Rajendran and Srirajinia, 2008). Stored product insects cause 10 percent postharvest losses in developing countries, but they also contaminate the food products by presence of live insects, insect products such as chemical excretions or silk, dead insects and insect body fragments. In India, only aluminum phosphide and methyl bromide are available for fumigation of stored commodities. The use of aluminum phosphide is restricted while methyl bromide has been banned and their injudicious use during many years induced resistance development in stored grain insects.

Essential oils from more than seventy five plant species belonging to different families, such as Anacardiaceae, Apiaceae, Araceae, Asteraceae, Brassicaceae, Chenopodiaceae, Cupressaceae, Graminaceae, Lamiaceae, Lauraceae, Liliaceae, Myrtaceae, Pinaceae, Rutaceae and Zingiberaceae have been studied for fumigant toxicity against several insect pests of stored grain (Rajendran and Srirajinia, 2008). In several storage structures, fumigants are the most economical and convenient tools for managing stored grain insects due to their easy penetration in stored commodities and avaibility at cheaper rates (Azelmat *et al.,* 2006). Recently research has been focusing on the utilization of essential oils and their bioactive constituents as possible alternative to traditional fumigants (Negahban *et al.,* 2007, Ogendo *et al.,* 2008). *Sitophilus oryzae* (L), *Rhyzopertha dominica* (F), and *Tribolium castaneum* (Herbst) are one of the important stored product beetles and cause serious loses to stored commodities worldwide (Kumar, 2016). *Murraya koenigii* is an annual herb growing as medicinal plants and their leaves are used as some culinary and treatment of human disease. *Curcuma longa* is used as spice while peel of *Citrus reticulata* is wastage materials. The attempt has been made to study the fumigant toxicity of essential oils and their combinations on

population buildup of three stored product coleoptera in stored wheat and their effect on quality of wheat**.**

Material and Methods

Culture of the insects

Pure culture of test insects were developed in the BOD incubator maintained at 27°C±1 temperature and 70±5% relative humidity. Plastic jars of 1000 ml capacity were used for rearing of insects. At the center of the lid a hole of 1.8 cm diameter was made and covered with 30 mesh copper wire net to facilitate aeration in the jar. Adults of *R. dominica* (F) (Coleoptera: Bostrichidae) and *S. oryzae* (L) (Coleoptera: Cuculionidae) were reared on the wheat variety PBW-343 while *T. castaneum* (Herbst) (Coleoptera: Tenebrionidae) was cultured on its flour fortified with 5 per cent yeast powder. Before use, wheat was disinfested in the oven at 60^{oC} for 12 hrs. After disinfestation the moisture content of the wheat was measured and raised to 13.5 per cent by mixing water in the grain. The quantity of water required to raise the moisture content was calculated by using the formula described by Pixton (1967).

Extraction of essential oils

Oils selected for the study were extracted from the locally available plants by steam distillation at Medicinal and Aromatic Plants Research and Development Centre, Pantnagar, and by Clevenger Apparatus in Post Harvest Entomology Laboratory Pantnagar.

Preparation of grain

All fumigation experiments on *R. dominica, S. oryzae* and *T. castaneum,* were conducted on untreated seed grade wheat of variety PBW-343. The experiment was conducted on *R. dominica, S. Oryzae* and *T. castaneum* to confirm the fumigant toxicity of essential oils and their combination and experiment was conducted same as rearing conditions.

Effect of essential oils on population build up of *R. dominica, S. oryzae*, and *T. castaneum*

The experiment was conducted in 2000 ml capacity air tight plastic jar to study the effect of essential oil and their combination on population build up of *R. dominica, S. oryzae* and *T. castaneum*. Wheat variety PBW- 343, (1500g) was filled in each plastic jar. Four sets comprising eight treatments with three replications were prepared. Twenty newly emerged adult (0-4 days old) of each specie were released in each jar after filling grains. The treatment applied after 5, 10, 15 and 20 days after artificial infestation, essential oil was poured on the absorbing mats and then mats were inserted inside the plastic jars. Screw cap of jars tightly closed and made completely airtight by sealing with parafilm wax strip. After one year of storage each jar was analyzed to count the number of adults emerged to calculate percent inhibition and the number of healthy and infested grain to calculate per cent infestation, per cent weight loss and germination atributes.

Organoleptic properties of *chapattis* made from grains treated with essential oils

Organoleptic test was performed on *chapattis* made from wheat grains treated with essential oils and their combination without washing and after washing thoroughly with water. 1000 g of grains was drawn out from each treatment and sieved thoroughly to remove unwanted impurities. After sieving 500 g wheat was used as such for preparation of flour while rest 500 g of the grain was washed thoroughly with water. Both washed and unwashed grains were sun dried for ten days, 8 hrs per day. The wheat grain was then ground in local market of Pantnagar to obtain wheat flour. The flour was then passed through a fine sieve to get a flour of the required fineness. Equal amount of flour was weighed and kneaded to dough using equal quantity of water and dough balls of same size were prepared. These balls were rolled out as thin as possible into a chapatti and were cooked on both sides on a hot iron plate without any fat or oil.

Various characteristics of chapatti i.e. colour, flavour, texture, taste, appearance and overall acceptability were tested as described by Amerine *et al.* (1965). For the evaluation of chapatti ten evaluators were invited randomly from the different departments of the university. Each member of the panel evaluated the characteristics of chapatti on a grading scale as 1-2 Very poor, 3-4 Poor, 5-6 Fair, 7-8 Good, 9-10 Very good.

Effect of essential oil on germination of wheat

Samples were drawn from experiment to record the effect of different essential oils and their combinations on germination of wheat. Germination test was done as per protocol of Chalam *et al.* (1967). Seedling vigour (vigour index) was computed as per Abdul-Baki and Anderson (1973).

Statistical analysis

Data were analyzed in Completely Randomized Design after suitable transformation with log (X+ 1).

Results

The efficacy of essential oils and their combinations was classified in different categories on the basis of first progeny production.The more weightage was given to suppression of first progeny, with this assumption, products inhibiting more than 90 percent of first progeny were classified as highly effective while inhibition of 80 to 89 and 70 to 79 percent were ranked as moderately and less effective respectively. The products showing less than 70 percent of first progeny suppression were ranked as least effective for the control of test insects.

Effect of essential oils and their combinations on population build up of *S. oryzae*

The essential oils and their combinations on population build up of *S. oryzae* is presented in Table 1. The table indicates that *M. koenigii* oil at 0.2 % and its combination with *C. reticulata* at 0.1 % each completely suppressed the feeding and breeding of the *S. oryzae* in all the treatments. The combination of *M. koenigii* + *C. longa* at 0.1 percent each was also highly effective against *S. oryzae* as caused 100, 99.81, 100 and 100 percent inhibition in grain fumigated after 5, 10, 15 and 20 days respectively. The oil of *C. reticulata* caused 100, 97.92, 100 and 93.84 % inhibition at 0.2 % in grain fumigated after 5, 10, 15 and 20 days, respectively. The combination containing *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each caused 95.69, 91.97, 100 and 77.44 percent inhibition in grain fumigated after 5, 10, 15 and 20 days respectively. The combination of *M. koenigii* + *C. longa*, *C. reticulata* + *C. longa* at 0.1 percent each and *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 each percent each was highly effective against *S. oryzae* in the grain fumigated after 5, 10, 15 and 20 days of artificial infestation.

Effect of essential oils and their combinations on Population build up of *R. dominica*

The effect of essential oils on population build up of *R. dominica* is given in Table 2 which indicates that *M. koenigii* at 0.2 percent concentration and its combination with *C. reticulata* at 0.1 percent each were highly effective as it completely suppressed feeding and breeding of the *R. dominica* after one year of stored grain fumigated after 5, 10, 15 and 20 days. The combination containing *M. koenigii* + *C. longa* at 0.1 percent each was also highly effective against *R. dominica* as it caused 100, 99.34, 100 and 100 percent inhibition in grain fumigated after 5, 10, 15 and 20 days respectively. The oil of *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each concentration caused 100, 97.88, 100 and 100 percent inhibition in grain fumigated after 5, 10, 15 and 20 days respectively. The oil of *C. reticulata* at 0.2 percent caused 100, 95.70, 100 and 97.32 percent inhibition at 0.2 percent in grain fumigated after 5, 10, 15 and 20 days respectively, while its combination with *C. longa* at 0.1 percent each caused 100, 90.60, 100 and 100 percent inhibition in grain fumigated after 5, 10, 15 and 20 days, respectively.

Effect of essential oils and their combinations on Population build up of *T. castaneum*

The effect of essential oils on population build up of *T. castaneum* after one year of storage is presented in Table 3, which indicates that only *M. koenigii* at 0.2 percent completely suppressed feeding and breeding of the *T. castaneum* in grain fumigated after 5, 10, 15 and 20 days. The oil of *C. reticulata* at 0.2 % was found effective at 15 days of artificial infestation, while its combination with *C. longa* at 0.1 percent each was effective at 20 days after artificial infestation.

Effect of essential oils and their combinations on infestation and weight loss

The effect of essential oils on infestation and weight loss due to *S. oryzae, R. dominica* and *T. castaneum* after one year of storage is presented in Table 4, which indicates that fumigation of grain with *M. koenigii* + *C. reticulata* or *C. longa* at 0.1% each or *C. longa* at 0.2 % observed 2.85, 2.42 and 2.61 percent infestation, respectively, which was very low as compared to untreated control which recorded 11.76 percent infestation. Fumigation of grain with *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each, *C. reticulata* + *C. longa* at 0.1% each and *C. longa* at 0.2% concentration permitted 0.69, 0.62 and 0.49% weight loss, respectively while 6.0 percent weight loss observed after one year of storage in untreated control. The fumigation after 10 days only *M. koenigii* at 0.2 percent completely suppressed the progeny development of *S. oryzae, R. dominica* and *T. castaneum,* while *M. koenigii* + *C. reticulata* at 0.1% each permitted very low infestation and weight loss. The combination of *C. reticulata* + *C. longa* oil at 0.1 percent each, *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each, *C. longa*, *C. reticulata* at 0.2 percent and *M. koenigii* + *C. longa* at 0.1 percent each 5.56, 5.35, 4.73, 3.88 and 3.66% infestation, respectively, while in untreated control 17.07 percent infestation was found. The percent weight loss in grain treated with *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each, *C. reticulata* + *C. longa*, *M. koenigii* + *C. longa* at 0.1 percent each, *C. longa* and *C. reticulata* at 0. 2 percent each concentration were 2.36, 1.63, 1.19, 1.11 and 0.39 as compare to untreated control in which 7.96 percent weight loss found after one year of storage. No infestation or weight loss was recorded in grain treated with *M. koenigii* or *C. reticulata* oil at 0.2 percent and its combination at 0.1 percent each in grain fumigated after 15 days. Very less infestation and weight loss was observed in grain treated with a combination of *M. koenigii* + *C. reticulata* + *C. longa* at 0.07 percent each, and *M. koenigii* + *C. reticulata* at 0.1 percent each concentration. The weight loss amounting to 0.67 and 0.38 percent were recorded in grain treated with *C. longa* at 0.2 percent and *C. reticulata* + *C. longa* at 0.1% each, respectively, while in untreated control 5.54 percent weight loss found, The grain was fumigated after 20 days, *M. koenigii* at 0.2 percent and *M. koenigii* + *C. reticulata* at 0.1 percent each concentration were completely suppressed the progeny of *S. oryzae, R. dominica, and T. castaneum* after one year of storage.

Effect of essential oils and their combinations on germination of wheat

Percent germinations is presented in table 5 which indicates that the 100% germination was recorded in grain treated with *M. koenigii* while 94.66 to 97.33% germination was recorded in grain treated with *C. reticulata, C. longa* and their combination with *M. koenigii*. Only 86.00% germination was recorded in untreated control. As compared to untreated control very high vigour index was recorded in seed treated with essential oils. The significance of viability was 1:1 in all treated grain after one year of storage.

Organoleptic properties of chapattis made from grain treated with essential oils

The organoleptic properties of chapattis made from wheat grain treated with essential oils is presented in table 5 which indicates that colour, flavor, texture, taste, appearance and overall acceptability of chapattis prepared from treated grain were supirior as compare to untreated grain. The overall acceptability rating of chapattis prepared from unwashed grain treated with *M. koenigii, C. reticulata* at 0.2% or at 0.1% each were very good as compare to untreated grain in which rating was good. Similarly the chapattis made from washed grain of different treatments showed very good overall acceptability in grain treated with *M. koenigii* and *C. reticulata* while remaining showed good overall acceptability as compare to untreated grain.

Discussion

Seventeen essential oils were evaluated against S. oryzae, R. dominica, T. castaneum and C. chinensis in wheat and checkpea, ane the ones extracted from Allium sativum, Artimisia annua, Callistemon citrinus, Chenopodium botrys, Cinnamomum zylanicum, Citrus reticulata, Cuminum cyminum, Foeniculum vulgare, Murraya koenigii, Pinus roxburghii and Piper nigrum were found highly effective at 0.2% (Kumar and Tiwari, 2017). The essential oils of Murraya koenigii, Citrus reticulata and Curcuma longa were evaluated against S. oryzae, R. dominica, T. castaneum in stored wheat to protect the grains for one year in metal bins and did not affect the organoleptic propertis of chapatti made from treated grains and germination of wheat (Kumar and Tiwari, 2017). The essential oils of Murraya koenigii, Citrus reticulata, Curcuma longa and Calistimone citrinus at 0.2% caused 100 percent mortality in R. dominica and T. castaneum after twenty four hours of treatment (Kumar et al., 2018). Essential oil of Sweet Annie, Artemisia annua evaluated by Tripathi et al.(2002) against T. castaneum and C. maculatus at 1% v/v proved to be adult repellent and revealed negative correlation between larval survival, pupal survival and adult emergence of T. castaneum. Bio-efficacy of leaf oil of Murraya koenigii was evaluated against C. chinensis, oil attracted insects at 25 mg dose and repelled at 300 mg dose in the dual choice repellency test. In both contact (0.125 mg/cm^2) and fumigant (22.5 mg/ml) toxicity test 100% mortality was observed with LC₅₀ value of 0.08 mg/cm^2 and 22.5 mg/ml, respectivily (Paranagama et al., 2002). Pathak et al. (1997) investigated toxicity and repellent activity of Murraya koenigii against C. chinensis in stored green gram, chickpea at 340 ppm and oil showed toxic effect and ovicidal properties. They concluded that the oil can be used for small level protection of legumes. Liu et. al. (2007) evaluated 40 species of Chinese medicinal herbs from 32 different botanical families for their contact, fumigant and feeding deterent activities against two stored grain coleopterans S. zeamais and T. castaneum. Thirty Chinese medicinal herbs exhibited insecticidal or feeding deterent activities against test insects. The oil of Artemisia argyi, Dictamnus dasycarpus, Evodia rutaecarpa, Lietsea cubeba, Narcissus tazetta var chinensis, Polygonum aviculare, Rhododendrum molle, Sophora flavescens, Stemona sessilifolia, Tripteryginni wilfordii, and Torreya grandis were most effective against both tested insects.

Resuls concluded that the exploration of fumigational potential of essential oils may leads to development of non-synthetic, economical, ecological safe and easily degradable alternative for sustainable stored grain insect pest management. Essential oils of *M. koenigii*, *C. reticulata* at 0.2% and *M. koenigii*+*C. reticulata*, *M. koenigii*+*C. longa* at 0.1% each were found highly effective against *S. oryzae* fumigated after 5, 10, 15 and 20 days. The oil of *M. koenigii* and *C. reticulata* at 0.2% *M.*

koenigii+C. reticulata, *M. koenigii+C. longa*, *C. reticulata+C. longa* at 0.1% each and *M. koenigii+C. reticulata+C. longa* at 0.07% each were found highly effective against *R. dominica* fumigated after 5, 10, 15 and 20 days. Only *M. koenigii* at 0.2% was found highly effective against *T. castaneum* fumigated after 5, 10, 15 and 20 day. The fumigation of grain with *M. koenigii* at 0.2% completely suppress the infestation and weight loss when it was fumigated after 5, 10, 15 and 20 days while very low infestation and weight loss was observed in grain treated with *M. koenigii +C. reticulata* at 0.1% each. Essential oils did not affect the organoleptic properties and germination of wheat.

Abstract

The insecticidal activity of essential oil vapors of *Haplophyllum tuberculatum* (Sapindales: Rutaceae) and *Nepeta crispa* (Lamiales: Lamiaceae) were evaluated on third instar larvae of *Plodia interpunctella* (Lepidoptera: Pyralidae) as one of the major insect pests of stored products. Essential oils of the plants were obtained using Clevenger-type water distillation. GC-MS analyses of the oils demonstrated that the main compounds of *H. tuberculatum* were ρ-menth-2-en-1-ol-cis (20.15 %), p-menth-2-en-1-ol-trans (16.92 %), trans-Piperitol (13.23 %), Piperitone (7.34 %) and cis-Piperitol (6.72 %). It is an important plant that has many medicinal properties. 1,8-Cineole (32.98 %), β-Pinene (8.70 %), 4aα,7α,7aα-Nepetalactone (8.08 %) and 4aβ,7α,7aβ-Nepetalactone (6.1 %) were detected as the predominant component in *N. crispa*. The aerial parts of that are used in traditional medicine. The LC_{50} values were estimated after 24 hours for *H. tuberculatum* and *N. crispa* as 4.301 and 5.579 µl L^{-1} air, respectively. LC_{50} values were projected using probit analysis. Results on *H. tuberculatum* showed more toxicity against the Indian meal moth compared to the *N. crispa*. In conclusion, the essential oil of the two plants could have potential for application to stored grain and agricultural commodities to control of stored crop pests in IPM programs.

Key Words: Essential oils, insecticidal toxicity, Plodia interpunctella, Haplophyllum tuberculatum, Nepeta crispa.

Introduction

Plodia interpunctella Hubner (Lepidoptera: Pyralidae), the Indian meal moth, is a common domestic pest, feeding on stored food products including nuts, beans, processed foods and dried fruits (Simmons and Nelson 1975). The larvae spoil stored food by spinning a silky web inside and on top of the food surface and feed in it (Phillips et al., 2000). According to earlier experiences, fumigants are commonly utilized for control of stored-products pests (Cox et al., 1984) Chemical insecticides led to various problems to our environment and health (Taylor, 1989). Plant-derived products have proved to be excellent source of a variety of volatiles with the potential for development as alternatives to conventional insecticides (Atta-ur-Rahman et al., 1999; Tripathi et al., 2000; Lee et al. 2004; Ebadollahi et al., 2010; Wu et al., 2015; Plata-Rueda et al., 2017).

The genus *Haplophyllum*, belongs to the Rutacea family, comprises about 70 species represented in Mediterranean, Saharo-Arabian, Irano-Turanian, and Sudano-Zambezian regions (Willis, 1980; Takhtajan, 1986). *Haplophyllum* species are generally used in traditional medicine as a remedy for headaches and arthritis, skin discoloration, wart removal, and against parasitic diseases and other infections. *Haplophyllum tuberculatum* Forssk is considered to protect livestock from biting insects and flies (Miller et al., 1988). Insecticidal activity of the aerial parts of *H. tuberculatum* against *Culex quinquefasciatus* has been proved (Zohair et al., 1989).

The genus *Nepeta* (Lamiaceae) contains almost 280 species endemic to Europe, Asia and a few parts of Africa (Rechinger, 1982). Some of the species of *Nepeta* are grown as a garden herb and some of the species used as medicinal herb for cancer, toothache, colds, anemia, headache, diarrhea, indigestion, tuberculosis, and other various ailments (Duke and Ayensu, 1985; Duke, 2002). This genus, with 67 species in Iran, also is reported to be used as phytotherapy in Iranian traditional medicine (Amin, 1991). Essential oils of some species of *Nepeta* have been described to possess insecticidal activity (Zhu et al., 2006; Ali et al., 2016).

The review of the literature revealed the scarcity of information over the toxicity of *H. tuberculatum* and *N. crispa* Willd essential oils. Hence at the present study, the potential of fumigant toxicity of the essential oils from the two aromatic plant species examined against the third instar larvae of the Indian meal moth, *P. interpunctella*, in order to contribute for the development of new approaches for controlling this insect pest.

Materials and methods

Rearing of insects

P. interpunctella was collected from the Department of Plant Protection, Faculty of Agriculture of Urmia University, Iran. It was reared using the method of Adler (2010), with some modifications, on a diet containing 400 g of wheat bran, 15 g of broken almonds, 48 g of glucose, 80 g of dried yeast,

80 ml of glycerin and 20 ml of water. Stock cultures were maintained in a temperature-controlled chamber with 25±5 °C and 65±5 % R.H. and photoperiod of 14:8 (L:D) h.

Plant material

Aerial parts of *Nepeta crispa* and *Haplophyllum tuberculatum* were collected at the flowering stages in the middle of August (from the mountain areas of West Azerbaijan province (Northwestern Iran)) and November (from the fields of Kerman province (Southern Iran)) 2016, respectively. Samples were dried at room temperature and chopped into small pieces. The essential oils were extracted from the samples using a Clevenger-type apparatus for 4 h. The obtained essential oils were kept in the refrigerator at 4 °C for subsequent experiments.

Analysis of the essential oil

Essential oils were analyzed using GC–MS. For GC–MS analysis an Agilent 7890. A gas chromatograph coupled to a 5975A mass spectrometer using a HP-5 MS capillary column (5% Phenyl Methylpolysiloxane, 30 m length, 0.25 mm i.d., 0.25 µm film thickness) was used. The oven temperature was programmed as follows: 3 min at 80 °C, subsequently 8 °C min^{-1} to 180 °C, held for 10 min at 180°C. Helium was used as carrier gas at a flow rate of 1 mL min^{-1} and Electronimpact (EI) was 70 eV. The injector was set in a split mode (split ratio of 1:500) and mass range acquisition was from 40 to 500 m/z. Essential oil constituents were identified by using the calculated linear retention indices (Wiley 2007; NIST 2005) and mass spectra with those reported in the NIST 05 and Wily 07.

Bioassays

Fumigant toxicity of essential oils from *H. tuberculatum* and *N. crispa* investigated against *P. interpunctella*. Fumigation experiments carried out using the method of Ziaee et al. (2013) with some modifications. Ten third instar larvae of the insect were presented to the 100 ml glass jars as experiment units. The jars were covered with muslin cloth for inhibition of larvae contact to filter paper. Different concentrations of the essential oils (2, 2.91, 4.24, 6.18 and 9 µl L^{-1} air for *H. tuberculatum*, 15, and 2, 3.31, 5.48, 9.06 and 15 µl L^{-1} air for *N. crispa*) were pipetted onto a filter paper (Whatman No.1) and appended to the under surface of the jar's lid. After 24 h, the data were recorded in terms of the number of dead larvae and percentage mortality determined for each insect. Each treatment was replicated six times. The bioassay was conducted at 25±5 °C and 65±5 % R.H. and photoperiod of 14:8 (L:D) h. The control groups were treated except that no essential oils were employed.

Data analysis

Analysis of variances, using SPSS 21.0 (followed by Tukey's test to compare differences among various treatments at α= 0.05 level), were carried out to determine the significance of differences between mortality of larvae of each species at different concentrations of essential oils. Probit analysis was used to estimate LC_{50} and LC_{95} values (Abbott, 1925).

Results

Chemical composition of essential oil

Thirty-one and 27 chemical constituents were identified which represented 93.64 and 91.62 % of the total oils of *H. tuberculatum and N. crispa*. The major components of *H. tuberculatum* oil were ρ-menth-2-en-1-ol-cis (20.15 %), p-menth-2-en-1-ol-trans (16.92 %), trans-Piperitol (13.23 %), Piperitone (7.34 %) and cis-Piperitol (6.72 %). Chemical components analysis of the essential oils revealed that the predominant composition of *N. crispa* oil was 1,8-Cineole (32.98 %) followed by β-Pinene (8.70 %), 4aα,7α,7aα-Nepetalactone (8.08 %) and 4aβ,7α,7aβ-Nepetalactone (6.1 %) (Tables 1 and 2).

Insecticidal activity of essential oils against *P. interpunctella* larvae

The essential oils of *H. tuberculatum* and *N. crispa* possessed fumigant toxicity on third instar larvae of *P. interpunctella* with the LC_{50} and LC_{95} values ($P < 0.0001$) of 4.301, 13.538 and 5.579, 24.808 µl L^{-1} air, respectively (Table 3).

The results of one-way analysis of variances represented that effect of concentrations of the essential oils of *H. tuberculatum* (F= 76.054; df= 4, 25; $P < 0.001$) and *N. crispa* (F= 81.709; df= 4, 25; $P < 0.001$) on the mortality of third instar larvae of *P. interpunctella* were significant. The mortalities of the larvae of *P. interpunctella* were 86.7 and 88.3 % after 24 h exposure to the highest concentrations of *H. tuberculatum* and *N. crispa* essential oils, respectively. The increasing concentration of essential oils created significant increase in mortality. (Table 4).

Discussion

Fumigation is one of the most effective methods of rapidly controlling insects infesting stored foods. A new approach for the control strategies that are environmentally sustainable and avoids the use of conventional pesticides is of paramount important. The essential oils of plants are assumed as viable alternative of controlling many insect pests (Mauchline et al., 2005; Lopez et al., 2008; Razavi 2012). Some reports have been stated that the most promising botanical insect-control agents belong to the families of Annonaceae, Asteraceae, Canellaceae, Apiaceae, Lamiaceae, Meliaceae and Rutaceae (Jacobson, 1989; Kim and Ahn, 2001; Chaubey, 2006, 2007; Taghizadeh-Saroukolai et al., 2010).

Chemical composition of essential oil

The insecticidal compositions and essential oils obtained of many plants are monoterpenoids (Ahn et al. 1998; Ayvaz et al., 2008). Monoterpenoids may inhibit the nervous system of insects (Tong, 2010).

In the current study, the principal constituents of *H. tuberculatum* essential oil were ρ-menth-2-en-1-ol-cis (20.15 %), p-menth-2-en-1-ol-trans (16.92 %), trans-Piperitol (13.23 %), Piperitone (7.34 %) and cis-Piperitol (6.72 %) that the toxic impacts of the oil could be attributed to the major constituents. Previous studies on the essential oil of this species demonstrated variable chemical components (Raissi et al., 2016). The main composition of the essential oil of *H. tuberculatum* were characterized as β-phellandrene (23.3%), limonene (12.6%), (Z)-β-ocimene (12.3%), β-caryophyllene (11.6%), myrcene (11.3%), and α-phellandrene (10.9%) (Al-Burtamani et al., 2005). Giles and Bisits (2007) isolated the chemical compounds of *H. tuberculatum* essential oil and found cis-p-menth-2-en-1-ol and trans-p-menth-2-en-1-ol (22.9 and 16.1 %, respectively) as the main constituents in the oil. *H. tuberculatum* essentials oils were constituted by oxygenated monoterpenes (71.0 % of the whole oil). In another investigation in Larestan, Iran, main constitute of *H. tuberculatum* was borneol (25.73%) followed by α-Pinene (14%), Bornyl acetate (18.07%) and β-caryophyllene (7.43%) (Vahdania et al., 2011). According the current review we revealed that all samples comprise mainly of monoterpenes, and the differences could be due to differences in time of harvest, plant parts applied, agroclimatic and geographic conditions.

The dominant compounds obtained from *N. crispa* essential oil contained 1,8-Cineole (32.98 %) followed by β-Pinene (8.70 %), 4aα,7α,7aα-Nepetalactone (8.08 %) and 4aβ,7α,7aβ-Nepetalactone (6.1 %). The major composition of *N. crispa* (71 %) and *N. menthoides* (41.1 %) oils were identified 1,8-cineole (Mojab et al., 2009). Ali et al (2016) stated 1,8-cineole was the main component of *Nepeta racemosa* and *N. faassenii* essential oils. While *N. sibirica* and *N. subsessilis* essential oils mainly possessed of sesquiterpenes: (Z)-β-farnesene, β-bisabolene, δ-cadinene or β-caryophyllene, and caryophyllene oxide. Previous investigations represented that the essential oils of *Nepeta* species consist mainly of 1,8-cineole (Sonboli et al., 2004; Sefidkon et al., 2006). It has been found that the main constitutes of *N. racemosa* essential oil, collected from a wild source in western Iran, were 1,8-cineole (37%) and nepetalactone (2.3%) (Daryasari et al., 2012). 1,8-cineole has been indicated as a toxic volatile against insect pests (Obeng-Ofori et al., 1997; Lee et al., 2004; Kordali et al., 2006; Stamopoulos et al., 2007; Rozman et al., 2007).

Insecticidal activity of essential oils against *P. interpunctella* larvae

Some previous studies have described that many of the plant's essential oils possess an insecticidal and antifeedant activity on stored-product pests (Negahban et al. 2007; Rajendran and Sriranjini 2008; Karabörklü et al. 2010, 2011; Saeidi and Yousefi, 2013; Wu et al., 2015; Plata-Rueda et al., 2017).

Current study is the first investigation on the insecticidal activity of the essential oils of *H. tuberculatum* and *N. crispa* against stored product pests. Based on the LC_{50} values (Table 3) the examined essential oils were strongly toxic against *P. interpunctella*. Mortality rate of 86.7 and 88.3 % observed in third instar larvae of *P. interpunctella* exposed to different concentrations of *H.*

tuberculatum and *N. crispa* oils, respectively. In both oils, mortality of larvae increased as concentration of the essential oils increased. Similar findings were obtained by El-Khyat et al. (2017) who reported insecticidal activity of *Matricaria chamomilla* L., *Origanum majorana* L. and *Citrus aurantium* L. on *Ephestia Cautella* and stated that the insecticidal activity increased with the increase of concentration. Rafiei-Karahroodi et al. (2011) investigated characterization of essential oil of different essential plant oils on *Plodia interpunctella* and detected that the oils have toxicant effect on first instar larvae of Indian meal moth. These reports are confirmed by Ebadollahi et al. (2010), Moazeni et al. (2013), and Pandir and Baş (2016) who indicated that essential plant oils were very toxic on insects due to their active volatiles. Ahmad et al. (2016) stated that crude extracts and fractions from *N. leavigata* and *N. kurramensis* indicated insecticidal activity against *Tribolium castaneum* which supports the traditional anti insect value (mosquito replant) of the Nepeta species (Baser et al., 2000). Insecticidal properties of *N. recomena* on *Sitophilus granaries*, *E. kuehniella* and *Lasioderma serricorne* has been reported (Aslan et al., 2005). The essential oil of *S. hortensis* has been reported to possess high toxic effect against *E. kuehniella* and *P. interpunctella* (Mollaei et al., 2011). Insecticidal activity of the essential oils varies depending on the experimental method, exposure time, origin of the essential oil, concentration of the oil, insect stage and species (Chiasson et al., 2001; Choi et al., 2003; Sedy and Koschier, 2003; Negahban et al. 2007; Ayvaz et al., 2010; Mollaei et al., 2011).

In conclusion, findings of this investigation revealed the essential oils from *H. tuberculatum* and *N. crispa* showed potent fumigant activities on *P. interpunctella*. Nevertheless further studies, including evaluation of the residues of the oils in food, flavor quality of food and persistence experiments, are required to clarify the competency of *H. tuberculatum* and *N. crispa* to reduce stored-products insect populations in IPM programs.

Acknowledgement

We are grateful to Mohammad Aghaei, Department Medicinal Plants, Faculty of Agriculture, Urmia University, for extraction of the oil from the plants. The authors thank Biotechnology center of Urmia University for GCMS analysis.

Abstract

In this study, ozone gas at different concentrations (16.7, 33.3 and 66.6 mg/L) were exposed to all biological stages (egg, larva, pupa and adult) placed at top and bottom of the hazelnut for various exposure periods (2, 4 and 6 hours). In biological tests conducted in presence of hazelnuts, 100% mortalities of all biological stages of *P. interpunctella* placed at top of the commodity were obtained at tested ozone concentrations and exposure periods while it was easier to kill the adult and pupa stages that the larva and egg stages. While it was possible to kill 100% of the adults and pupae placed at bottom of the commodity at tested ozone concentrations and exposure periods, 100% mortality of the larvae and eggs were not obtained at any of the ozone treatments. Generally, the mortalities of all life stages of *P. interpunctella* placed at bottom of the commodity for ozone treatments were lower than those placed at top of the commodity. It was easy to kill the pupae and adults of *P. interpunctella* placed at bottom of the commodity while the ozone treatments resulted in low mortalities of the egg and larvae placed at bottom of the commodity. Just as 100% mortalities of the larva and adult stages were not obtained even at the highest ozone concentration for the longest exposure period. In conclusion, in this study, it was observed that ozone gas only at high concentrations can control all biological stages of *P. interpunctella* in hazelnut and therefore could have an alternative potential for methyl bromide in quarantine applications in short application period.

Keywords: *Plodia interpunctella*, ozone gas, hazelnut, fumigation

Introduction

Hazelnut production is an important agricultural activity in Turkey. Hazelnut cultivation is mainly performed on steeplands in Black Sea region of Turkey and it is being an important source of income for a large number of family farms (Dikmen, 1999). Turkey produces 73% of world production and exports 84% of its production, which accounts for around 20% of total agricultural exports from Turkey (Fiskobirlik, 2003). Storage pests infesting hazelnut especially during drying and storage period may cause significant problems in hazelnut sector. The Indianmeal moth (*Plodia intepunctella* (Hubner)) reduces fruit quality by feeding and damaging the fruit and contaminating by leaving its excretions and other residues as silky net weaves (Damarlı et al., 1997). Large populations can develop before being detected and severe damage may occur rapidly (Jarratt, 2001). Moreover, from a phytosanitary point of view, during export, the presence of insects, or their fragments, has cost inestimable losses due to cargo returns.

Ozone is a triatomic form of oxygen (O_3) and is referred to as activated oxygen, allotropic oxygen or pure air. It is an unstable gas and its life span lasts about 20 minute, depending on the temperature. Electrical generation of ozone eliminates the handling, storage, and disposal problems of conventionally used post-harvest pesticides. Attractive aspect of ozone is that it decomposes rapidly (half-life of 20-50 min) to molecular oxygen without leaving a residue. These attributes make ozone an attractive candidate for controlling insects and fungi in stored products. Ozone in its gaseous form has been also considered to have potential to kill insect pests in commodities and was subjected of several research studies (Erdman, 1980; Mason et al., 1997; Kells et al., 2001). High mortality was achieved for adults of the maize weevil, *Sitophilus zeamais* (Mostsch.), and the red flour beetle *Tribolium confusum* (Jacqueline de Val), and the larval stage of the Indian meal moth, *Plodia interpunctella* (Hübner) exposed to lower ozone concentrations ranging from to 5 to 45 ppm (Erdman, 1980; Kells et al., 2001).

Methyl bromide has frequently used as a fumigant for disinfestations of other stored agricultural commodities such as nuts, cereals and fruits since it kills the insects rapidly, has a wide spectrum of activity and relatively low-cost (Fields and White, 2002). However it had been banned in developed countries since 2005 and scheduled for worldwide withdrawal from routine use as a fumigant in 2015 under the directive of the Montreal Protocol on Substances that Deplete Ozone Layer (Schneider et al., 2003) except quarantine, laboratory and pre-shipment purposes. As a consequence, there is a critical need to develop new fumigants for quarantine purposes, where rapid insect mortality is required (exposure time less than 1 day). Thus, the objective of present study was to determine toxicity of ozone at high concentrations and short exposure time against all life stages of *Plodia interpunctella* (Hübner) in hazelnut under laboratory conditions.

Material and Methods

Commodity

In-shell hazelnuts with m.c. of 10.5%±0.5 were used in the tests. In order to minimize the reaction of microbial loads in the commodity with ozone the hazelnuts used in the tests were sterilized under high pressurized stem.

Fumigation chambers

Test chambers consisted of 3 liter glass jar, each capped with a metal stopper equipped with entry and exit tubing. Two pieces of rubber tubing, 5 cm long, 6.2 mm ID, were attached to the tubing and sealed with pinch-clamps. The desiccators were sealed with silicone vacuum grease.

Test insects

Tests were carried out on all life stages (adult, larva, pupa and egg) of *P. interpunctella*. All life stages of *P. interpunctella* were obtained from cultures reared at 26 ± 1°C and 65 ± 5% r.h. on a diet of a 10:2:1 mixture of wheat flour: wheat germ: dried Brewers yeast using standard culture techniques. Eggs aged 1-2 days in 9 cm Petri dishes were placed in 3 litter jars and then were exposed to the treatments. Larvae were removed from culture jars and exposed to the treatments 21 days after oviposition. Two days old pupae were obtained by daily separation from culture jars and were exposed to the treatments. Newly emerged, aged 0-1 day, adults were placed in culture jars and then were exposed to the treatments.

Ozone fumigation procedures

Ozone generator in laboratory scale was provided from the company Ozomax Inc., Ozone gas was generated using a laboratory corona discharge ozone generator (Model OZO-1VTT) from purified extra dry oxygen feed gas. Ozone was introduced as gaseous into the exposure jars using an ozone generator. Pressure in each jar was measured using a 0 to 800 mm Hg vacuum digital gauge. The 100 mm Hg measure referred to herein is absolute pressure, with 760 mm Hg considered as atmospheric pressure. Prior to each test, twenty larvae, pupae or adults were confined, separately, inside 3 cm diameter by 8 cm long wire-mesh cages. For eggs mortality evaluation, fifty eggs placed in opened Petri dishes were used per fumigation.

For intermittently repeated ozone treatment in presence of commodity, each desiccators was loaded separately with 1.3 kg of in-shell hazelnut, and then 50 eggs, 25 pupae, adults and larvae were confined inside the wire-mesh cages and inserted into top and bottom position of the commodity, and the desiccators were briefly evacuated to 760 mm Hg. Afterwards, ozone gaseous at concentrations of 16.7, 33.3 and 66.6 mg/L was flushed into exposure jar until reaching atmospheric pressure and it was repeated every half an hour for 2, 4 and 6 hours. Untreated control insects were exposed to atmospheric conditions. Each test was replicated at three times. For all ozone fumigations, r.h. and temperature were maintained at 65±5% at atmospheric pressure and 26±1°C, respectively.

Data processing and analysis

After each treatment, larvae, pupae, and adults were transferred to 250-mL jars containing standard diets and were held at 26 ± 1°C and 65 ± 5% r.h. until examined for mortality. The eggs in their Perspex slides were held under the same conditions until the oviposition sites were examined for egg hatch. Mortality data was subjected to Arcsin transformation and then, were analyzed using one-way analysis of variance (ANOVA). The means were separated using the LSD method at 5% level.

Results and Discussion

Toxicity data for empty space ozone treatments indicated a remarkable difference in susceptibility between the life stages of *P. interpunctella*. Adult and pupae stages mortality rates were found to be high at low ozone concentrations (8.4 and 16.7 mg/L) and short application periods (30 at 60 minute), whereas egg and larval mortality rates were very low. High mortality rates were obtained from the larvae and egg stages with the increase in the application period, but 100% mortality of the larvae and egg was achieved at the highest exposure times (240 and 360 minutes) and ozone gas concentration (66.6 mg/L). In empty space fumigation of ozone, susceptibility of the adult and pupae stages was similar to ozone gas while they were sensitive to ozone gas than the larvae and egg. As a result, it was easy to kill the adults and pupas at low ozone concentrations for short exposure times while higher ozone concentrations and longer exposure periods were required to obtain complete mortality of the larvae and eggs.

In biological tests conducted in presence of hazelnuts, 100% mortalities of all biological stages of *P. interpunctella* placed at top of the commodity were obtained at tested ozone concentrations and exposure periods while it was easier to kill the adult and pupae that the larvae and egg stages. While it was possible to kill 100% of the adults and pupas placed at bottom of the commodity at tested ozone concentrations and exposure periods, 100% mortality of the larvae and egg were not obtained. Similarly to the results obtained from empty space ozone fumigation, there was significant difference in susceptibility of biological stages of *P. interpunctella* to ozone treatments. The mortalities of the adults and pupas was higher than those of the larvae and eggs. Generally, the mortalities of all life stages of *P. interpunctella* placed at bottom of the commodity for ozone treatments were lower than those placed at top of the commodity. It was easy to kill the pupas and adults of *P. interpunctella* placed at bottom of the commodity, while the ozone treatments resulted in low mortalities of the egg and larvae placed at bottom of the commodity. Complete (100%) mortalities of the larvae and adult stages were not obtained, even with the combination of the highest ozone concentration and the longest exposure period.

Two ethyl formate/nitrogen in-transit trials have been conducted on containerized goods in shipping containers under winter and summer temperature ranges to provide a representative dataset of year round temperature conditions in Western Australia. The winter trial was conducted in September 2017 and the summer trial in December 2017. Overall, the trials demonstrated that ethyl formate/nitrogen fumigation exposure periods could be successfully completed in-transit, with zero risk to the public or workers from exposure to ethyl formate throughout the two-day journey. The results show that more than half of the applied ethyl formate/nitrogen concentration was maintained over the six-hour exposure period. This is consistent with the fumigant decay of a shipping container undergoing a stationary fumigation exposure period. These results also show that the environmental influence on a moving container under fumigation was negligible in reducing the efficacy of the treatment. Environmental gas concentration measurements taken throughout the journey indicated nil presence of ethyl formate in the immediate surroundings of the containers up to 15 metres downwind, as well as inside the cab of the truck. These results further suggest that there would be zero risk to workers if the containers were vented at the end of the two-day journey. Continuing the in-transit period would eliminate the requirement for ventilation screens to be installed whilst undergoing ventilation.

Safe and cost-effective method for application of liquid ethyl formate (Fumate™) as a methyl bromide alternative for perishable commodities

Abstract

The cylinderized liquid ethyl formate (EF) formulated with CO_2 is one of the great potential fumigants to replace methyl bromide (MeBr) for fresh fruit. However, it is too expensive to adapt commercial practices, and also involves work place safety issue including handling of heavy cylinders as well as restrict emission of CO_2, particularly for use in large scale commercial fumigationw. Therefore, it is urgently needed to develop environmental friendly, safe for workers and cost-effective alternative method for application of liquid ethyl formate as a MeBr alternative for perishable commodities. Recently, the environmentally friendly, cost-effective and practically safe use of liquid EF (Fumate™, registered name) with nitrogen gas has been developed and commercialized in Republic of Korea and Australia. The new technology for application of liquid EF is 100 times safer than MeBr in terms of threshold values (EF, TLV = 100 ppm). Ethyl formate is known as food additive and naturally occurred substances as well as a non-ozone depletion chemical. In this report, we demonstrate the liquid EF application technology that offers a clean environment (no ozone depletions and CO_2 emissions), safe to fumigators and related workers and practically cost-effective technology to fumigation industry.

Keywords: Quarantine fumigation, Ethyl formate, Fumate™, perishable commodities.

1. Introduction

Methyl bromide (MeBr) had being planned for phasing out and recommended to reduce its usage by the International Plant Protection Convention (IPPC) since the 1990s. Therefore, from point of view of protecting ozone policy and conducting safe fumigation by operators and related workers, MeBr must be urgently replaced. Intially ethyl formate (EF) with carbon dioxide formulation in cylinder offered replacment of MeBr for fumigation of fresh fruit (Ryan et al., 2013). However, cyliderized EF formulation has some hudles for its broad commerical use. This is because it is too expensive to use as fumigant, especially at a high dose rate (70g m^{-3}), such as fumigation of citrus. It also frequently involved worker safety issue for handling of heavy cylinders. In order to sucessfully achieve cost-effective and practically safe use of liquid EF with nitrogen gas, long-term and continousely cooperative research and developement has been conducted between Murdoch University and Animal and Plant Quarantine Agency (APQA). Here, we report various commerical demonstration trials with new liquid EF application technology on perishable commodities such as orange, banana, lemon and grapefruit and vertify the current quarntine protocols in Korea.

2. Materials and Methods

2.1 Fumigants and fumigation

Ethyl formate (Fumate™, 99%) was supplied from Safefume Inc. Korea. Ethyl formate was vaporized with heated nitrogen gas through the nitrogen heater, which fitted in vaporizer (SFM-1) and discharged into the fumigation chamber.

2-2. Commercial scale fumigation tests

Commercial scale trials were performed at Busan port, South Korea. A 40ft shipping container and PVC-tarpaulin fumigation chambers (81-424 m^3) were used. Ethyl formate was applied with SFM-1 (EF vaporizer) at dose rate of 70 g m^{-3} for citrus (orange, lemon and grapefruit) and 35 g m^{-3} for banana; exposed at > 5°C (citrus) and >13°C (bananas) for 4 hours. After 4 hours of fumigation, the container and chamber were opened and ventilated for > 1 hours. The phytotoxicity of ethyl formate on commodity was investigated after 2 weeks of fumigation held at room temperature conditions.

2-3.Measurement of fumigant concentration

Ethyl formate was drawn with an electric pump at timed interval and stored in Tedlar's gas sampling bags (1L, SKC Inc.). The concentration of EF was measured by a portable EF analyzer (iBRD MX, Industrial Scientific) and some random gas samples were analysed with a GC-FID (Agilent Technology 7890N) at laboratory to compare accuracy of portable EF analyzer.

3. Results and Discussion

The cumulative Ct products of ethyl formate in inside and outside bag of banana were calculated at the range of 26.1 to 42.0 g h m^{-3} and 35.5 to 78.8 g h m^{-3}, respectivly. In case of citrus fumigation, the Ct products were 102.6 to 133.7 g h m^{-3}. However, the same commodites even treated with same calulated dose of fumigant, the Ct products can be significantly different which depend on the conditons of loading ratio, types of application facilities (period of application) etc. The commercial trials with liquid EF applied with SFM-1 (EF vaporizer) have obtained different Ct products at different treatment conditions. However, liquid EF fumigation with nitrogen has met the current quarantine protocols on fruit fumigaiton in Korea. The efficacy of fumigation with EF achieved complete control of target pests such as citrus mealy bugs (*Planococcus citri*), California red scale (*Aonidiella aurantii*), Foller'rose weevil (Naupactus godmanni) etc. on imported Citrus and *Aspidiotus excisus* on banana. The results from phytotoxic acessment demonstrated privously by Kim et al., (2017) and Yang et al., (2016, 2017) and indicate that this new technology to apply liquid EF suits

the commercial fumigation practice and regulatory point of view for replacement of MeBr and conducting of good fumigation practice to ensure worker and envorimental safety.

4. Acknowlodgements

We thank for Donga Fumigator Co. in Busan, Korea for providing and supporting all fumigation facilities, Fumate™ and operation for the tirals.

Table 1. Cumulative CTP (Concentation X Time product, g h m^{-3}) of 4 hr Ethyl formate fumigation on imported fruits depending on different conditions in commercial trials

Abstract

There have been significantly increased reports of finding invasive quarantine pests with increasing import plants into Korea. Moreover, the efficacy and work safety issues have been reported regarding use of methyl bromide (MeBr) for fumigation of imported nursery plants. For replacement of MeBr use on imported plants, a new technology of using liquid ethyl formate has been registered in South Korea as Fumate™. The technology involved to mix ethyl format with nitrogen gas to form non-flamable ethyl format formulation. It has been evaluated on various imported plants. The Fumate™ is recently developed and commercialized in Republic of Korea and Australia for quarantine treatments on fresh fruits, grains etc. Fumigation with Fumate™ offers environmental-friendly and practically safe use of liquid ethyl formate. We have extended the use of liquid EF application technology to quarantine treatment of imported nursery plants.

Keywords: Quarantine fumigation, Ethyl formate, FumateTM, Nursery plantsIntroduction

1. Introduction

Methyl bromide (MeBr) had long been planned for its phasing out and recommended for reduction of its usage by the International Plant Protection Convention (IPPC). Therefore, for protecting the ozone policy and work safe applications, MeBr needs to be urgently replaced. Ethyl formate (EF) offers great potential to replace MeBr for fresh fruit fumigation. The Animal and Plant Quarantine Agency (APQA) of the Korean Government, is under progress for developing new alternative fumigants and fumigation technology to replace MeBr. However, intially, the cylinderized liquid EF with carbon dioxide formulation faced with challenges from higher costs, work safety issues and phytotoxicity of furits and vegetables (Ryan et al., 2003; Simpson et al., 2004). Recently, the cost-effective and practically safe use of liquid EF with nitrogen gas has been developed by cooperative research between Murdoch University in Australia and APQA in Korea. An innovative application of EF (Fumate™) with nitrogen is replacing cylinderized formulation because new EF application technology benefits to reduce operation costs of fumigation, provide safety for workers, handling heavy cylinders as well as reduction of green house gas (Yang et al., 2016). Here, we report the phytotoxicity of EF on imported nursery plants.

2. Materials and Methods

2-1. Preparation of samples

In this preliminary test, 12 different variety of imported nursery plants were used as listed below:

Alocasia amazonica, Cactaceae spp, Sansevieria trifasciata, Codiaeum variegatum, Peperomia obtusifolia, Peperomia puteolata, Hoya carnosa, Viburnum odoratissimum, Spathiphyllum wallisii, Rhapis excalsa, Hedera helix, Fatsia japonica and Sansevieria stuckyi.

2-2. Fumigant

Fumate™ (Ethyl formate, 99%) was supplied from Safefume Inc., Korea. EF was vaporized with heated nitrogen gas through a nitrogen heater, which was fitted in vaporizer (SFM-1) and discharged into the fumigation chamber.

2-3. Preliminary test of phytotoxicity to nursery plants

Phytotoxic tests were performed at Gyeongsang National University (GNU) site. A fumigation chamber (0.55m x 0.50m x 1m) was used and the loading ratio of plants was 5 to 15%. After loading the nursery plants, we calculated the required dosage of EF (70 g m^{-3}) that was injected into the chamber for fumigation for 4 hours. The air temperature in fumigation room was controlled with an air conditioner at 20±2°C. After fumigation, the chamber was ventilated for more than 1 hour, and phytotoxicity on nursery plant was investigated after 1st and 7th day after treatment. Assessment for recovery of post-fumigated plants was undertaken after 4 weeks after treatment.

2-4. Measurement of fumigant concentration

For monitoring concentration of EF in the chamber, gas samples were drawn with an electric pump at timed intervals and stored in Tedlar gas sampling bags (1 liter, SKC Inc.) before analysis. The concentration of EF was determined by using an Agilent Technology 7890N gas chromatography (GC) equipped with a flame ionization detector (FID) after isothermal separation on a 30 m × 0.32 mm I.D. HP-5 (0.25 μm film)-fused silica capillary column (Restek Co. Ltd.). The GC oven, injector and detector temperature were 150, 200 and 200°C, respectively. Helium was used as the carrier gas at a rate of 2 mL/min. The peak areas were calibrated periodically using a standard (inject the known volume of ethanedinitrile in 1 L Tedlar gas sampling bags).

2-5. Assessmenet of post-fumigation phytotoxicity

The market qualities on nursery plants post-fumigation was assessed by three different ways. The external damage was measured by researchers and numbered as index ranged from 0 (none) to 4 (severe). Chrolophyll contents were measured with chrolophyll meter. Color changes of leaf was measured with colorimeter. Unfumigated nursery plants were used as controls for these assessments.

3. Results

Phytotoxicity of EF to nursery plants

The cumulative concentation X time products (Ct) of EF were 74.9 to 143.4 g h m^{-3}. The Ct products decreased with the increase of loading ratio of plants. Even though there were small damages in terms of reducion of chlorphyll and changes in colors in post-fumigated nursery plants within the first week, there were no serious damages found in terms of recoveries at 4 weeks post-fumigation. This is the time (4 weeks), at which, usually post-quarantine plants are distributed in markets in Korea. However, there was no recoveries in *Spathiphyllum wallisii* and *Peperomia puteolata* plants (Table 1)

Tab. 1 One week end point damage of nursery plants after 4 hr EF fumigation (20°C)

4. Discussion

Although EF fumigation caused decrease of chrolophyll contents on leaf and withering from some imported plants after one week of fumigation, this research showed that ethyl formate (EF) fumigation could be potentially used on imported nursery plants in terms of recoveries, 2 weeks post-fumigation, which is more than the period required in Korea to distribute the plants to consumers. The imported nursery plants in Korea might be grown in remote nusery sites for several months depending on plants for satisfication of market values and to certify disease-free, and during this period the damaged plant can be recoverred. The degree of phytotoxic damages with EF fumigation could be various depending on species, ages and physical conditions of plants when imported in Korea. It is known that MeBr fumigation can cause serious and unrecoverable damage on imported nursery plants as well as chronic inhalation damages to fumigator and related workers in post-fumgation process (Kim et al., 2016). Ethyl formate fumigation of nursery plants could be provide better options than current MeBr application in tems of work safety and less phytotoxic to commodities as well as classification of definatly non-ozone depletion chemical.

Abstract

As increased agricultural insecticide uses and trends in insecticide resistance, increased labor cost to apply insecticide and limited its application to fertility season in green house. There is a need of a safe, labor-saving and confined space application concept to manage control tiny-scale insect pest such as thrips and whitefly. Fumigation with ethyl formate (EF), which is considered as effective to various insect pest and safely use in quarantine treatment, was evaluated in the confined space (glass house) and semi-confined space (vinyl house). The new application technology for application of liquid EF could be the one of the key options for control of tiny flying insects in greenhouses that would save labor and operation costs. It could be connected to smart-farm technologies in the near future.

Keywords: Ethyl formate, Inert gas application, green houses, future smart-farm technology

1. Introduction

Fumigants, like methyl bromide (MeBr) and phosphine, are widely used for quarantine and pre-shipment (QPS) fumigations and restriced use in preplant soil disinfestation because physically fumigants have less residues than solid/liquid active ingredients. Its use has advantages for better efficacies because it can penetrate into deep and easy in application even in tiny small space without addtional labor work. This means that fumigants have a potential to replace liquid/solid pesticides in plant cultivation in case they are grown in sealed or semi-sealed enviroments. Even though we know the benefits, usage of fumigant in agricultural purpose especially in sealed system is limited because most fumigants are expensive to apply and normally higher toxic to mammals and human being in terms of acute inhalation toxicity. Ethyl formate (EF), a MeBr alternative which was re-evaluated and commercialized in recent years, is less toxic than other fumigants and has less risk on environments (Muthu et al, 1984). Use of EF on plant cultivation could solve the issue like emerging and increasing pesticide resistant insects (PSI) and residues on harvest. Moreover, in case of application in a sealed system, workers do not need to be exposed to pesticide solution directly which is hazardous and there will be decreased labor-cost. EF fumigation in greenhouse was considered as higher operation costs than pesticide and concerns of leaked out environments. In recent report, liquid EF (Fumate™) with inert gas application was cost-effective and safer protocols than formulated in gas cylinder to apply various imported and exported fruits (Kim et al, 2017, Yang et al, 2016, 2017a, 2017b). In the preliminary studies, efficacies of EF on tiny small insect pest in cucumber green house was reported by Kim et al (2016). In this research, we reported liquid EF with nitrogen applied in the confined space (glass house) and semi-confined space (vinyl house) model and was evaluated for the accumulative Ct product in two system and monitoring of ethyl formate level in spaces after fumigations and aerations for accessment of worker safety.

2. Materials and Methods

2.1. Green houses

Two types of green houses were used, one was vinyl house (3.5m x 20.0m x 5.0m scales) and the other was glass house (8.0m x 5.0m x 24.0m), located at KNU site in Jinju, Korea.

2.2. Fumigation, gas sample collection and aeration

Ethyl formate (FumateTM, 99%) was supplied from Safefume Inc., Korea. Ethyl formate was vaporized with SFM-1 vaporizer system which fitted with an internal gas heater to heat inert gas (nitrogen or carbon dioxide) through the liquid ethyl formate and purge mixture into the greenhouse. For analyzing of EF concentration inside greenhouse, gas sampling lines were placed in green houses (6 locations in vinyl house (VH) and 12 locations in glass house (GH)). The gas samples in greenhouse were taken at timed interval by withdrawing the gas through an air pump into gas bag (SKC Tedlar bag, 1L). Prior to fumigation, the green houses were sealed and calculated dosages of ethyl formate (10 g m-3 for VH trials and 5 g m-3 for GH trials) were applied. For assessment of work safety in work environment, ambient air samples were collected from 4 locations (W, E, S and N) with jumbo syringe (1L, SGE); during during application (0-30 min), fumigation holding period (4-12 hours) and aeration (2 hours). The gas samples were stored in Tedlar gas bags until analysis.

2.3. A nalysis of collected gas sample.

The concentration of EF was determined using a Agilent Technology 7890N gas chromatography (GC) equipped with a flame ionization detector (FID) after isothermal separation on a 30 m × 0.32 mm I.D. HP-5 (0.25 μm film) fused silica capillary column (Restek Co. Ltd.). The temperatures of the GC oven, injector and detector were 150, 200 and 200°C, respectively. Helium was used as the carrier gas at a rate of 2 mL/min. The peak areas were calibrated periodically using a standard.

3. Results

3.1. Concentration of EF inside green house during fumigation

The concentration of EF was continuously decreased at both vinyl house (VH) and glass house (GH). However, the aspects of decrease in two trials were different. Concentration decreased rapidly at overnight in VH and at day time in GH. EF concentration in VH was higher than GH at both 4 and 12 hr trials. Although there were little difference in concentration of EF depending on location of samples, there was no signicant difference in tems of cumulative CT products. The cumulative CT products of EF were 17.53 and 22.67 g h m^{-3} for overnight (12hr) and day time (4hr) application, respectively, in VH application. In GH trials, CT products of EF were lower than VH's, 4.53 and 2.62 g h m^{-3} for overnight (12hr) and day time (4hr) application, respectively. (Fig. 1-Fig.4). Even though 2 times dose applied in VH, concentration of EF in VH is lower than expected. It could be different depending on sealing conditions, temperature when applied etc.

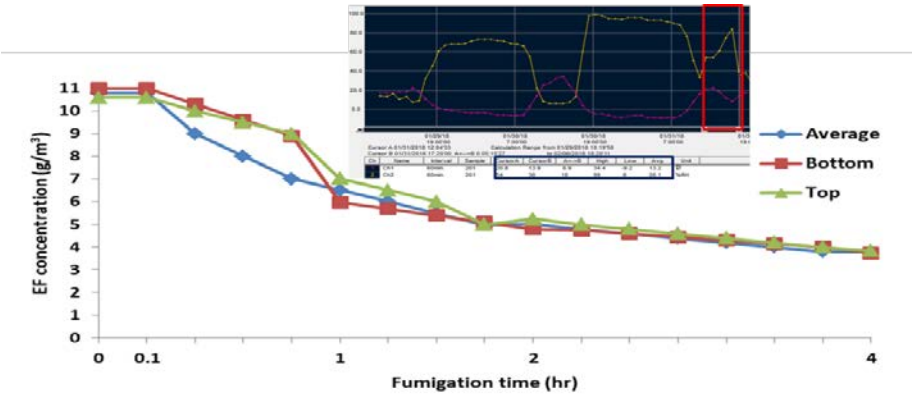

Fig. 2 Concentration of EF (g m^{-3}) inside vinyl house 4 hr fumigation.

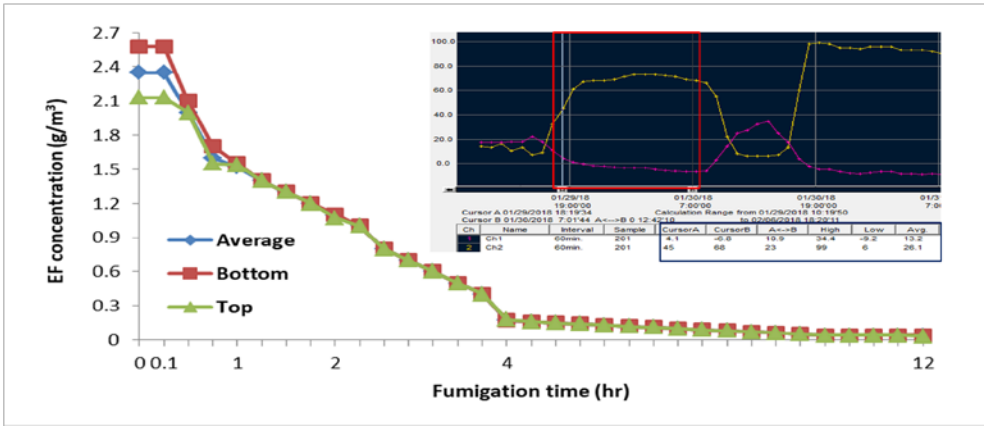

Fig. 3 Concentration of EF (g m^{-3}) inside glass house for 12 hr fumigation.

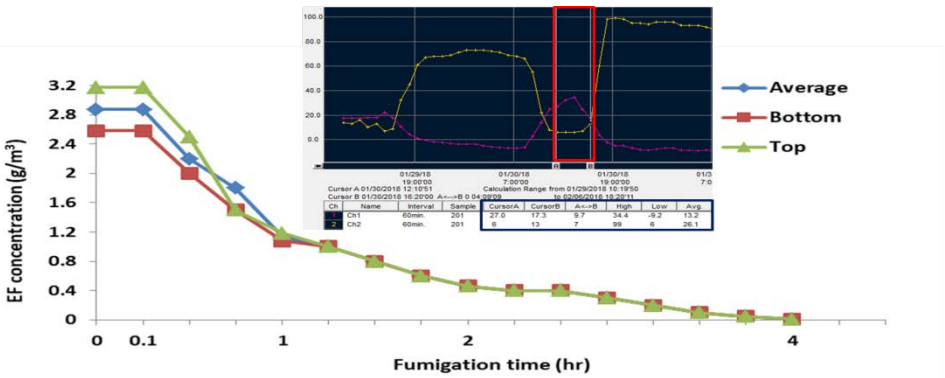

Fig. 4 Concentration of EF (g m^{-3}) inside glass house for 4 hr fumigation.

3.2. Ethyl formate levels in the air samples outside green house during the EF application.

Ethyl formate levels from all ambient air samples were < 50 ppm in all trials during the 30 min application of EF (Tab. 1, 2).

Tab. 1. Ethyl formate levels surrounding vinyl house after 0 - 30 min of injection in 4 and 12 hr fumigation experiment.

Sampling time (min)	12 hr fumigation EF concentration (ppm)				4 hr fumigation EF concentration (ppm)			
	East	West	South	North	East	West	South	North
0	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50
10	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50
20	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50
30	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50

Tab. 2. Ethyl formate levels surrounding glass house after 0 - 30 min of injection in 4 and 12 hr fumigation experiment.

Sampling time (min)	12 hr fumigation EF concentration (ppm)				4 hr fumigation EF concentration (ppm)			
	East	West	South	North	East	West	South	North
0	< 5	< 5	< 5	< 5	20	20	20	20
10	< 5	< 5	< 5	< 5	20	40	20	< 5
20	< 5	< 5	< 5	< 5	7	< 5	< 5	< 5
30	< 5	< 5	< 5	< 5	< 5	< 5	< 5	< 5

3.3. EFhyl formate levels inside green house during 2 hours of ventilation.

EF levels in the green house (GH) during 2 hours of ventialion were shown in Tab 3. As expected, EF levels in green house were continuously decreasing. After 30 min-ventilation, EF levels in GH was decreased to <10 ppm at both trials.

3.4. Carbon dioxide levels inside green house during the fumigation.

In case of 12hr-EF application in green house fumigation, liquid EF applied with inert gas (carbon doxoide) as carrier gas, it could be expect to help growing plants some crops depending on variety, concentration and exposure time of CO_2 etc. In this experiment, carbon doxoide (CO_2) levels inside green house (GH) for 12hr fumigation was also monitored in Fig. 5 and 6. The levels of CO_2 was initially increased up to 700-800 ppm and decreased to 600-700 ppm at the end of fumigation.

4. Discussion

In this preliminary study on vinyl house, we found that liquid EF with inert gas (nitrogen or carbon dioxide) application, was cost-effective and labor-saving, which showed the promise for further reseaches. Because vinyl house application showed better sealed sytem than glass house system and EF levels during the application and ventilation after completion of fumigation was relatively safe in terms of current workplace safety guideline of EF (TLV-TWA, 100 ppm). The cumulative Ct products (>10 g h m^{-3}) calculated in vinyl house both for 4 and 24 hr applications could be expected to be enough to control especially flying insect such as whitefly and thirps, which are hard to control with insecticides in green house system. However, for commercial use of EF in green house system, there is more researche required in terms of phytotoxic damages of different plants and their growing stages as well as fumigation conditions such as temperature and humidity in detail. Nevertheless, this newly emering liquid EF technology could provide a new concept to partly replace intergrated insecticide approach, which leads to build-up of resistance to insecticide and restricts application frequencies when crops are ready for markets.

Abstract

Cargo containers and wooden packing materials are fumigated to control the spread of pests and micro-organisms. However, fumigant gases are toxic and present a danger to human health even at low concentrations. Additionally, products shipped in containers may release VOCs from the solvents, coatings and glues used in manufacturing processes, and the concentrations of these vapors may be significant in the confined space of the container. Gas measurements are required in order to protect the health of any workers involved in opening these containers.

As potentially hazardous gases originate from a variety of different sources, the amount of gases that need to be monitored, in order to ensure a safe working environment, is very large. The Fourier Transform Infra-Red (FTIR) measurement principle allows simultaneous measurement of a large amount of inorganic and organic substances, regardless of their molecular weight. The portable Gasmet™ DX4040 Multicomponent FTIR Gas Analyzer records infrared spectra at 10 scans/second and is capable of sub-ppm detection. When used with a laptop computer and the pro version of Calcmet™ software, the DX4040 is capable of analyzing up to 50 components simultaneously with compensation for cross-interference effects.

A standard application has been developed for container measurements. The application consists of a gas library of 50 gases that has been configured to include all of the most important fumigants and other hazardous gases found in containers, along with a number of other commonly found gases for correction of cross-interference effects. A built-in QA/QC routine ensures reliable results and alerts the user of the possibility of unknown gases in the sample.

If the presence of unknown gases in the sample is suspected, these can be identified using the library search function available in the CalcmetTM software. Identification is undertaken by automatically finding matching spectra in the library of hundreds of different reference spectra measured by Gasmet for different compounds. Once the unknown compound has been identified, it can be added to the analysis for quantification. The measured sample spectra are not altered by the analysis and are saved so they can be re-analyzed at a later time if needed.

The Gasmet™ DX4040 is battery powered, backpack sized designed for use in field conditions. The analyzer is portable, so there is no need for separate sampling and the sample can be collected and analyzed directly on site. Quick and easy sampling, coupled with fast, simultaneous analysis of all compounds makes for an

exceptionally quick measurement procedure per container. The DX4040 requires no span gas calibrations and uses no consumables for sampling or analysis. Only a short zero calibration with nitrogen is required once per day. This means that containers can be measured quickly and with a negligible cost per measurement.

The Gasmet DX4040 provides a powerful and cost effective solution to the challenge of measuring gases inside cargo containers. The use of FTIR technology enables the simultaneous measurement of an unparalleled amount of gases for a portable device, which leads to improved safety of workers. The DX4040 is also durable, requires no calibration gases (other than N2 for zero measurement) and requires no consumables for sampling. This means that the cost of ownership for this solution is also exceptionally low.

Efficiency of phosphine and modified atmospheres against five different stored products insects

Abstract

There has been a notorious resistance to phosphine over the last decade, and a wide variety of factors can be associated with this rise to tolerance in stored products in the northwest of México, which can be due to bad exposition times and application of phosphine, and others causes; investigations were conducted in a warehouse place comparing the efficacy of phosphine with the use of mixtures gases in order to create the modified atmosphere against five diferrent adults: *Cryptolestes ferrugineus* (Stephens), *Tribolium castaneum* (Hbst.), *Rhyzopertha dominica* (Fabricius.), *Oryzaephilus surinamensis* (L.), and *Prostephanus truncatus* (Horn.). An application of 1.4 ± .21 gr/m^3 of phosphine for 72 ± 1 h exposure time could achieve 100% mortality to four species just like: of *Tribolium castaneum*, *Rhyzopertha dominica*, *Oryzaephilus surinamensis*, and *Prostephanus truncatus*. While for *C. ferrugineus* the 100% mortality could be achieved after 4.2 ± 63 gr/m^3 of phosphine for 120h exposure time.

Modeling the distribution of phosphine in cylindrical grain silos with CFD methods for precision fumigation

Abstract

In the present study, the distribution of phosphine gas in a cylindrical silo was modeled and compared with available sensor data. The cylindrical silo was filled with wheat and a recirculation system was used to enhance the diffusion of phosphine throughout the grain volume. A Computational Fluid Dynamics (CFD) model was developed with OpenFoam software, which accounted for gas transport in porous media and sorption effects of phosphine into the grain. A time-dependent source was used to model the phosphine release from Aluminum Phosphide bags. Furthermore, simulation results were obtained for insect mortality as a function of their exposure to phosphine gas. The phosphine concentration measurements were available from calibrated wireless sensors provided by Centaur Analytics, placed near the silo walls at various heights. As the agreement of phosphine measured data with the simulation results was satisfying, it led to considering that the proposed CFD model (equations, boundary conditions, grain properties, recirculation system approach, etc.) was accurate. Utilizing the capabilities of fumigation modeling, the phosphine concentration could then be determined for every location inside the storage volume and at any given time, thus a prediction method for fumigation

duration and success could be enabled. Additionally, as the CFD model correlates phosphine exposure with insect mortality, a methodology for planning precision fumigations can now be established.

Keywords: phosphine, modeling, fumigation, cylindrical silo.

Introduction

Phosphine (PH_3) is the single most relied-upon fumigant to control grain pests, due to its inexpensiveness, ease of application and universal acceptance as a residue-free treatment. Since the use of Methyl Bromide was phased out due to its significant contribution to the destruction of the earth's stratospheric ozone layer, phosphine has emerged as a viable replacement. However, there are several factors that occasionally prevent phosphine fumigations to be successful (e.g. phosphine sorption, leaky storage structures, poor monitoring procedures). Improper use leaves the treated commodity susceptible to insects, increasing the possibility of spoilage, but is also known to lead to tolerant strains among key stored product insects throughout the world (Athanassiou et al., 2016).

In view of the above, it is important to bolster the effectiveness of phosphine fumigation processes and ensure the ecosystem can continue to rely on this important fumigant. To achieve this, an in-depth knowledge and understanding of fumigant behavior are crucial. An efficient method for tackling this is through the combination of field experiments and computer simulation. To the authors' knowledge, there are a limited number of studies in the literature adopting this approach. Except for Lawrence et al. (2013), none of them combine field experiments with detailed numerical simulations. Lawrence et al. (2013) presented a 3D transient heat, mass, momentum, and species transfer model for the stored grain ecosystem which was developed using the finite element method. However, they validate their model against average phosphine concentration measurements which are not indicative of treatment effectiveness. Other relevant publications concerning phosphine simulations are the ones by Boac et al. (2014), Isa et al. (2016), but both are lacking validation with experimental data. Specifically, Boac et al. (2014) studied phosphine distributions in bulk storage structures (bunkers) including the effect of wind phenomena, whereas Isa et al. (2016) made predictions of phosphine flow during grain fumigation in leaky cylindrical silos. Mills et al. (2001) studied a positive pressure system for combating dilution during phosphine fumigations of bulk grain. Nonetheless, their CFD model is not extensively documented. Chayaprasert et al. (2006) used CFD to develop 3D computer models for structural fumigations upon datasets collected at a fumigation treatment in a commercial flour mill. The fumigation models were divided into two parts: internal and external flow models.

In this work, a detailed description of the fumigation treatment inside a cylindrical silo is presented, presenting – for the first time – correlations of numerical (CFD) analysis with wireless gas sensor readings based on a rich sample of phosphine distribution during the entire duration of treatment. Numerical results are employed to provide a map of insect mortality rates, thus binding the analysis with the end objective of pest treatment. Additionally, information about the PH_3 sensing devices as well as the simulation approach is given and a methodology for planning and implementing precision fumigations is outlined.

Materials and Methods

Silo description

The silo under consideration (Fig. **11**) was located in the area of Volos, Greece and the fumigation treatment took place during December. The steel silo diameter was D=15 (m) and its height was H=12 (m). A recirculation system was installed and used during the process. Stored grain (whole wheat) temperature was 12 (°C).

Measurement of phosphine concentration

Data collection of phosphine concentration inside the silo was made with sensor devices provided by Centaur Analytics, Inc. The devices are based on electrochemical sensors thus providing high

accuracy, and are equipped with wireless connectivity with the ability to transmit data frequently (e.g. every 2 hours) from inside stored grain. The data were transmitted in real time to Centaur's cloud platform, from which they were downloaded and further processed. Fig. **11** shows the position of the 4 sensors inside the silo, whereas Fig. **12** shows how one of the sensors is installed inside the silo.

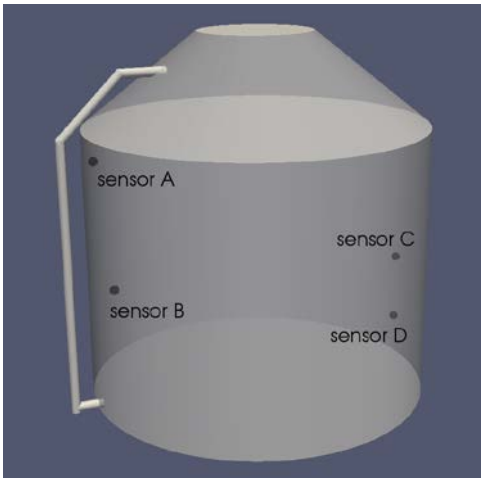

Fig. 11 The three-dimensional model of the cylindrical silo considered in this work

Fig. 12 Installation of sensor B inside the silo

Fumigation parameters

Phosphine gas was generated using Aluminum Phosphide bags. Approximately 10 gr of AlP per tonne of stored product was used, which is equivalent to 2.53 gr of phosphine gas per m^3. The degassing evolution of phosphine is presented in Fig. **13**.

Simulation technique

In phosphine fumigations, it is important to ensure that phosphine concentration exceeds the predefined ppm levels in the entire storage space, to eliminate all insects (for 99.9% mortality). In order to increase the spatial resolution of sensor data, Computational Fluid Dynamics (CFD) models are used. CFD is a branch of fluid mechanics that uses numerical analysis and data structures to solve and analyze problems that involve fluid flows. Computers (typically on the cloud) are used to perform the calculations required to simulate the interaction of liquids and gases with surfaces defined by boundary conditions.

Governing equations

The CFD solver is implemented using OpenFoam v.3.0.1 (OpenFOAM Foundation, Ltd.) in order to solve the following transport equations for incompressible fluid flow, heat, and mass transfer, accounting for porous media effects:

$$\nabla u = 0 \quad (1a)$$

$$\frac{\partial u}{\partial t} + \frac{1}{\phi} u \nabla u = -\phi \nabla p + \nu \nabla^2 u - \phi \frac{\nu}{K} u - \phi \frac{F_e}{\sqrt{K}} |u| u + \phi g \beta (T - T_{ref}) + \phi g \beta_c (C - C_{ref}) \quad (1b)$$

$$\frac{\partial T}{\partial t} + \phi \frac{(\rho C_p)_f}{(\rho C_p)_{eff}} u\nabla T = \frac{k_{eff}}{(\rho C_p)_{eff}} \nabla^2 T \qquad (1c)$$

$$\phi \frac{\partial C}{\partial t} + \phi u\nabla C = \phi\nabla^2 (\frac{D_m}{\tau} C) - \phi B_1 C + B_2 q \qquad (1d)$$

$$\frac{\partial q}{\partial t} = -B_3 q + \phi B_4 C \qquad (1e)$$

In the above equations (1a-1e), u is the velocity vector, and p, T, and C are the pressure, temperature, and phosphine concentration in air, respectively. D_m is the binary diffusion coefficient ($m^2\ s^{-1}$). Buoyancy forces created by both temperature and concentration gradients are considered in the momentum equations using the Boussinesq approximation. Under the Boussinesq approximation, the variation of density ρ with temperature T is linear, according to $\rho = \rho_{eff} - \rho_{eff}\beta(T - T_{ref})$. The volumetric coefficient of thermal expansion β and the species expansion coefficient β_c for ideal gases are given by Eqs. 2a and 2b respectively:

$$\beta = -\frac{1}{\rho}(\frac{\partial \rho}{\partial T})_p = \frac{1}{T} \quad (2a) \qquad \text{and} \qquad \beta_c = -\frac{1}{\rho}(\frac{\partial \rho}{\partial C})_p = \frac{1}{\rho_{air}}(\frac{MW_{air}}{MW_{gas}} - 1) \quad (2b)$$

where MW_{air} and MW_{gas} are the molecular weights of air and phosphine gas respectively.

According to Shen et al. (2007) in order to represent the role of porosity on ordinary molecular diffusion, the diffusion coefficient must be scaled with tortuosity. Specifically, an effective diffusivity coefficient could be set as:

$$D_{eff} = \frac{D_m}{\tau} \qquad (3)$$

Neethirajan et al. (2008) calculated τ = 2.4 for wheat.

Porous media approach

In order to account the effect of grains on the gas flow, the grains were assumed to be a porous medium. Flow in porous layers is described by the Darcy-Brinkman formulation. The geometric function Fe and the permeability K of the porous medium are related to the porosity φ based on Ergun's experimental investigations:

$$F_e = \frac{1.75}{\sqrt{150\ \phi^3}} \qquad (4a) \qquad \text{and} \qquad K = \frac{\phi^3\ d_p^2}{150(1-\phi)^2} \qquad (4b)$$

The effective properties $(\rho\ C_p)_{eff}$ and k_{eff} are calculated as a function of the fluid and porous material:

$$(\rho\ C_p)_{eff} = (1-\varphi)(\rho\ C_p)_{solid} + \varphi(\rho\ C_p)_f \qquad (5a)$$

$$k_{eff} = (1-\varphi)\ k_{solid} + \varphi\ k_f \qquad (5b)$$

Sorption effects

Phosphine is adsorbed by grain at differing rates depending on the grain type. Sorption can reduce the concentrations of fumigation doses to sublethal levels before grain has been disinfected. A model to predict fumigant losses due to sorption is considered necessary. Researchers (Darby, 2008) have suggested that the relationship between the fumigant concentration in the interstices between the grain, C, and the average concentration of fumigant within the grain kernel q, is modelled by Eqs 1d and 1e which assert that phosphine is absorbed into the grain and at the same time also degrades in air. The coefficients B_1, B_2, B_3, and B_4, are independent of C and q.

$$B_1 = \frac{S_{sorp}\, k_f}{B_{fill}} \quad (6a), \qquad B_2 = \frac{S_{sorp}\, k_f}{B_{fill} F} \quad (6b)$$

$$B_3 = \frac{S_{sorp}\, k_f}{(1-\phi)F} + k_{bind} \quad (6c), \qquad B_4 = \frac{S_{sorp}\, k_f}{(1-\phi)} \quad (6d)$$

$$B_{fill} = \varphi + \frac{1-R_{fill}}{R_{fill}} \quad (6e)$$

where: S_{sorp} is the specific adsorption surface area, k_f is a linear mass transfer coefficient, F is the partition relation coefficient, k_{bind} is the coefficient for irreversible reaction/binding of the adsorbed fumigant in the grain kernel. For wheat, the above parameters have the following values: $S_{sorp}\, k_f$ =0.0125, F=0.3, and k_{bind}=0.0569.

Boundary conditions

In order to evaluate accurately the storage (computational domain) interaction with its surroundings, the following convective boundary conditions were used for phosphine concentration and heat transfer (Barreto et al., 2013), respectively:

$$-D_m \frac{\partial C}{\partial x}|_{x=0} = h_m (C - C_{amb}) \quad (7a)$$

$$-k \frac{\partial T}{\partial x}|_{x=0} = h_c (T - T_{amb}) - \alpha_h G + \epsilon \sigma (T^4 - T_{sky}^4) \quad (7b)$$

Coefficients h_m, h are a function of silo geometry (cylinder, orthogonal), fluid medium (air, water) and fluid velocity (e.g. wind velocity). In Eq. 7b, the second term on the right-hand side is the heat gain due to solar radiation and the third term is the net radiation heat loss rate for a hot object which is radiating energy to its cooler surroundings (Adelard et al., 1998):

$$T_{sky} = 0.0552\, T_{amb} \sqrt{T_{amb}} \quad (8a)$$

$$h_c = 10.45 - U_{wind} + 10 \sqrt{U_{wind}} \quad (8b)$$

For the purposes of the present study, the time series of ambient temperature, wind velocity, and solar radiation that are used as inputs are presented in **Fig. 14**.

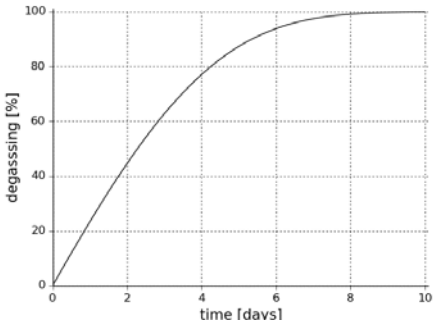

Fig. 13 Degassing evolution of phosphine gas from AlP bags during fumigation (data provided by Detia Degesch)

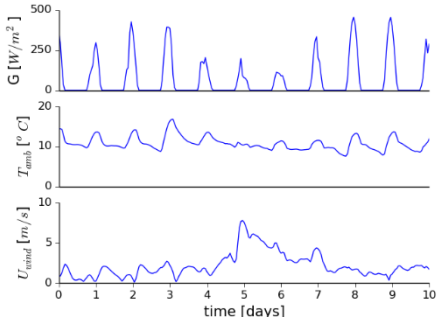

Fig. 14 Time variation of ambient conditions: solar radiation, temperature and wind velocity

Domain discretization

Meshing is the discrete representation of the geometry that is involved in the problem. Essentially, it partitions space into cells over which the equations can be approximate. In the present study, the computational grid used (Fig. **15**) was structured, thus ensuring greater accuracy, and all cells

(approximately 85000) were hexahedra. Furthermore, grid-clustering was employed near the side to properly capture large gradients.

Insect mortality

It is known that the effect of phosphine on the mortality of grain insects is due to both the level of the phosphine concentration and the time of exposure (Collins et al., 2005; Isa et al., 2016). An insect mortality indicator function IM(x, t) could be defined as:

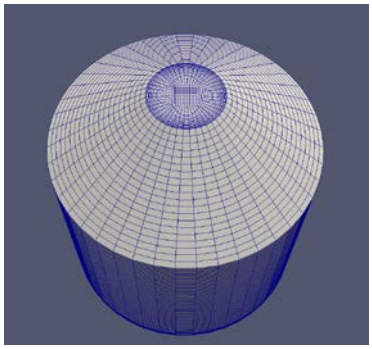
$$IM(x,t) = \frac{1}{K_1}\int_0^t C(x,t)^{K_2}\, dt \qquad (9)$$

The constants K_1 and K_2 are empirical and depend on the species and strain of insect. IM(x,t) account for the period of exposure to phosphine that an insect has encountered. For a given point in the grain, when IM(x,t)<1 there are some insects in the grain still alive. When IM(x,t)>1 at least 99.9% of the insect population have been killed. For the present simulations K_1=4.04 and K_2=0.6105 which accounts for the *Rhyzopertha dominica*.

Results

The simulation model yielded, among other results, the development of phosphine concentration for the entire duration of the fumigation treatment (9 days). In **Fig. 16**, the time evolution of phosphine at the 4 locations is presented. Specifically, sensor data are compared against model predictions. The best correlation occurs for A and B positions which are located on the silo side where the recirculation system was installed. Their maximum concentration is reached at the end of the 4th day, followed by a decrease due to diffusion, losses, and sorption by the stored product. Concerning, locations C and D, sensor data reveal lower concentration values as the model also predicts. A small discrepancy is observed on the time that the maximum value is reached. According to sensor data, phosphine concentration has an upward trend until the end of the 7th day, whereas the CFD model underestimates to the end of the 5th day. Minor fluctuations, with hourly timescales, occur due to natural convection currents which are the result of temperature differences imposed by the unsteadiness of ambient conditions. The currents create upward and downward air movements that transport phosphine along.

The overall performance of the CFD model is considered satisfactory ensuring the validity of the phosphine concentration predictions for the entire silo space as the ones presented in **Fig. 17**. Particularly, **Fig. 17** shows the spatial distribution of phosphine at four time instances. The advantages of using a recirculation system can be clearly seen since at the second day, phosphine has reached every position inside the silo. Until the 6th day, higher concentration values are observed on the top regions of the silo, near the aluminum phosphide bags but as their degassification completes a more uniform phosphine distribution is reached (**Fig. 17**, 8th day). A video showing the model predictions for the entire fumigation process could be found here: https://youtu.be/iISBS7eoWb8



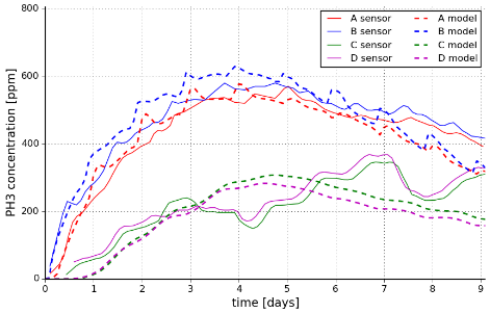


Fig. 15 The computational mesh used for the silo simulation

Fig. 16 Phosphine concentration (ppm) comparison of sensor data (solid lines) vs. simulation predictions (dashed lines) at 4 locations inside the storage.

A useful augmentation of the phosphine concentration profiles is the prediction of the insect extinction. **Fig. 18** shows the areas (red color) in which the Rhyzopertha Dominica species could not survive the fumigation process. As expected, areas near the Aluminum Phosphide bags and at the piping outlet are the first ones that reach lethal levels. According to the simulation, at the end of the 7th day there are still some areas that insects could be still alive. A video showing the insect extinction predictions for the entire fumigation process could be found here: https://youtu.be/54uJ1ZJlkrk

Discussion

A 3D heat, momentum, and species transfer model for stored grain ecosystems was developed in this work, able to predict phosphine concentration changes. As the agreement of phosphine measured data with the simulation results was satisfying, it is safe to assume that the proposed CFD model (equations, boundary conditions, grain properties, recirculation system approach, etc.) is accurate for the purpose. Utilizing the capabilities of fumigation modeling, the phosphine concentration was determined for every location inside the storage at any given time, thus a prediction of fumigation duration and pest elimination success could be provided. The main benefit of the CFD approach is its wide applicability on any type of commodity, storage or phosphine formulation. As the CFD model correlates phosphine exposure with insect mortality, a methodology for planning precision fumigations can be established.

In general, the results presented here illustrate that gas distribution is uneven during the entire treatment period, suggesting that there are large areas within the treated area that are exposed to low concentrations. This may result in increased survival of the exposed insects in these areas, and, to some extent, lead to tolerance development. Circulation of phosphine (through J-system) may be a solution to this implication, but additional experimental work is needed to estimate the relative benefits. In light of the present findings, it is evident that distribution is uneven right after the start of the application, and is likely to exhibit "diurnal circles", as has been previously reported for other trials (Athanassiou et al., 2016). By the use of sensors, however, monitoring of these variations may provide the inferences necessary for designing a strategy to overcome this phenomenon, under the premise of a 'precision fumigation' approach. This was definitely not possible, at least not at an acceptable accuracy level, with the 'traditional' phosphine concentration measurement techniques.

Abstract

Phosphine is a widely used fumigant for controlling insects in stored grain, but fumigation effectiveness is often compromised by suboptimal distribution of the gas. Leaks in the grain bin wall and roof, foreign material in the grain, and phosphine placement contribute to regions of insufficient concentration of fumigant, resulting in insect survival and leading to phosphine-resistant insect populations. Phosphine distribution was studied during field tests in temporarily sealed bins to compare distribution from conventional probed tablets to the distribution using a closed-loop recirculation system. The results showed uneven distribution patterns and leakage over time with conventional probed tablets, which resulted in some areas in the lower half of the grain

mass receiving no phosphine and some other locations remaining below the target phosphine concentration for the entire period of fumigation. The closed-loop fumigations with the same phosphine dosage yielded much more uniform phosphine concentrations, but suffered from equal or greater phosphine leakage losses.

Keywords: grain storage, phosphine resistance, stored product insects, closed-loop fumigation.

Introduction

The fumigant phosphine is extensively used for stored grain insect control and is considered one of the most effective insect control measures when properly applied (Philips et al., 2012). With this widespread use and high expectations, the effectiveness of phosphine fumigations is a fundamental concern for all users; however, there is little or no control of where gas may go during conventional fumigation. Improper application or leakage from the storage structure can result in insufficiently treated areas in the bin that will harbor surviving insects and likely select for resistant insects in the survivors. Thus, ineffective fumigations increase grain losses and contribute to the development of pesticide resistance in stored grain insects.

Conventional phosphine fumigation methods include probe and tarp, automatic dispenser, and gravity fumigation (Kenkel et al., 1993; Noyes et al., 1995). Phosphine is usually applied to grain as aluminum or magnesium phosphide in pellet or tablet form. The pellets or tablets react with water vapor in the air to produce phosphine gas. In gravity fumigation diffusion is used to distribute phosphine gas throughout the grain mass. There is little or no control of where gas may go during conventional fumigations. Each of these conventional methods offers increased risk of exposure during insertion of fumigant into the grain and the distribution of phosphine is often suboptimal. Leaks in the grain storage bin and foreign material in the grain can lead to regions of insufficient concentration of fumigant. Phosphine is also available in gaseous form mixed with carbon dioxide which can be directly injected into a grain storage bin. In the probe and tarp method, Noyes et al. (1995) recommended using a probe to place about three-quarters of the fumigant dosage 0.3 to 1.5 m below the surface of the grain mass and placing the remaining fumigant in aeration ducts in the base of the structure. Tarps can then be applied to partially filled bins to limit the fumigated volume and minimize leakage. In probe and tarp fumigation, workers must enter the grain bin and are exposed to entrapment hazards and fumigants during the tarping process.

A concentration of 200 ppm for 100 hours is the guideline to kill common stored wheat pests in Oklahoma (Noyes and Phillips, 2004) and in Kansas. It is virtually impossible to completely seal existing grain storage bins so that some phosphine does not leak out over the course of the fumigation. When sufficient levels of phosphine are not maintained for the duration required to eradicate all life stages of insects, the surviving life stages can continue to infest the grain. Furthermore, the surviving insects are likely to be the most resistant members of the population. Incomplete fumigations are a significant cause of development of phosphine resistance, which has been reported in stored grain pests (Benhalima et al., 2004; Lorini et al., 2007). Resistance to phosphine is a critical concern for grain storage managers because of the widespread use pattern.

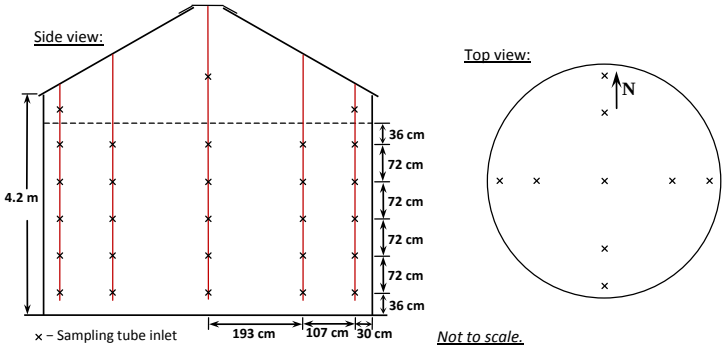
A safer and more effective alternative to traditional fumigation practices is the use of closed-loop fumigation (CLF) systems in grain handling and storage facilities. The typical CLF system uses a small fan and duct system to recirculate fumigant in the grain storage bin by drawing it out of the headspace and injecting it back into the bottom of the grain storage bin. The fumigant rises up through the grain until it enters the headspace where the cycle repeats. After several cycles through the grain storage bin the fumigant is evenly distributed. Recommended CLF flow rates of 0.0016 to 0.008 m^3/min per m^3 grain (0.002 to 0.010 cfm/bu) provide several air changes through the grain storage bin per day to provide sufficient mixing in the usual time that phosphine pellets/tablets react (Noyes et al., 2002). CLF systems that distribute fumigant evenly throughout a grain storage bin can allow the use of less phosphine in a fumigation because the manufacturer's recommended application rates are elevated to allow for unequal fumigant distributions in typical grain storage bin (Kenkel et al., 1993; Noyes and Kenkel, 1994; Noyes et al., 1995; Hardin et al., 2009).

Phosphine is chemically stable at the normal conditions inside a grain storage bin and diffusion through the envelope of the structure is generally negligible, while the major loss of phosphine is through leakage from the structure through cracks and other openings. Pressure from wind and thermal buoyancy are the primary forces that drive the exchange of fumigant with the air outside the structure (Cryer, 2008). Wind flowing around a grain storage bin induces areas of high and low pressure. Wind velocity, direction, and the presence of other structures all affect the pressure distribution on the grain storage bin, and in turn, influence leakage (Mulhearn et al., 1976; Banks et al., 1983; Bibby and Conyers, 1998). CLF systems produce a pressure differential across the grain mass that can significantly contribute to leakage in a grain bin that is not sufficiently sealed.

The objective of this study was to evaluate the distribution of phosphine in temporarily sealed grain storage bins during conventional fumigation with probed tablets and compare to distribution during closed-loop fumigation of the same bins.

Materials and Methods

The fumigation experiments were conducted in two corrugated steel bins each containing 95 metric ton of hard red winter wheat. Bins were 6.6 m in diameter with 4.2 m eave height and 6.0 m peak height. The wheat was center-loaded in the bin and leveled at 3.6 m deep. Plastic sampling tubes (3 mm inside diameter) were attached to support cables, which were installed with two in each cardinal direction plus one in the center with five sampling tubes on each support cable (Fig. 1). This provided nine sampling tube inlets at each of five depths in the grain mass plus three in the headspace, giving 45 sampling points distributed through the grain mass out of 48 total sampling points in the bin. The tubes ran outside the bins through an opening designed for that purpose with the ends arranged in a grid on a board for easy access. The bins were temporarily sealed using 4 mil plastic sheets covering all opening using contact adhesive. The sidewall to eave joint had been



previously sealed with caulk.

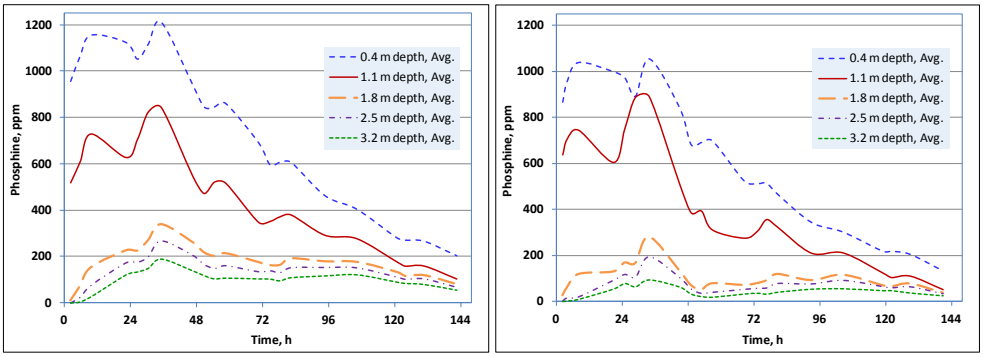
Fig. 1 Experimental bin showing sampling tube locations.

Each bin was fumigated at the minimum label rate of 90 tablets per 27 metric ton of grain for both conventional and CLF fumigations. In the conventional fumigations the tablets were evenly dispersed among three depths of 1.2, 0.6, and 0.3 m from the surface at nine locations near the nine support cables. In the CLF fumigations the tablets were dispersed across the top surface of the grain and circulation fans were run for 45 minutes every six hours throughout the fumigation. After phosphine application, the concentrations of phosphine gas at various depths were measured manually with a Dräger X-am 5000 (Drägerwerk AG & Co., Lübeck, Germany) personal monitoring instrument using a Dräger X-am 1/2/5000 pump to draw the gas from the grain mass through the sampling tube and the lines of the gas sensor. The readings were collected approximately at 4-8 h intervals for 5 to 6 days. Phosphine concentrations were averaged for all nine sampling points at each depth in the grain and for the three sampling points in the headspace and the resulting means

graphed versus time. The full data from all 45 sampling points in the grain were analyzed to determine statistics such as mean, standard deviation, minima, and maxima for each sampling time.

Results

Figure 2 shows phosphine concentrations during a six-day conventional fumigation in the two bins. The two monitored depths with the highest readings (0.36 m and 1.1 m) had average doses above 200 ppm for most of the first five days, with only minor differences in the trends between the two bins. These two depths with the highest readings were the two nearest the top surface and fell within the range of depths where the pellets were introduced. The three lower depths monitored (1.8, 2.5, and 3.2 m), all below the depths where the pellets were placed, received average doses at each level less than 200 ppm with a few exceptions between 20 and 60 h. The peak readings at those three lower depths occurred at 34 to 35 h in both bins and one of the six average readings at those depths (from three readings each in two bins) reached 339 ppm at that peak (Fig. 2), while the rest were all below 300 ppm at the peak. The readings at the upper two depths also peaked at 34 to 35 h indicating the aluminum phosphide tablets were spent shortly after that time and the subsequent declining phosphine readings resulted from continued leakage out of the bins. In general, bin 2 had slightly lower average phosphine readings at all depths and at all times than did bin 1. These lower readings were likely due to bin 2 having slightly greater overall leakage around the upper portions of the bin, where maximum concentrations occurred, than did bin 1. The upper two depths in these bins (0.4 m and 1.1 m) had average concentrations above 200 ppm for the recommended 100 h (Jones et al, 2008), but lower three depths did not in either bin.

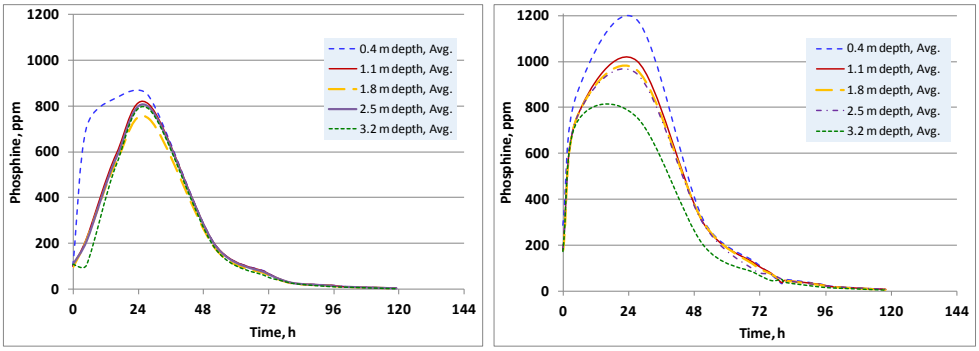


(a) (b)

Fig. 2 Phosphine concentrations during conventional, probed-tablet fumigation in (a) bin 1 and (b) bin 2, each containing 95 metric ton of wheat at 24°C.

Some of the individual sampling points at the lower three depths had zero readings for much of, and occasionally all of, the six-day conventional fumigation. The maximum number of sample points with a zero phosphine reading was 26 and 24 for bin 1 and 2, respectively, which occurred at the first reading (2.3 h). The minimum number of sample points with a zero phosphine reading was six and ten for bin 1 and 2, respectively, which occurred at 104 h. After 104 h the number of sample points with a zero reading began to increase again in both bins. It was also observed that 14 of 45 monitored locations in both grain masses received no phosphine (all readings during the fumigation were zero) or nearly no phosphine (majority of readings during the fumigation were zero). Both bins had similar patterns of phosphine average dosage for all depths, but there was slightly more variation observed between the two bins for the highest monitored depths (Fig. 2 and 3). However, the greater variability at the upper two depths could be due to the overall higher phosphine readings for those depths having proportionally higher deviations than in the lower three depths with the lower readings.

Figure 3 shows phosphine concentrations during a five-day CLF fumigation of the two bins. All peak readings, which occurred during the first 48 hours of fumigation, were in the same range as the highest peak readings in the conventional fumigations, 800 to 1200 ppm, with no depths having very low peaks (below 300 ppm) as seen at many of the lower depths in the conventional fumigations.



(a) (b)

Fig. 3 Phosphine concentrations during CLF fumigation in (a) bin 1 and (b) bin 2, each containing 95 metric ton of wheat at 24°C.

In bin 1, the distribution of average readings at each depth showed very little variation with only one data point early in the fumigation, at 5 h, deviating from the uniform trends. The peak readings at 28 h in bin 1 were all very close to each other at approximately 750 to 850 ppm. In bin 2, the peaks at 27 h varied from 800 ppm to 1200 ppm, but these were much more uniform than the peaks in the conventional fumigations. For both bins, average concentrations remained above 200 ppm for all five heights for 48 h, but no depths stayed above 200 pm for more than 60 h. In general, bin 1 had slightly lower average phosphine readings at all depths and at all times than did bin 2. These lower readings may have been due to bin 1 having slightly greater overall leakage around the lower portions of the bin, which received the maximum pressurization from the circulation fan, than did bin 2.

The variation between readings at different depths in both bins for both conventional and CLF fumigations was evaluated by calculating the coefficient of variation from the mean and standard deviation of the 45 concentration values in each bin (Fig. 4). The conventional fumigations showed much larger values of coefficient of variation because of the large deviation between readings at different locations, especially between different depths (Fig. 2), within the grain mass. The CLF fumigations almost always had coefficients of variation under 30% except one data point in one test early before the recirculating airflow had produced uniform distribution.

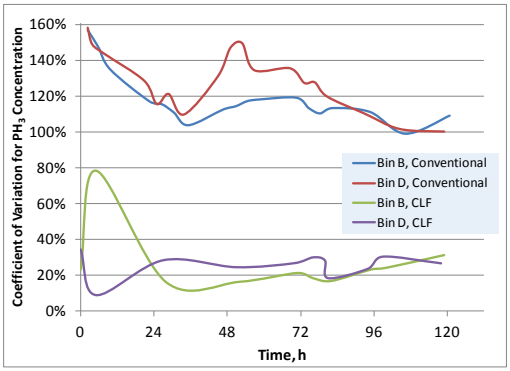


Fig. 4 Coefficient of variation over time for the average of the phosphine concentrations at 45 locations in the four bins during fumigations.

Discussion

Flinn and Reed (2008) found similar results to ours in tall concrete bins when fumigating with pellets. In the absence of wind or chimney effects the phosphine gas did not move far from the pellets so that locations in the bins without pellets did not receive lethal concentrations of gas for fumigation. When there were significant chimney effects in those tall bins due to temperature differences, the phosphine gas moved to other locations and moved out of the bins through leakage from openings in the top and bottom of the bins. Cook (2016) measured phosphine gas concentrations during CLF fumigation of small (45 to 50 metric ton), well-sealed metal bins. Gas was circulated using a thermosiphon system (Boland, 1984). The CLF systems of Cook also maintained relatively uniform, but higher, phosphine gas concentrations during fumigations similar to our CLF fumigations. With the well-sealed bins in that study, phosphine gas concentrations always remained above 100 ppm for 125 h. The longer maintenance of gas concentrations was clearly a result of more effective sealing on those bins compared to the temporary sealing of our bins.

Fumigation treatments reported by Jones at al. (2008) demonstrated some similarities and some differences in comparison to our results. In their tests, pellets were distributed uniformly in tall concrete bins while turning the grain in the conventional application and the resulting gas concentrations were compared to those in identical bins under CLF fumigation. In the CLF bins, the same number of pellets were distributed on the top surface of the grain with phosphine gas then distributed with intermittent running of a recirculation fan. In the conventional bins the three monitored locations, top, middle, and bottom never reached 200 ppm of phosphine gas at any time during 72 h of monitoring, which is like the locations in our conventional fumigation bins that were not in close proximity to the tablets. CLF bins in their tests maintained an average phosphine gas concentration above 1000 ppm for approximately the last 60 h of the same test period, which indicates there was much less leakage from those concrete CLF bins than from our steel CLF bins.

Our measurements showed uneven phosphine distribution patterns and leakage over time when fumigating with conventional and CLF techniques. With the conventional probed tablet fumigation, the uneven distribution of phosphine at the minimum label rate resulted in effective doses in only some portions of the bin. The distribution of phosphine gas was much more uniform when using the CLF fumigation method. Both types of fumigations exhibited wind-driven leakage that was often excessive, while the CLF bins also exhibited continual high leakage due to the fan pressures in the bin and ductwork during the intermittent fan operation. Leakage driven by wind effects and recirculation fan pressure in these temporarily sealed bins prevented lethal phosphine gas dosages for the recommended length of time in all or part of the bin in all tests.

Since many decades, fumigations of stored products are an accepted and worldwide used method to control pest organisms. Infested stored goods can be treated with anoxia and chemical fumigants to eradicate pests very effectively and without any movement of the products. Stored-product insects present a serious problem causing economic loss and contamination of food destined for animal or human consumption as well as a direct physical damage of materials and objects.

Therefore, fumigations are an effective option in manufacturing, storage and shipment. Since the International Standard for Phytosanitary Measures No. 15 (ISPM 15) is approved, container fumigations against quarantine pest have become important and customary in international trade.

We investigated several subjects related to fumigation such as occupational safety, modification of flavor profiles in fumigated crops and the development of resistance against fumigants.

Fumigation of goods for protection against pests is common practice in the context of global trading. One of the most commonly used fumigants for this purpose is phosphine (PH3). Apples are fumigated prior to export to control eggs of pest insects like the codling moth (*Cydia pomonella*). In this study we addressed the question whether phosphine fumigation affects the aroma profile of apples (*Malus domestica* 'Royal Gala'). For this purpose, a headspace solid-phase micro-extraction (HS-SPME) technique was developed and coupled to subsequent gas chromatography-mass spectrometry (GC-MS).

Previously we looked into the desorption behavior of phosphine after the fumigation of apples and sunflower seeds. Furthermore, the effects of fumigation on the overall volatile profiles were studied. Alterations of the volatile profiles were observed for apples and sunflower seeds.

A second question addressed concerns the adsorption and desorption behavior of phosphine from apples and sunflower seeds under different conditions as well as the chemical residues. The impact of the initial fumigation concentration and of the storage temperature was analyzed. The phosphine concentration was thereby monitored using GC-MS instrumentation.

Dates fumigation with phosphine

Abstract

Stored dates are usually infested by sap beetles and moths. For years, the common practice for dates disinfestation was fumigation with methyl bromide (MB). After MB phase-out, heat treatment and modified atmosphere are used. However, there are several limitations of these methods. In search for alternatives for dates disinfestation, fumigation by phosphine was evaluated.

Commercial fumigations of Medjool dates variety using phosphine were conducted in a standard 20 ft. shipping container. Two formulations of phosphine were used: Magtoxin® Plates 56% (Detia Freyberg GmbH, Germany), and Phostoxin® Tablets 56% (Detia Freyberg GmbH, Germany). The phosphine dosage range was 1-4 g/m^3. The exposure time range was 24-72 hrs. Several fumigations were carried out by an innovative phosphine generator model OMT 501 developed by Universal Probes. Most fumigations carried out demonstrated total dates disinfestation. The application of Magtoxin plates, especially using the OMT 501 demonstrates significant advantages versus Phostoxin tablets; the advantages were in quicker gas development, and achieving much higher maximum and pre-ventilation phosphine concentration levels. Upon fumigation using the OMT 501, plates are easily collected and disposed, no residual dust left on the dates, which avoided their contamination. No phosphine residues were found in the fumigated dates, neither changes in organoleptic properties were noted. Phosphine fumigation using the phosphine generator model OMT 501 provides safer, quicker, more efficient dates disinfestation.

Keywords: fumigation, phosphine, dates

Introduction

Stored dates are usually infested by sap beetles and moths. For years, the common practice for dates disinfestation was fumigation with methyl bromide (MB). After MB phase-out, heat treatment and modified atmosphere are in use (Navarro, 2006; Navarro and Navarro, 2015; Rafaeli et al., 2006). However, there are several limitations of these methods. Today, phosphine is the main fumigant for postharvest treatment in stored products, such as grain and dry food. To improve the phosphine

fumigation some innovative technologies were suggested (Kostyukovsky and Shaaya, 2012; Kostyukovsky et al., 2010; 2013). In search for alternatives for dates disinfestation, fumigation by phosphine was evaluated.

Materials and Methods

Two standard 20 Ft shipping container were used for the fumigations. One container was used as it is without special sealing. The other one was sealed especially for the treatments.

Two formulations of phosphine were used: Magtoxin Plates, 56% (Detia-Degesh, Germany), or Phostoxin Tablets, 55% (Detia-Degesch, Germany). The range of phosphine concentrations used was 1-4 g/m^3. The range of exposure time was 24-72 hrs (1-3 days). The treatments were done with or without the phosphine generator model OMT 501 (Universal Probes, Israel). The list with all fumigation treatments is shown in table 1.

Tab. 1 Fumigation treatments

Trial #	Phosphine formulation	OMT 501	Dosage g/m^3	Quantity	Exposure time
1	**Magtoxin Plates**	V	4	4 Plates	1 day
2	**Magtoxin Plates**	V	2	2 Plates	1 day
3	**Magtoxin Plates**	V	2	2 Plates	2 days
4	**Magtoxin Plates**	-	2	2 Plates	3 days
5	**Phostoxin Tablets**	-	2	66 Tablets	5 days
6	**Phostoxin Tablets**	-	1	33 Tablets	1 day
7	**Phostoxin Tablets**	-	2	66 Tablets	1 day
8	**Magtoxin Plates**	-	2	2 Plates	1 day
9	**Magtoxin Plates**	V	1	1 Plates	1 day
10	**Phostoxin Tablets**	-	3	99 Tablets	2 days

Before starting the fumigation treatments, a sample of non-treated dates of 1 kg each, was taken as a control for efficacy evaluation. After the fumigation treatments, three dates samples 0.5 kg each were taken from different locations in the container for efficacy evaluation and phosphine residues analysis.

During the entire fumigation period, the phosphine concentrations levels inside the containers were monitored every two hours.

Results

The results showed that concentrations of phosphine in the non-special-sealed containers were very low (table 2, trials 4, 5). In contrast, in the container that passed special sealing before fumigation, a much higher concentration of phosphine were recorded (table 2, trials 1-3, 6-10). The highest concentrations were reached using Magtoxin plates, 4 g/m3 X 24 hrs with the phosphine generator model OMT 501 (table 2, trial 1). However, also at lower dosage of 2 g/m3 X 24 hrs and 2 g/m3 X 48 hrs using the OMT 501, high phosphine concentrations were achieved (table 2, trials 2, 3). The exposure time of 48 hrs does not have a significant advantage compared with 24 hrs (trials 2, 3). When the Magtoxin plates were used without the OMT 501, the highest concentrations were recorded much later compared with the trials with the OMT 501 (Table 2, trials 2, 9). Using Phostoxin tablets, only at the dosage of 3 g/m3 X 48 hrs the concentrations of phosphine were satisfactory (table 2, trial 10), but were reached much later compared with the Magtoxin plates and especially when using the OMT 501.

* - non-special-sealed containers

The range of the dates infestation in the control was 3% to 30%. The dates were infested with alive adults of sap beetles (Coleoptera: Nitidulidae) and the larva of moths. Post fumigations no live insects were found. The dates infestation by dead insects in Magtoxin plates using the OMT 501 was 0-1%, in plates without the OMT 501 2%, in the trials with the tablets 2-18% (table 3).

Tab. 3 The efficacy of Phosphine fumigation in dates disinfestation in the field trials

Trial #	Phosphine formulation	OMT 501	Dosage g/m³	Exposure time h	Date infestation % control		treatment	
					alive	dead	alive	dead
1	**Magtoxin Plates**	V	4	24	6	0	0	0
2	**Magtoxin Plates**	V	2	24	9	0	0	3
3	**Magtoxin Plates**	V	2	48	6	0	0	2
6	**Phostoxin Tablets**	-	1	24	3	0	0	2
7	**Phostoxin Tablets**	-	2	24	6	0	0	18
8	**Magtoxin Plates**	-	2	24	12	0	0	2
9	**Magtoxin Plates**	V	1	24	22	7	0	5
10	**Phostoxin Tablets**	-	3	48	3	3	0	8

No phosphine residues were found in any of the fumigated dates.

Discussion

The best results were achieved in the trials with Magtoxin plates using the OMT 501. The plates have significant advantages versus tablets by achieving the highest levels of phosphine concentrations much faster, resulting in dates disinfestation. In addition, plates have obvious safety advantages versus tablets. Standard (common) containers without special sealing are not suitable for fumigation.

Determination of phosphine concentration for *Cryptolestes ferrugineus* (S.) control in wheat in Sonora, Mexico

María Fernanda Esparza-Soltero[1], José Luis López-Valdez[2], Alberto Olguín-Moreno[2], Francisco Javier Wong-Corral*[2]

[1]Degesch de México
[2]Universidad de Sonora, DIPA, México
Corresponding author: francisco.wong@unison.mx
DOI 10.5073/jka.2018.463.158

The rusty grain beetle (*Cryptolestes ferrugineus*) is one of the most common insect pest of stored products. Phosphine (PH_3) is a major fumigant used for treating various food commodities, and the wrong aplication has led to resistance to phosphine. The development of high levels of resistance to phosphine has been reported in México. For that reason, different doses and exposure times were used to control of *C. ferrugineus* in two stages, larvae, and adult. In a warehouse using a Grainbag (GrainPro®) with 50 kg of wheat (*Triticum aestivum* L.) as support. Three doses of phosphine were used, 1.4 gr/m^3, 2.8 gr/m^3 and 4.2 gr/m^3 and 3, 5 and 7 days to determine the proper dose and exposure time for control *C. ferrugineus*. An application of 2.8 gr/m^3 with 5 days could achieve 100% mortality in both stages.

Efficacy Studies on $ECO_2FUME^®$ Phosphine Fumigant for Complete control of *Sitophilus zeamais* and *Tribolium castaneum* in stored maize in Thailand

Abstract

$ECO_2FUME^®$ fumigation of maize bag stacks under gas proof sheets was conducted to establish the optimal dosages (application rate) and exposure times (fumigation period) against mixed-age cultures of *Sitophilus zeamais* and *Tribolium castaneum*. The Complete Randomized Design (CRD) experimental design was employed, with 3 replications and 4 treatments. The experiments were divided into three groups: 1) treatment with a 25 g/m^3 $ECO_2FUME^®$ application rate (350 ppm phosphine) for 3, 4, and 5 days and a control treatment; 2) treatment with an $ECO_2FUME^®$ application rate of 50 g/m^3 (700 ppm phosphine) for 2, 3, and 4 days and a control treatment; and 3) treatment with a 70 g/m^3 $ECO_2FUME^®$ application rate (1,000 ppm phosphine) for 1, 2, and 3 days and a control treatment. The three target phosphine concentrations of 350 ppm, 700 ppm and 1,000 ppm were maintained during the whole fumigation period. Results of the studies showed that no insect was alive at all dosages and exposure times. The studies also indicated that fumigation with $ECO_2FUME^®$ could reduce the fumigation period by increasing the phosphine concentration. The effective fumigation protocols on maize against mixed-age cultures of *S. zeamais* and *T. castaneum* were ECO_2FUME application rates of 25 g/m^3 for 3 days, 50 g/m^3 for 2 days and 70 g/m^3 for 1 day. The target phosphine concentration must be maintained throughout the fumigation period to achieve 100% mortality of all stages of insects.

Keywords: $ECO_2FUME^®$ phosphine fumigant, stored-product insects, *Sitophilus zeamais*, *Tribolium castaneum,* fumigation protocols, stored maize

1. Introduction

Maize is a primary ingredient of animal feed. Thailand's maize demand in 2016 was 5.85 million tons, which increased by 2.77% from 5.72 million tons in 2015. Because of the expansion of the livestock industry, demand for maize for animal feed increased. In 2016, Thailand exported 0.58 million tons of maize with total value of 4,855.34 million baht, a significant increase from 0.08 million tons with total value of 716.79 million baht in 2015. Maize production and value increased 7.25 and 6.77 times, respectively, because maize was increasingly exported to ASEAN markets including The Philippines, Indonesia and Vietnam (Office of Agricultural Economics, 2016).

For use as animal feed, maize must be stored for several months to sustain the continuous supply to the feed processors. When maize is stored at the production sites for a period longer than 3 months, insect infestation becomes a common and serious problem. The major insect pests that negatively affect the quality and quantity of stored maize in Thailand are *Sitophilus zeamais*, *Tribolium castaneum* and *Crytolestes ferrugineus* among others.

In Thailand, phosphine has been used as an effective fumigant to control several stored grain insect pests for more than 50 years (Sukprakarn et al., 1996). Formulations of phosphine available in Thailand are tablets or blankets of the metallic salts aluminium phosphide and magnesium phosphide that emit phosphine gas (PH_3) when exposed to air and moisture. Following application of tablets, concentration of PH_3 increases over several hours or days until all of the material is reacted. The increase rate of concentration depends on temperature and relative humidity. It is highly important to establish and maintain the most appropriate concentrations and exposure times in each particular situation. Precise dosing of PH_3 and the assurance of appropriate exposure times are difficult to achieve because of the dynamic release characteristics of the gas from tablet formulations and inherent structural leaks. There is the relative ease and safety in applying tablets to grain mass, but the influence of efficacy due to leaky structures may be a disadvantage (Banks, 1994; Bonjour, 1998).

$ECO_2FUME^®$ fumigant gas is a cylinderised formulation of PH_3 dissolved in liquid carbon dioxide at approximately 2% PH_3 and 98% CO_2 by weight. It is packaged in a high-pressure aluminium steel cylinder, with a net content of 31 kg of PH_3/CO_2 mixture and an equivalent phosphine amount of 620 g (Tumambing et al., 2012). $ECO_2FUME^®$ was established and approved in the U.S.A., which allows a shorter fumigation time of 24 hours for a 500 - 1,000 ppm phosphine concentration at 27°C or higher temperatures. The mixture of PH_3 and CO_2 is not flammable, which eliminates all safety concerns with the dispensing rate or dilution rate. Traditional solid formulations can generate PH_3 concentration above the lower flammability limit for PH_3 thereby creating a hazard (Cavasin et al., 2001).

There are several advantages when applying $ECO_2FUME^®$. The dose of $ECO_2FUME^®$ phosphine fumigant applied to the commodity is rapid delivery, easy maintenance of the required dose during the fumigation period, shorter exposures and ease of application. $ECO_2FUME^®$ does not require the applicator to enter the fumigation space. The ready-to-use cylinders can be dispensed from outside of silos or structures being fumigated. This eliminates the need for entry into confined spaces to apply fumigants and solid waste disposal (Bonjour, 1998; Phillips, 1998).

The controlled application of fumigant gas resulting in less fumigant was introduced in stored product instead of the traditional solid formulation. It relies on the generation of a high initial phosphine concentration followed by a slow deterioration to ensure that the phosphine concentration - time product (CT) - will result in an effective fumigation. With $ECO_2FUME^®$ fumigant gas, the concentration can be easily controlled by the applicator to maintain an efficacious concentration and can be precisely measured by adding the required amount of gas when needed. Disposal of solid waste products from tablets is becoming more difficult every day. $ECO_2FUME^®$ fumigant gas eliminates the concern associated with deactivating unspent metal phosphide residue and disposal of the waste product (Cavasin et al., 2001).

$ECO_2FUME^®$ is currently being considered for registration as an alternative to methyl bromide in Thailand by Genera Asia Co. Ltd. in 2011. Because $ECO_2FUME^®$ has never been used in Thailand therefore the study on this fumigant was needed.

The objective of this study was to establish the optimal dosages (application rate) and exposure times (fumigation period) of $ECO_2FUME^®$ phosphine gas for killing mixed-age of the major stored product insects in stored maize (*S. zeamais* and *T. castaneum*) in Thailand.

2. Materials and Methods

Test insects and preparation of mixed-age cultures

All insects of *S. zeamais* and *T. castaneum* used in this study were obtained from the stored-product insect colonies maintained at the Post-harvest and Processing Research and Development Division of the Thailand Department of Agriculture. The mixed-age cultures were prepared by adding 50 young adults (2-3 week olds) of each species (*S. zeamais* and *T. castaneum*) into a glass bottle

containing 200 g of a culture medium which was different for each species; brown rice for *S. zeamais*, rice bran for *T. castaneum* and covered with filter paper for 3 weeks. Afterwards, all adults were removed and kept in the laboratory for 4 weeks at 30±2°C temperature and 65±5% relative humidity before fumigation. All life stages were examined for their presence in the mixed-age culture glass bottle prior to fumigation.

Fumigant

$ECO_2FUME^®$ phosphine fumigant is a product of Solvay's Niagara Falls, Canada, facility (known by its legal entity name, Cytec Canada).

Fumigation of mixed-age cultures

The experiment was conducted in a concrete warehouse of Bangkok Food Products Co., Ltd. (CPF), located at the Phra Bhuttabat district, Saraburi province, Thailand, in 2014. Maize used for the trials was packaged in jumbo bags (1,000 kg capacity). The concrete floor was thoroughly cleaned, and black polyethylene floor sheets (0.5 mm thickness) were then laid out on the ground as an under-layer sheet. For construction of the stack, 8 jumbo bags of maize were piled on the floor sheet. Stack sizes were between 6.7 to 7.5 m^3. A cage of mixed-age test insects in a culture medium was placed into the maize jumbo bag on top of the stack. Each maize stack with test insects was then covered with a clear polyvinyl chloride (PVC) sheet (0.2 mm thickness) to construct fumigation enclosures. The fumigation sheet was then sealed to the floor with sand snakes (cotton bags of 100 cm x15 cm filled to 80% with sand). Considerable attention was given to the sealing operation to ensure that the fumigation sheet was neatly folded, without wrinkles, that it extended at least 1 meter away from the stack edges, and that overlapping sand snakes were laid in double rows at the corners. This type of setup was taken to ensure minimum gas leakage.

Efficacy trials were designed in Complete Randomized Design (CRD) with 3 replications and 4 treatments. The experiments were divided into 3 groups:

1) Treatment with a 25 g/m^3 $ECO_2FUME^®$ application rate (350 ppm phosphine equivalent) for 3, 4, and 5 days, and a control treatment (untreated).

2) Treatment with a 50 g/m^3 $ECO_2FUME^®$ application rate (700 ppm phosphine equivalent) for 2, 3, and 4 days, and a control treatment.

3) Treatment with a 70 g/m^3 $ECO_2FUME^®$ application rate (1,000 ppm phosphine equivalent) for 1, 2, and 3 days, and a control treatment.

The required amount of phosphine from $ECO_2FUME^®$ was injected inside the trap using a stainless steel hose and a gas injector with a gas flow rate of 6.85 kg/min. The exact amount of dispensed $ECO_2FUME^®$ was determined by the weight change of the cylinder on the top of a 100-kg digital scale with an accuracy of 0.01 kg or 10 g.

Monitoring of gas concentration

Phosphine concentration was monitored at each of the following intervals: 1) 1 and 18 hours for a 1-day exposure time; 2) same as item 1 plus 24 and 42 hours for a 2-day exposure time; 3) same as item 2 plus 48 and 66 hours for a 3-day exposure time; 4) same as item 3 plus 72 and 90 hours for a 4-day exposure time; and same as item 4 plus 96 and 114 hours for a 5-day exposure time. Three target phosphine concentrations of 350 ppm, 700 ppm and 1,000 ppm were maintained during the whole fumigation period. When the phosphine concentration fell below the target concentration, $ECO_2FUME^®$ was topped up to bring back the concentration at or above the target concentration. Phosphine concentration was monitored with calibrated SILOCHEK phosphine monitor (0 - 2000 ppm).

Fumigation was terminated at 1, 2, 3, 4 and 5 days of exposure time, followed by aeration of the slightly opened enclosure until the phosphine concentration reached the threshold limit value (TLV)

of 0.3 ppm or lower. The plastic cover sheet at each of the treatment stacks was completely removed afterwards.

Assessment of insect mortality

Effectiveness of $ECO_2FUME^®$ against the test insect was determined by mortality of mixed-age cultures. After fumigation, the glass bottles with the test insects were retrieved from each stack and the mortality of adults from each experiment was recorded. Dead and alive insects were separated, and each culture medium was returned to the bottles and kept in the laboratory at 30±2°C and 65±5% for 6 weeks. The bottles were observed weekly to determine if any newly emerged adults surfaced from hatched eggs. This period was sufficient for emergence of all insects in the treatment as well as the control. The occasional dead insect from the control treatment was corrected by Abbott's formula (Abbott, 1925).

Monitoring of temperature, relative humidity and moisture content

The temperature and relative humidity in the warehouse were monitored by a thermo-recorder every day during the fumigation period. The moisture contents of maize were measured before and after the treatment by applying the samples to a SB 900 Steinlite moisture meter.

3. Results

The effectiveness of $ECO_2FUME^®$

The effectiveness of $ECO_2FUME^®$ fumigation at different concentrations and exposure periods against mixed-age cultures of *S. zeamais* and *T. castaneum* are shown in Table 1. Results indicated that both insect species were completely controlled (100% mortality), and no live insects were observed immediately after fumigation or throughout the 6 weeks of monitoring. The test insects in the non-fumigated control samples continued to develop and emerged normally.

All of the application rates (25, 50 and 70 g/m³ $ECO_2FUME^®$) at any exposure time in each experiment were equally effective against mixed-age cultures of the two insect species in maize fumigation.

The concentration of phosphine

The phosphine concentration profile on the maize stack fumigated with 25g/m³ $ECO_2FUME^®$ at 3, 4 and 5 days of exposure time is shown in Figure 1. One hour after gas injection, the phosphine

concentration at 3, 4 and 5 days inside the maize stacks were 677, 682 and 527 ppm, respectively. The higher phosphine concentration compared to the target concentration was due to the phosphine gas initially occupying only the free space inside the stack. As the calculation of $ECO_2FUME^®$ dose is based on total empty space volume, the free space volume becomes smaller due to volume occupied by the maize stacks. Phosphine gas will then penetrate through the whole maize stack until equilibrium concentration is reached. After fumigation for 18 hours, the concentrations decreased and dropped down to 302, 318 and 282 ppm, respectively, indicating the distribution of phosphine gas in the entire maize stack. There was high fluctuation in the phosphine concentration inside the maize stack due to the addition of $ECO_2FUME^®$ to maintain the target phosphine concentration.

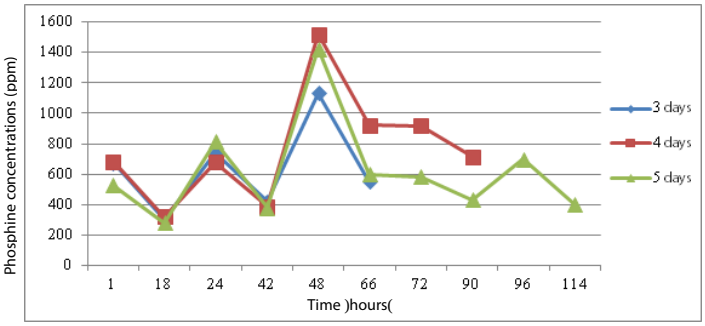

Fig. 1 Average phosphine concentrations inside the maize stacks during fumigation at the different times with $ECO_2FUME^®$ dosage 25 g/m³ (350 ppm).

The phosphine concentration curves of maize stack treated with 50 g/m³ $ECO_2FUME^®$ at 2, 3 and 4 days of exposure periods, as shown in Figure 2, display similar variations of phosphine concentrations with the treatment at 25 g/m³ $ECO_2FUME^®$. The phosphine concentration was below the target concentration after fumigation for 18 hours.

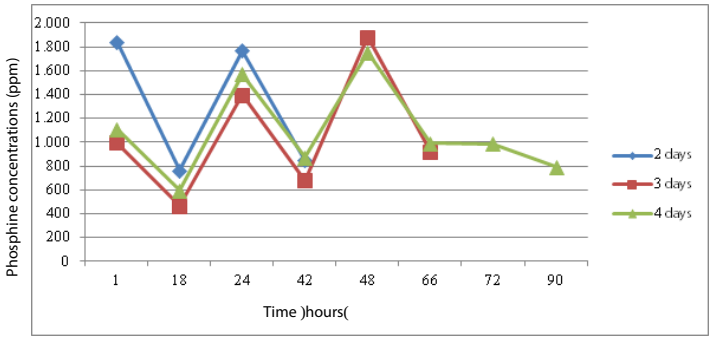

Fig. 2 Average phosphine concentrations inside the maize stacks during fumigation at the different times with $ECO_2FUME^®$ dosage 50 g/m³ (700 ppm).

The phosphine concentration profile of maize stacks fumigated with 70 g/m³ $ECO_2FUME^®$ at 1, 2 and 3 days of exposure periods is shown in Figure 3. The variation of phosphine concentration of this treatment was quite similar to the treatment with 25 g/m³ $ECO_2FUME^®$ in that the phosphine concentration reduction from an initial concentration of 2000 ppm almost hit the target concentration of 1000 ppm after a fumigation period of 18 hours.

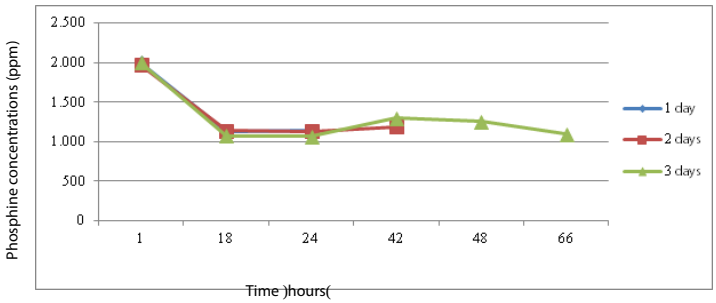

Fig. 3 Average phosphine concentrations inside the maize stacks during fumigation at the different times with $ECO_2FUME^®$ dosage 70 g/m³ (1,000 ppm).

Maintenance of target concentration

As shown in Table 2, there was addition of $ECO_2FUME^®$ conducted at 18 hours and 42 hours for the 3 days and 4 days of fumigation, and at 18, hours, 42 hours and 92 hours for the 5 days of fumigation as top up procedure. This was to maintain the target phosphine concentration at 350 ppm. Every time top up was done, the phosphine concentration was much higher than the target concentration due to the initial occupancy of free space by the gas before equilibrium distribution is reached.

In case of the treatment with 50 g/m³ $ECO_2FUME^®$ (700 ppm phosphine), Table 3 shows that top up was required at 18 hours for the 2 day fumigation, and at 18 hours and 42 hours for 3 and 4 day fumigation. For the treatment with 70 g/m³ $ECO_2FUME^®$ (1000 ppm phosphine), Table 4 shows that there was no top up needed for one day fumigation, and top up was required at 18 hours for the 2 and 3 day fumigation but there was an inconvenient in this experiment, therefore, the top up was done after fumigation for 24 hours instead of 18 hours.

The need for top up meant that maize used in the experiment absorbed some of the phosphine gas inside the stack, which caused the reduction of the phosphine concentration during the fumigation period. In this study, maize could absorb up to 40% of the initial phosphine concentration. As the gas absorption continues during fumigation, the amount increases as the fumigation period is increased. When the phosphine concentration fell below the target concentration, top up of $ECO_2FUME^®$ dosing was conducted to bring back concentration at or above the target concentration. With the ability to safely top up the stacks with $ECO_2FUME^®$, the desired concentration was maintained.

Monitoring of temperature, relative humidity and moisture content

The moisture content of maize was 13.2-13.8%. Temperature and relative humidity ranges inside the stacks were 29 - 35°C and 43 - 66%, respectively.

4. Discussion

Fumigation with ECO_2FUME® could reduce the fumigation period by increasing the phosphine concentration. The effective ECO_2FUME® fumigation protocols on maize against mixed-age cultures of *S. zeamais* and *T. castaneum* were 25 g/m³ (350 ppm phosphine) for 3 days, 50 g/m³ (700 ppm phosphine) for 2 days, and 70 g/m³ (1,000 ppm phosphine) for one day.

The phosphine target concentration must be maintained throughout the fumigation period to achieve 100% mortality of all stages of insects. It is necessary to monitor phosphine concentrations during fumigation. If the concentration of phosphine is not regularly monitored during the entire exposure period, the fumigation will be ineffective. Therefore, it is best fumigation practice to monitor the concentration of fumigant inside the sealed stack regularly to keep the phosphine concentration at the recommended minimum concentration.

Abstract

The development of phosphine resistance in storage insect pests is now problematic, so the increase of rate and frequency of phosphine fumigation in a storage room is needed. However, an adverse effect on seed germination, and human hazard needs to be tested. This experiment was aimed to find the most suitable methods used in combination with phosphine fumigation to reduce the risk of phosphine exposure. The treatments were (1) phosphine fumigation for 7 days and then open a plastic cloth (2) phosphine fumigation for 7 days and continue to cover a plastic cloth (3) phosphine fumigation for 7 days and spray pirimiphos methyl on sack (4) phosphine fumigation for 7 days and use a light trap (5) treat seeds with sweet flag powder before phosphine fumigation for 7 days (6) no phosphine fumigation with plastic cloth opening and (7) no phosphine fumigation with plastic cloth covering. In each treatment, seeds were sampled every month for 12 months to determine seed quality and insect populations. The results showed that seeds treated with sweet flag powder and fumed with phosphine for 7 days can significantly control storage rice insect pests in the first and the second year of experiments. The seed moisture content in each treatment changed in a similar pattern throughout 12 months storage in both years (13.4 – 13.7%). The seed germination showed similar results (more than 80% after 6 months storage), except the treatment of 7 days phosphine fumigation with plastic cloth covering which resulted in a slowly decline in germination. Seed weight losses and numbers of insect pests in the treatment with sweet flag powder were significantly less than the others.

Introduction

Storage rice insect pests are the main cause of rice seed damage and deterioration by eating of seeds by both larvae and adults (Kaewnango et al., 2016). It also makes the amount of innert matter increases causing deterioration of seed quality and interferes in the standardization of grain types (Visarathanon et al., 2005). Particularly, the damage of the foundation seed from insect pests can affect the production of registered seed and certified seed. Phosphine fumigation is the most popular method for preventing insect pests damage to rice seeds after harvesting because it can kill insects at all stages of growth, no toxic residue and easy to operate. Phosphine fumigation under a sealed canvas for 7 days can kill insects at all stages of growth but if not used properly, it can cause insect resistance (Bullen, 2007). Increasing the frequency of use and rate of phosphine is a way to solve the problem of insect resistance; however, this method is not only harmful to the users, but also can impact on seed germination. So finding a safe way to undertake phosphine fumigation for control storage rice insect pests is probably a good solution to this problem. In addition to reducing the cost of seed storage, it also protects farmers from the toxic residues of phosphine in rice seeds.

Materials and Methods

A two - year experiment was conducted at Pattani Rice Research Center, Rice Department, Thailand, with Randomized Complete Block Design (RCBD) of 4 replications. The details of the operation are as follows.

Foundation seeds of Leb Nok Pattani variety packed in 60 kilograms of jute sacks was used as test specimens.

Testing of insect pests control in rice seeds, which was prepared with 7 treatments include:

1. Phosphine fumigation of 7 days and open plastic cloth
2. Phosphine fumigation of 7 days and cover plastic cloth

3. Phosphine fumigation of 7 days and spray pirimiphos methyl on sack
4. Phosphine fumihation of 7 days and use light trap
5. Treat seed with sweet flag powder and fumigant phosphine for 7 days
6. No fumigation with open plastic cloth (control)
7. No fumigation with cover plastic cloth (control)

Placing of rice seeds that was tested with each treatment in the storage shed for 12 months. Each month, about 1 kilogram of rice seeds was sampled for the following purposes:

- 500 grams for identification of insect pest species and recording their numbers
- 250 grams for moisture content measurement
- 50 grams for counting and weighing of normal seeds and broken seeds to calculate percentage of weight losses by insect damage from the formula of Adams (1976)
- 400 seeds for germination test

Statistical analysis and Duncan's Multiple Range Test (DMRT) comparison.

The experiment of the first year was conducted during May 2014 to April 2015 and May 2015 to April 2016 in the second year.

Results

The effect of using phosphine fumigant with other methods for control storage rice insect pests

The number of storage rice insect pests found in rice seeds from some treatments was highly significantly ($p < 0.01$) in both years. The best treatment for insect pests control was found to be treating seeds with sweet flag powder and fumigation with phosphine for 7 days, as supported by the results of the lowest number of insect pests recorded in seed samples: 602.3 and 625.5 insects/500 grams seeds, in the first and second year, respectively. The second most successful treatment of seed was phosphine fumigantion for 7 days and sprayed with pirimiphos methyl on sack and phosphine fumigantion for 7 days and covered plastic cloth, respectively. While phosphine fumigantion for 7 days and opened plastic cloth was effective in the first year only. We found that phosphine fumigantion for 7 days and use of light trap was not able to control insect pests in both years (Tab. 1)

Rice seed quality

The seed moisture content in each treatment changed similarly throughout 12 months storage in both years **(**13.4 **-** 13.7%). The seed germination showed similar results **(**more than 80% after 6 months storage**)** except the treatment of 7 days phosphine fumigation with plastic covering which result in slowly declined germination**.** Seed weight losses and number of insect pests in the treatment with sweet flag powder were significantly less than the others**.**

Discussion

From the results which showed that seeds was treated with sweet flag powder and fumed with phosphine for 7 days was the best treatment for control storage rice insect pests because essential oils (acalamol aldehyde) in the rhizomes of sweet flag which is toxic to the nervous system of insects. It also has the effect of repelling, inhibit eating and inhibit the reproduction of insects. (Supawan, 2014) Whereas Paneru *et al*. (1997) studied on wheat seeds treated with sweet flag powder for control storage rice insect pests which found that wheat seeds was treated with 2% w/w of sweet flag powder could control 100% of adults of rice weevil (*Sitophilus oryzae* Linnaeus) and grain weevil (*Sitophilus granaries*) within 7 days. In addition, Shuka *et al*. (2009) also found that chick peas seeds that was treated with 0.3 - 0.4 mg/g of sweet flag powder could decrease oviposition and egg hatchability of southern cowpea weevil (*Callosobruchus sinensis* Linnaeus) and seed germination remained 100% after 6 months.

In this study, efficacy of local diatomaceous earths (DE) collected from different regions of Turkey against stored grain insects, *Sitophilus oryzae* (L.), *Tribolium confusum* du Val. and *Rhyzopertha dominica* (F.), was investigated. For this purpose, biological tests were carried out at concentrations of 500 and 1000 ppm (mg DE / kg wheat) of 9 local diatomaceous earths and one commercial diatomaceous earth, namely Silicosec® as positive control at 25 ± 1 ° C temperature and 65 ± 5% relative humidity in wheat. In addition, the studies on some of the chemical and physical analysis of the tested diatomaceous earths (silicon dioxide (SiO_2) ratio, particle size and adhesion rate on commodity) were also conducted. In biological tests conducted at 500 ppm concentration for 14 days of exposure in wheat the highest mortality rates (97 to 98%) of *S. oryzae* adults were recorded in CB2N-1, AGN-1 and BGN-1 diatomaceous earths, while the highest mortality rates of *T. onfusum* adults were obtained from only AGN-1 and BGN-1 diatomaceous earths. In the case of *R. dominica*, the highest mortality rate (64.4%) was recorded only in CB2N-1 diatomaceous earth. At concentration of 1000 ppm for 14 days of exposure in wheat, 100% mortality of *S. oryzae* adults was observed in all tested local diatomaceous earths except FB2N-1 and Silicosec® while mortality rates of *T. confusum* adults ranging from % 95 to %100 were obtained in all tested local diatomaceous earths except FB2N-1, FBN-1 and Silicosec®. In the case of *R. dominica* adults, mortality rates ranging from 80% to 93% were recorded in CB2N-1, CCN-1 and AG2N-1 diatomaceous earths. In conclusion, laboratory bioassays indicated that CB2N-1 and BGN-1 local diatomaceous earths had high efficacy against *S. oryzae*, *T. confusum* and *R. dominica* adults and thus could be potential to be successfully used for controlling stored grain insect pests as a grain protectant.

Key Words: Turkish diatomaceous earth, wheat, Sitophilus oryzae, Tribolium confusum, Rhyzopertha dominica

Introduction

Stored products and especially grains and their by-products are the most important durable food category for human nutrition. During storage, these commodities are attacked by a numerous pests, particularly insect species, known as stored product pests, which cause very serious quantitative losses and qualitative degradations. Apart from the direct infestation *per se*, the presence of these pests and the substances that they produce may seriously endanger human health. In these commodities, which are also known as durable stored products, residual contact insecticides and fumigants are currently used as the main way to avoid insect infestation. Nevertheless, most of these pesticides are very toxic to mammals, and some of them leave dangerous residues on the product which may accumulate in the human body through the food chain. Moreover, most major insect species are now resistant to many of these pesticides, while some of these substances, such as methyl bromide, are extremely dangerous for both human health and the environment. Methyl bromide was thus banned by 2005 in industrialized countries according to the Montreal protocol, and it is expected to be completely withdrawn from the developing countries until 2015 (Bell 2000). Therefore, there is an urgent need to evaluate alternatives to traditional pesticides, which will have low mammalian toxicity, will be cost-effective and will be environmentally-compatible.

One of the most promising alternatives over the use of traditional pesticides in durable stored products is the use of diatomaceous earths (DEs). DEs are composed by the fossil skeletons of phytoplanktons, also known as diatoms, which occur in fresh and salt water since the Eocene period

and produce a soft sedimentary rock, which is composed mainly by amorphous silica ($SiO_2 + H_2O$). The DEs currently mined vary remarkably in their insecticidal activity, depending upon species composition, geological and geographical origin as well as certain chemical characteristics, such as SiO_2 content, pH and tapped density (Korunic 1997). DEs are probably the most efficacious natural resource-based dry materials that can be used as insecticides (Korunic 1998). DEs act in the insects' exoskeleton (cuticle) causing rapid desiccation resulting in death through water loss. They are non-toxic to mammals (rat oral LD_{50}>5000 mg/kg of body weight), leave no toxic residues on the product and according to the US EPA they are classified in the category of GRAS (Generally Recognized As Safe) since they are used as food or feed additives (FDA 1995). Moreover, they are used as insulating materials against both heat and sound, as explosive additive, as well as in filters for beverages such as beer or fruit juice and abrasives in tooth paste (Korunic 1998). Finally, DEs are completely compatible with organic food production (Subramanyam and Roesli 2000). Regarding their insecticidal use, DEs can be applied with the same application technology with traditional grain protectants, which means that no specialized equipment is required (Athanassiou et al. 2005). Moreover, since they are inert (silicaceous) materials, no interaction with the environment occurs. Thus, DEs persist in the treated substrate, providing a long-term protection against pests, which is currently a ''red flag'' for the use of conventional pesticides.

Several DEs, based on natural deposits, are now commercially available, and have proved very effective against stored grain pests (Subramanyam and Roesli 2000, Athanassiou et al. 2011). However, the investigation for newer, naturally-occurring DEs that are more effective in insect control is still in progress, especially in areas rich to silicaceous rocks. Korunic (1997, 1998) in an extensive screening of DEs from several parts of the world, found that local DEs from the Former Yugoslavia were very effective, and could be used with success against stored-grain pests. Similar results have been reported by Indic et al. (1998) for certain DEs from Serbia. An extensive screening by Athanassiou et al. (2011) also illustrated the presence of several DE deposits that have certain insecticidal properties from Croatia, Serbia and Slovenia. The DEs of this area have been used in the past for several applications, including their use as insecticides, and some of them are now the main ingredients in commercially available formulations. For instance, an amorphous silica DE from the Former Yugoslavia Republic of Macedonia (FUROM) is the main ingredient for the DE formulation Protect-It (Hedley Technologies, Canada), which is one of the most commonly used DE-based insecticides worldwide (Fields and Korunic 2000).

Based on the first evidence and preliminary samplings, it seems that Turkey is considered to have rich natural DE deposits, and there is clear evidence for the existence of large DE deposits at some areas in Turkey (Özbey and Atamer 1987, Mete 1988, Sıvacı and Dere, 2006, Çetin and Taş 2012). The European continent has the richest reserves in terms of diatomite reserve in the world and America has been following it. Diatomite reserve of Turkey is about 125 million tons. Hırka (Kayseri) known in Turkey has the largest diatomite reserve (106 million tons) (Çetin and Taş 2012). However, there is no information on the efficiency of local DEs from these areas in Turkey against stored grain insects. The objective of this study was to determine the physiochemical properties of the local DE deposits in Turkey and their efficacy against several stored grain insects.

Materials and methods

Test insects:

The rice weevil, *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae), adults used in the bioassays were taken from a culture that was kept in the laboratory on whole wheat at 26 ± 1ºC, 65 ± 5 % relative humidity (RH) whereas the lesser grain borer*, Rhyzopertha dominica* (F.) (Coleoptera: Bostrychidae), adults were taken from a culture kept on whole wheat 29 ± 1ºC, 65 ± 5 % RH. The confused flour beetle*, Tribolium confusum* du Val (Coleoptera: Tenebrionidae), adults were obtained from cultures reared in 1 l glass jars at 25 ± 1°C and 65± 5 % relative humidity (RH) on a diet of wheat flour mixed

with dry brewer's yeast (17:1, wt:wt) using standard culture techniques. All individuals used in the tests were < 2 week old.

Wheat variety

Untreated, clean, with very little dockage (0.8%) and infestation-free wheat (*Triticum aestivum* L., variety of Elbistan Yazlığı) was used for experimentation. One gram of wheat variety tested corresponds to 21.3 seeds. The moisture content of the three products, as determined by a Dickey-John moisture meter (Dickey-John Multigrain CACII, DICKEY-John Co., Lawrence, KS), ranged between 11.0 and 11.4%.

Sampling, collection and preparation of local diatomaceous earths

In biological tests, diatomite earths with code of CCNA-1, CB2N-1 (Çankırı province), AGN-1, ACN-1, AG2N-1 (Ankara province), BGN-1, BHN-1 (Kayseri province), FB2N- 1 and FBN-1 (Aydın province) collected from different regions of Turkey and commercial DE, namely Silicosec® (Biofa Company-Germany) were used in the biological tests. In each DE reserve, 10 DE samples with 500 gr were randomly taken from different points of DE reserve. At least totally 5 kg DE sample was taken from each DE reserve. The DE samples were cut into small pieces with the aid of a hammer and placed in metal trays and then dried at a temperature of 100 ± 10ºC for 24 hours in a ventilated oven (MEMMERT UN75, Germany) to a moisture content of 3-5%. After drying, small pieces of DE samples were ground in a laboratory mill at full speed for 10 sec. All samples were then shifted through a standard sieve of 149 µm. After these DE process, final DE product called as natural DE deposit was used in the biological tests.

Physical and chemical determination of local diatomaceous earths:

The adherence percentage of DEs on wheat kernels was determined. The cleaned 500 g sample of wheat grain was then mixed by hand (by shaking) with 1000 ppm of DE (1 g/kg, or 0.5 g/500 g) in a tightly closed glass jar for 1 min. Treated grain was then sieved thoroughly using laboratory sieve No. 10 (2 mm openings) with a lid and bottom, for 1 min by hand to separate dust from the grain. The sieve, with closed lid and bottom, was left undisturbed after sieving for at least 1 min. The dust collected in the bottom of the sieve was then measured with a precision balance (mg). The weight was subtracted from 500 mg, and the value was expressed as a percentage of adherence of DE on the wheat kernel. Particle size distribution of the diatom earths were determined using the Laser Diffraction Method Silicon dioxide (SiO_2) ratio was measured by dissolution in acid and Atomic Absorption Spectroscopy (AAS) method. These analyzes were carried out in the accredited Analysis Laboratory of the General Directorate of Mineral Research and Exploration (MTA).

Bioassays procedures:

The tested insect species were the adults of three major stored grain pests, *S. oryzae*, *R. dominica* and *T. confusum*. The bioassay protocol was 3 X 3 replicates (each series of tests was repeated three times, by preparing new lots each time). In this series of tests, the DEs was applied in 1-kg lots of soft bread wheat (*Triticum aestivum* L., variety of Elbistan Yazlığı) with 11% moisture content (m.c) at the DE dose rates of 500 and 1000 ppm (one lot per dose). The grain was left previously for 7 d at the appropriate conditions to equilibrate with the desired relative humidity levels. Based on the standard procedure, the lots were placed in glass jars, and shaken manually for approx. 3 min., to achieve equal distribution of the DE dust to the entire grain mass. There was an additional series of lots with untreated grain which serve as a control. Then, 3 samples, of 50 g each, were taken from each lot, and these samples were placed in small glass vials, which were closed, apart from a 1.5 cm hole at the top, covered with fine mesh for ventilation. After this procedure, 30 mixed sex adults, <15 d old were placed in each lot. The lots were placed in incubators set at 25±1 °C temperature and 65±5% RH. The mortality was assessed after 7 and 14 d of exposure in the treated substrate.

Data processing and analysis:

For tested three species, the control mortality was very low, but where it was considered necessary the mortality counts were corrected by using the formula of Abbot (1925). The data were analyzed, separately for each species, by using the GLM Procedure of SAS (SAS Institute 1995), with insect mortality as the response variable and type of DE formulation and dose rate, as the main effects. Means were separated by using the Least Significant Difference (LSD) test at $P<0.05$.

Results and Discussion

Laboratory analysis results showed that there were significant differences in the SiO_2 ratio of the local diatomaceous earths collected from different regions of Turkey. The highest SiO_2 ratio was obtained from the local diatomaceous earths collected from Aydın (FB2N-1) and Kayseri (BHN-1) province. The particle size of all local diatomaceous earths except FBN-1 diatomaceous earths ranged from 12.31 to 20.05 µm, while the particle size of the commercial formulation of Silicosec® was 12.51 µm. Adherence rates of FB2N-1, ACN-1, BHN-1, CCN-1 and Silicosec® diatomaceous earths on wheat kernel were found to be 89% or <89% while adherence rates of AGCN-1 and FBN-1 diatomaceous earth ranged from 80% to 89%. In the adherence test no diatomaceous earths had an adherence rate below 75%.

In biological tests conducted at 500 ppm concentration for 7 days of exposure in wheat the highest mortality rates of *S. oryzae* and *R. dominica* adults were obtained from CB2N-1, AGN-1 and CCN-1 diatomaceous earths while the highest mortality rates of *T. confusum* were recorded in CB2N-1, AGN-1, ACN-1 and CCN-1 diatomaceous earths. After 14 days of exposure at 500 ppm concentration, the highest mortality rates (97 to 98%) of *S. oryzae* adults were recorded in CB2N-1, AGN-1 and BGN-1 diatomaceous earths, while the highest mortality rates of *T. onfusum* adults were obtained from only AGN-1 and BGN-1 diatomaceous earths. In the case of *R. dominica*, the highest mortality rate (64.4%) was recorded only in CB2N-1 diatomaceous earth. At concentration of 1000 ppm for 7 days of exposure in wheat, mortality rates of *S. oryzae* adults ranging from 92% to 100% were found in CB2N-1, AGN-1, CCN-1, ACN-1, AG2N-1 and BGN-1 diatomaceous earths while mortality rates of *T. confusum* adults ranging from 86% to 98% were detected in AGN-1, CCN-1 and AG2N-1 diatomaceous earths. After 14 days of exposure at 1000 ppm concentration, 100% mortality of *S. oryzae* adults was observed in all tested local diatomaceous earths except FB2N-1 and Silicosec while mortality rates of *T. confusum* adults ranging from % 95 to %100 were obtained in all tested local diatomaceous earths except FB2N-1, FBN-1 and Silicosec. In the case of *R. dominica* adults, mortality rates ranging from 80% to 93% were recorded in CB2N-1, CCN-1 and AG2N-1 diatomaceous earths. In this study, it was determined that *S. oryzae* adults were more susceptible to tested diatomaceous earths than *T. confusum* and *R. dominica* adults. Whereas the susceptibility of *T. confusum* and *R. dominica* to tested diatomaceous earths was found to be mostly similar.

Conclusion

Laboratory bioassays indicated that CB2N-1 and BGN-1 local diatomaceous earths had high efficacy against *S. oryzae*, *T. confusum* and *R. dominica* adults and thus could be potential to be successfully used for controlling stored grain insect pests as a grain protectant.

DOI 10.5073/jka.2018.463.162

In this study, mortality effects of BGN-1 which is local diatomaceous earths, were investigated against adults of German cockroach (*Blatella gemanica* (L.)) on concrete, ceramic floor tile and laminate flooring. On these three different surfaces, *B. germanica* adults were exposed to BGN-1 diatomaceous earth at the doses of 2.5, 5, 10, 20 g/m^2 along 6 days. In all surface applications of BGN-1 diatomaceous earth, exposure time and dose caused significant effect on mortality rates of *B. germanica* adults. It was determined that BGN-1 coded Turkish diatomaceous earth has the lowest mortality effect on all application surfaces at the dose of 2.5 g/m^2. 2.5 g/m^2 BGN-1 caused 100 % mortality after 6 days concrete surface and caused 100 % mortality at the end of the fourth day on ceramic floor tile and laminate flooring. On the other hand, doses of 5 and 10 g/m^2 of BGN-1 caused 100% *B. germanica* mortality on all surfaces at the end of the second day, while the highest dose of 20 g /m^2 of BGN-1 reached 100% *B. germanica* mortality at the end of the first day on all application surfaces. In general, the mortality activity of BGN-1 diatomites against *B. germanica* adults was found to be similar on all three surfaces. At the end of this study, local diatomaceous earth coded BGN-1 was found to be good alternatives for controlling *B. germanica* which is a medical pest insect.

Keywords: Turkish diatomaceous earth, *Blatella germanica*, surface application.

Introduction

The German cockroach is commonly found living area with people and scattered all over the world. It is also a major carriers of pathogens and main source of allergens. Therefore it is an important primary medical and economical insect pest. The cockroach is mainly controlled by synthetic insecticides (Rust et al., 1993). However, this cockroach widely developed resistance to these

insecticides (Jialin et al., 2007). Hence, the development of new types of selective cockroach-control alternatives are needed.

Diatomaceous earth (DE) is a component of organic origin and is a precipitate formed from the fossilized siliceous shells of algae that have lived in all aquatic ecosystems. The cell walls of the algae are amorphous cystite (SiO2 + H2O). Recent studies have shown that DE has a significant impact on warehouse pests (Waksh and Shabbir, 2005; Athanassiou et al., 2007). In addition to the insecticidal effect of DE, it can be used as filtration, absorbant, filling material in the industry, silicon reinforcing in humans, and as a moisture retainer in the packaging of nutrients (Durmuşkaya, 2009). Diatomaceous earth is probably the most effective of the natural powders that can be used as insecticides. The insecticidal effect of diatomaceous earth is regarded as a method of physical struggle because it does not have a chemical effect on insects. This physical struggle; DE has an effect on the insect cuticle and results in death of the insect's water loss (Ebeling, 1971). DE, besides its water absorber feature, can also abrade the oil quite well. For this reason it is also very effective on the protective waxy layer present on the insect cuticle. As a result, death in insects occurs due to water loss and drying (Cloarec et al., 1992).

Furthermore, the killing effect of insects may vary significantly depending on the test conditions used, the diathermy (marine or freshwater diatoms), the geographical area taken, the formulation process, the oil absorption capacity and the chemical / mechanical modification of the diatomaceous earths (Faulde ve ark., 2006). Therefore, in this study, mortality effects of BGN-1 which is local diatomaceous earths, were investigated against adults of German cockroach (*Blatella gemanica* (L.)) on concrete, ceramic floor tile and laminate flooring.

Materials and Methods

Insect

Colonies of *B. germanica* were reared in plastic containers (60 liter) and maintained at room temperature. The cockroaches were provided with water in glass tubes with cotton stoppers and dry dog food. Each container was provided with paper egg cartons as shelter. The adult cockroaches (5-10 days old) were tested for each bioassays at 25 (± 2) ºC and 50 (±5) % relatıve humidity.

Local diatoms used in biological tests:

In this study, BGN-1 coded local diatoms from Kayseri/Turkey province were used. At least 5 kg samples were taken from the diatom reserve. The samples were mixed in the gutters and brought to the laboratory. The diatom specimen brought in rock form is prepared in natural form. For natural (natural) preparation of the diatom specimen, it was dried at 100 ± 10 ° C for 2 hours, until it had a 3-5% moisture content in a controllable ventilated oven. After drying, the small pieces were grinded in a laboratory mill for 10 seconds at the highest speed. All samples were then sieved through a 100 mesh (149 µm) standard sieve and the damp, soft small pieces left under the sieve were dried in a ventilated oven at 40 ° C for 24 hours. Thus, natural powdered diatomaceous earth of a particle size of 149 microns or less is obtained.

Surfaces used in biological tests

During the test, concrete, ceramic, parquet surfaces were prepared in plastic boxes (100x100x60 mm) and ventilation holes were opened with the help of a needle to the cover parts of plastic boxes in order to provide air in and out during the established tests.

Concrete Surface: The mortar obtained by using 200 g + 50 ml water was poured into plastic boxes (100x100x60 mm) and the mortar was obtained by drying.

Ceramic Substrate: The ceramic surfaces used during this work were produced from a mixture of clay, kaolin, quartz, feldspar and limestone in sizes of 150x150x5.5 mm according to TS202 standards. The ceramic surfaces produced in TS202 standards are reduced in dimensions of 100x100 mm and working dimensions are obtained.

Parquet Substrate: Laminated parcels which are manufactured according to the standards of High Density Fiberboard (HDF) and 717 E-1 are 8x195x1200 mm in size and 100x100 mm in size and working dimensions are obtained.

Biological tests and test method

Biological tests were carried out in the climate chamber with 25 ± 1 ° C and 65 ± 5% relative humidity. Water and feed were not given to insects during the experiment and insects were exposed to 2.5, 5, 10, 20 g / m2 doses of diatomaceous earth. Diatomaceous earth weighed with the aid of precision scales for dosing experiments is placed on concrete, ceramic and parquet surfaces. After the diatomaceous earth was distributed on the surface, ten newborn individuals from *B. germanica*, which we cultured in the laboratory environment, were left. The experiments were carried out in four replicates, with 10 individuals each time. The control unit was also set up in four replications and no diathermy was applied, such as water and feed. Dose experiments were taken into the climate chamber as soon as the establishment was established and dead-live insects were counted for six days. For the time trials, 6, 9, 12, 18, 24 hour experiments were set up as separate treatments, keeping the highest dose rate constant during the dose trials, thus setting up separate control units for each exposure period. The time experiments were carried out again with four repetitions and 10 individuals each time.

Conclusion

In all surface applications of BGN-1 diatomaceous earth, exposure time and dose caused significant effect on mortality rates of *B. germanica* adults. It was determined that BGN-1 coded Turkish diatomaceous earth has the lowest mortality effect on all application surfaces at the dose of 2.5 g/m^2. 2.5 g/m^2 BGN-1 caused 100 % mortality after 6 days concrete surface and caused 100 % mortality at the end of the fourth day on ceramic floor tile and laminate flooring. On the other hand, doses of 5 and 10 g/m^2 of BGN-1 caused 100% *B. germanica* mortality on all surfaces at the end of the second day, while the highest dose of 20 g /m^2 of BGN-1 reached 100% *B. germanica* mortality at the end of the first day on all application surfaces. The dose of 10 and 20 g / m^2 on the concrete surface of the native diatomaceous earth of BGN-1, which had been used in the experiment, had statistically similar effect on the concrete surface after 24 hours and was more effective than 2.5 and 5 g / m^2 doses. The BGN-1-coded native diatomaceous earth used in the experiment had the highest activity as a 20 g / m^2 dose statistically 24 h later on the parquet surface while it was found to have the lowest activity as 2.5 g / m^2 statistically. The dose of 10 g / m^2 was statistically found to have similar efficacy with both 5 g / m^2 and 20 g / m^2. The BGN-1-coded native diatomaceous earth used in the experiment had the highest activity as a 20 g / m ^{2} dose statistically 24 h on the ceramic surface and the lowest activity as 2.5 g / m^2 statistically. The dose of 10 g / m^2 was statistically found to have similar efficacy with both 5 g / m^2 and 20 g / m^2. In general, the mortality activity of BGN-1 diatomites against *B. germanica* adults was found to be similar on all three surfaces. The mortality rates obtained from *B. germanica* adults exposed to BGN-1-coded diatomaceous earth for a period of 6, 9, 12 hours for a dose of 20 g / m^2 are statistically similar. However, at the end of 18th hour mortality rate was the highest for concrete surface and reached to 100%, whereas parquet and ceramic surfaces were statistically similar. Mortality rates following 24-hour exposure were 100% for all surfaces. The mortality rate increases as the exposure time for all surfaces increases. In addition, exposure of the BGN-1 coded native diatomaceous earth to 20 g / m^2 for 18 hours resulted in 100% mortality for the concrete surface, while the other two surfaces reached 100% mortality after 24 hours.

All these results demonstrate that BGN-1 encoded native diatomaceous earth has potential for use in the B. germanica adult struggle and may be an alternative to synthetic instecticides with a broad-spectrum spectrum used in the struggle for this bug. However, diatom earth species should be demonstrated in a comprehensive study of the applicability of the German cockroach under natural

habitat conditions and the determination of its interaction with other living factors outside cockroaches when applied in natural conditions.

Abstract

In this study, insecticidal efficacy of seven different local diatomaceous earths (DE) obtained from different deposits in Turkey together with two commercial DEs, Silicosec® (Biofa AG- Germany) and Desect® (Ep Naturals-America) against *Callosobruchus maculatus* (F.) (Coleoptera: Chrysomelidae: Bruchninae) an important pest of stored chickpea at five different concentrations (100, 300, 500, 1000 and 1500 ppm) was evaluated. The local DEs were coded as BGN, BHN, AG2N, AC2N, CB2N, CCN, FB2N. Mortality of the adults was assessed after 1, 3, 5 and 7 days of exposure, and consequently progeny (F1) production on treated chickpeas was recorded 42 days later. The tests were carried out under laboratory conditions of 25±1 °C, 55±5 % R.H. in a dark place. The most effective DEs after 1 day of exposure were CCN, AG2N and BHN causing 75%, 59%, 58% mortalities, respectively at 1500 ppm concentration. Silicosec®, Desect®, BGN, AC2N, applied at 1500 ppm concentration achieved 98-100% mortality of *C.maculatus* after 7 days of exposure, showing similar high insecticidal efficacy. The CCN, BHN, AG2N and CB2N caused 97-99% reduction in progeny (F1) production. Generally, increasing concentration significantly reduced the progeny production. In conclusion, this study has shown that three Turkish DEs, namelyCCN, AG2N and BHN highly toxic to *C. maculatus* after 3 days of exposurein comparison with commercial DEs Silicosec® and Desect®. These local DEs could be used in the management of pests of stored chickpea.

Keywords: Turkish diatomaceous earths, Silicosec®, Desect®, *Callosobruchus maculatus*, chickpea.

Introduction

Chickpea (*Cicer arietinum* L.) is one of the rare plants that have been cultivated since thousands of years and the Turkey's southeast region is known as the homeland of the crop. Globally, it is known that cowpea beetle, *Callosobruchus maculatus* (F.) is the most important pest of stored cowpea and other legumes (Taylor, 1981) and its origin is West Africa (Decelle, 1981). This insect can damage 100% of stored products causing weight losses of up to 60% (Tanzubil, 1991). Fumigants and contact insecticides have several problems such as development of resistance, chemical residues in food, as well as harmful effects on the environment and human health. Researchers are therefore searching for alternative methods of stored product protection. Diatomaceous Earths (DE) have less

resistance problems and leave no residue in the stored product., and less harm to the environment and mammals (Fields 1998). There are a lot of commercial DE formulations which have been applied against a wide range of insect species (Fields 2000, Athanassiou et. al., 2004). The efficacy of DE products depends on several factors such as diatom morphology, DE physical properties, type of grains, temperature and relative humidity (Korunic, 1998).

Turkey is considered to have rich natural DE deposits, and there is clear evidence for the existence of large DE deposits in some regions of Turkey (Özbey and Atamer, 1987; Mete, 1988; Sıvacı and Dere, 2006; Çetin and Taş, 2012). The efficacy of DEs to control stored product insects have been studied by several researchers for almost 20 years. However, there are a few studies using DEs against *C. maculatus* in Turkey. The purpose of this study was to determine the efficacy of two commercially available DEs and seven Turkish local diatomaceous earths formulations against *C. maculatus* on chickpea.

2. Materials and Methods

2.1. Test İnsects

The Test insects, *C. maculatus* were obtained from laboratory cultures maintained on chickpea seeds at the Toxicology Laboratory of the Department of Plant Protection, University of Namik Kemal, Turkey. For this study, new cultures were set up on the chickpea seeds at 25±1°C and 55 % r.h. Adults emerging from the chickpea seeds, aged 48 h old were used in the experiments.

2.2. DE formulations

Seven local diatomaceous earth samples (coded as BGN, BHN, AG2N, AC2N, CB2N, CCN, FB2N) were mostly collected from DE reserves located at middle Anatolia of Turkey, commercial DEs were purchased from the agricultural market.

2.3. Chickpea

The seeds of the chickpea cultivar Koçbaşı (*Cicer arietinum* L.) were obtained from a supermarket. Chickpeas were sterilized at -20°C for 3-5 days before they were used in the experiments

2.4. Experimental procedure

About 500 g of chickpeas used in the experimentsput into 3-liter volume glass jars. Each diatomaceous earth was placed on the products in the glass jar, weighing 0,050, 0,150, 0,250, 0,500 and 0,750 g (100, 300, 500, 1000 and 1500 ppm) on the precision scale. Then the lids of these jars were tightly closed and shaken manually for 3 minutes to homogenize the diatomaceous earth over the chickpea. Each lot was divided into five parts of 100g and in each vial, 20 *C. maculatus* adults of mixed-sex were added with the help of a fine brush .The vials were tightly closed with a tulle which provided air inlet and outlet. One lot was kept as the untreated control. The vials were stored in incubators maintained at 25±1°C temperature and 55±5% relative humidity. Adult mortality was recorded after 1, 3, 5 and 7d. Live and dead adults were counted and recorded. After the 7th day counting, all insects have been taken out from the vials. The chickpeas were seperated according to their doses and placed in plastic containers which were drilled with the help of a pin. They were kept in the dark 80 l volume plastic container for 42 days at a temperature of 26±1°C and 65±5 % relative humidity. Sodium Bromide (94.32 g NaBr / 100 ml water) solution was used to keep the ambient air humidity constant. After 42 d, the jars were opened and the total number of F1 adults were recorded.

2.5. Statistical analysis

Mortality rates obtained from control counts were corrected using Abbot's correction formula (Abbott 1925). After applying the Arcsin transformation to the corrected mortality rates, two-way

variance analysis (ANOVA) was performed in the SPSS 15.0 Evaluation Version statistical program. F1 emergence adults were subjected to direct variance analysis (ANOVA) without any corrections. Using the Duncan test at the 5% significance level, the differences between the mean of mortality rates and the number of new generation adults were determined.

Table 1 Mean percentage mortality (±SE) of *Callosobruchus maculatus* adults exposed to 5 different concentrations of 9 DEs after 72h

Table 2 Mean (±SE) number of *Callosobruchus maculatus* F1 progeny produced after 42 d on chickpea treated with eight DE formulations at five dose rates.
*Two-way variance analysis (ANOVA) was applied to the data and the differences between the averages were based on the 5% significance level. The different uppercase letters in the same column and the different lowercase letters in the same line are statistically different.

Mortality of *C. maculatus* adults after 3 d of exposure to DE treated chickpea increased with increase in DE dose rate.Two-way ANOVAs showed statistically significant effects on the mortality rates of the DEs ($F_{8,180}$ = 73.866, P <0.0001) and concentrations ($F_{4,180}$ = 659.275, P <0.0001) and the interaction between these two factors $F_{32,180}$ = 9.179, P <0.0001) were found to be statistically significant. The CCN and AG2N coded DEswere found to be similar in efficacy at a concentration of 1500 ppm. Within this exposure interval, the highest (100%) mortality were recorded on AG2N coded DE at 1500 ppm. CCN-coded DE showed 96 and 98% mortality rates at 1000 and 1500 ppm

concentrations, respectively. Silicosec® and Desect® commercial DEs showed 82.9% and 71.7% mortality of the beetles, respectively. At the lowest dose rate of each of the DE formulations the efficacy was very low.

F1 progeny production

The main effects of both DE formulation and dose rate as well as their interaction were significant ($P \leq 0.0001$) for number of progeny produced by *C. maculatus*. The mean number of progeny in the untreated control was significantly higher than the numbers that developed on treated chickpeas. Progeny production was reduced by increasing DE dose rate. On treated chickpea seeds, the lowest number of progeny was 0.4 and 1.4, respectively. At 1500 ppm concentration of CCN and BHN coded Des, very few new generation adults emerged. İn all DE treatments, the number of new generation adults that emerged from the control treatments ranged from 93 to 138 and was statistically similar. Generally, as the concentration Des was increased, there was a decrease in the emergence of new generation adults.

Discussion

A few researchers have studied the toxicity of various diatomaceous earth formulations on *C. maculatus.* Most researchers have applied diatomaceous earths of different origins against adult insects at different temperature, humidity and time (Prasantha et al., 2002, Stathers et al., 2004, Islam et al., 2010, Wakil et al., 2010, Shams et al., 2011, Parsaeyan et al., 2012, Tofel et al., 2012, Badii et al., 2013, Chelav et al., 2013, Ofuya et al., 2015, Doğanay et al., 2017). The results presented in this study indicate that local Turkish DE's are effective in controlling *C. maculatus* on chickpea. However, among them, CCN, AG2N, BHN and CB2N coded DEs were found to be more effective after one day of exposure. Our results and those of previous studies suggest that as the DE dose and exposure time increased, the adult mortality rates also increased (Vayias and Athanassiou 2004, Athanassiou and Kavallieratos 2005, Korunic and Fields 2006, Vayias and Stephan 2009, Baytekin and Sağlam 2017). İn the present study at the end of the third day, only AG2N coded DE showed a 100% mortality at 1500 ppm concentration. Stathers et al., (2004) found that 0.1 g of Dryacid® commercial DE killed 100% of adults of *C. maculatus* after 3 days' exposure. Similar results were obtained with the AG2N encoded DE in this current study. When we applied at 1500 ppm concentration of Siicosec® for 3 days 83% mortality was recorded. Shams et al. (2011) conducted studies on Silicosec® on *C. maculatus* at 500 ppm concentration for 2 days and obtained a 95% mortality rate. Tofel et al. (2012) achieved a 100% mortality rate when they applied Silicosec® 2000 ppm concentration for 4 days. Islam et. al (2010) reported that after 3 days of exposure Silicosec® at 1000 ppm concentration the mortality of *C. maculatus* was 90%. İn the present study Silicosec® had a 99% mortality rate on the 5th day, but a 100% mortality rate was reached at the 7th day at 1500 ppm concentration. It is thought that the differences between the studies may be due to differences between the experimental conditions, product type and the insect populations. İn this study, it was concluded that local Des were effective in controlling *C. maculatus* adults on chickpea, but among them, CCN, AG2N, BHN and CB2N coded Des were found to be most effective. Diatomaceous earth is a potential alternative method that can be used in an integrated pest management of stored product pests. Progeny production was also significantly reduced by the application of the local DEs.Field studies on the practicial application of local DEs for the protection of grains against insect pest infestation n Turkey are necessary.

Abstract

Rhyzopertha dominica and *Tribolium castaneum* cause massive losses in stored food. These insects are effectively controlled by synthetic insecticides and fumigants but they accompany many demerits on biotic and abiotic environment. Spinosad is a bacterial formulation and a reduced-risk insecticide which is registered for stored grain protection in many countries. Despite many avenues of research on spinosad, its residual efficacy on certain insect species remains undiscovered. The objective of this research was to evaluate the residual efficacy of spinosad-treated surfaces on the survival of *R. dominica* and *T. castaneum* adults. The label rate of spinosad (25 ppm) was sprayed on polypropylene, jute, polythene, metal and filter paper. One-month-old twenty adults of *R. dominica* or *T. castaneum* were introduced on to the surfaces treated with spinosad and maintained at ambient environmental conditions. The mortality was counted at 2 and 6 days following introduction of adults. The mortality differed with the surface, insect species and duration of exposure. The current study highlights the possibility of controlling *R. dominica* or *T. castaneum* by spinosad sprayed on different surfaces.

Keywords: *Rhyzopertha dominica*, *Tribolium castaneum*, Spinosad, Surfaces, Residual efficacy

Introduction

Rhyzopertha dominica and *Tribolium castaneum* are serious pests of stored products. The synthetic neurotoxic insecticides are the common control methods for these insects (Ghimire *et al*., 2016; Wijayaratne *et al*, 2018) but they have many disadvantages such as negative impacts on human, animals and environment (Arthur, 1996). Reduced-risk insecticides (Arthur, 2007) are better options to overcome the above problems (Phillips and Throne, 2010). Spinosad is a bacterial formulation derived from *Saccharopolyspora spinosa* (Bacteria: Actinobacteridae) (Mertz and Yao, 1990). Spinosad negatively affects the insect nervous system (Salgado and Sparks, 2005). It has been tested against several stored-product insects (Boina *et al*., 2012; Subramanyam *et al*., 2016; Wijayaratne and Rajapakse, 2018) but information on its residual effect on different surfaces is lacking. Therefore, the objective of this research was to evaluate the residual effect of spinosad applied on different surfaces on the survival of *R. dominica* and *T. castaneum* adults.

Material and methods

The experiments were conducted at ambient environmental conditions according to completely randomized design. There were four replicates. Commercially-available spinosad was sprayed on polypropylene, gunny bag (jute), filter paper, polythene and metal at the label rate. Twenty adults of *R. dominica* or *T. castaneum* were introduced onto each surface. Survival of insects was observed at 2 and 6 days following introduction.

Results and discussion

Higher residual efficacy of spinosad was observed on polypropylene, gunny bag (jute) and filter paper than metal and polythene. Increased exposure to spinosad recorded higher mortality in both *T. castaneum* and *R. dominica*.

The objective of this study was to evaluate spinosad and spinetoram effectiveness against *S. granarius, S. oryzae*, *T. confusum*, *T. castaneum* and *R. dominica* in wheat grain under high relative humidity (75%). The insecticides were applied at the rates of 0.5, 1 and 2 mg a.i./kg. Mortality was assessed after 2, 7, 14 and 21 days, and progeny reduction and grain damage caused by the insects were also assessed.

All rates of both insecticides caused 98-100% mortality of *R. dominica* after 7 days, and 100% mortality after 14 and 21 days of exposure. Both insecticides achieved high mortality (97-100%) after 21 days of contact of *S. granarius* with 1 and 2 mg/kg, and *S. oryzae* with 2 mg/kg rate. The highest mortality of *T. confusum* and *T. castaneum* was recorded after 21 days of contact with 2 mg/kg of both insecticides, 54-55% and 25-31%, respectively. All rates of both insecticides caused high progeny reduction of >99% of *R. dominica*, >90% of *T. confusum* and 94% of *T. castaneum* (only with 2 mg/kg). The highest *S. granarius* progeny reduction (>90%) was found in wheat treated with 2 mg/kg spinosad and 1-2 mg/kg spinetoram, while the greatest progeny reduction of *S. oryzae* was observed in wheat treated with 2 mg/kg spinetoram. Wheat grain damage caused by *R. dominica* was very low, i.e. up to 0.2% in wheat treated with all rates of spinosad and spinetoram, while *S. granarius* and *S. oryzae* caused up to 5% damage only in wheat treated with 2 mg/kg of spinetoram.

1. Introduction

Traditional grain protecting organophosphates (OP) and pyrethroids (PY) still constitute the most important segment in the concept of IPM programs and the first option for control of stored insects in storages in which fumigation is not possible (Arthur 2012; Arthur and Subramanyam, 2012). Further use of these insecticides is limited by resistance that populations of stored-product insects have developed to traditional grain protectants and especially by an increasing consumer demand for products that are free of insects and insecticide residues and their negative impact on the environment (Phillips and Throne, 2010; Boyer et al., 2012). Dealing with the challenge and improvement of anti-resistance tactics and control programs for stored-product insects becomes possible with new insecticides that have different mechanisms of activity and good toxicological and ecotoxicological profiles (Phillips and Throne, 2010; Hertlein et al., 2011). Over the past 20 years, only spinosad and diatomaceous earths have proved to be good alternative to OPs and PYs and have been registered as grain protectants in many countries (Arthur and Subramanyam, 2012; Kljajić et al., 2014). Spinosad is a broad-spectrum insecticide of low mammalian toxicity, a mixture of spinosyn A and spinosyn D, secondary metabolites of the soil actinomycete *Saccaropolyspora spinosa* Mertz and Yao (Hertlein et al., 2011). Spinetoram is a new member of the spinosyn group, and a mixture of two synthetically modified spinosyns (spinosyn J and spinosyn L), which are also metabolites of *S. spinosa*. In the latest research, spinetoram has shown similar or higher effectiveness than spinosad against stored-product insects, and may therefore be expected to play an important role in future control of stored-product insects (Vassilakos et al., 2012; Vassilakos and Athanassiou, 2013; Athanassiou and Kavallieratos, 2014; Vassilakos et al., 2015; Rumbos et al., 2018). Unlike traditional grain protectants, such as OPs that achieve their high efficacy after exposure periods of 2-7 days (Kljajić and Perić 2009; Rumbos et al., 2013) spinosad and spinetoram show slower activity, reaching peak efficacy against most stored-product insects after 14-21 days (Fang et al., 2002; Nayak et al., 2005; Athanassiou et al., 2008; Vayias et al., 2009; Andrić et al., 2011; Vassilakos et al., 2012; Vassilakos and Athanassiou, 2013; Vassilakos et al., 2015; Rumbos et al., 2018). As a result, environmental conditions, such as temperature and relative humidity, may significantly affect the efficacy of spinosad and spinetoram. While higher temperature usually increases efficacy, high humidity mostly leads to efficacy reduction (Athanassiou et al., 2008; Vassilakos and Athanassiou, 2013). Besides reducing insecticide efficacy, high relative humidity most often has a positive effect on progeny production, insect distribution and abundance (Hagstrum et al., 1996). High humidity, especially when it extends over a longer period of time, also leads to greater grain moisture, so that wheat grains become softer and more prone to insect infestation (Gaines et al., 1996).

To our knowledge, the efficacy of spinetoram against the granary weevil *Sitophilus granarius* (L.) and red flour beetle *Tribolium castaneum* (Herbst) under high relative humidity conditions has not been

tested so far. The intention of this study was to examine and compare the efficacies of spinosad and spinetoram against *S. granarius*, rice weevil *Sitophilus oryzae* (L.), lesser grain borer *Rhyzopertha dominica (F.)*, confused flour beetle *Tribolium confusum* (Du Val) and *T. castaneum* under high relative humidity (75%), as well as their effects on progeny production/reduction in F_1 generation, and grain damage.

2. Materials and Methods

Test Insects and insecticides used

Laboratory populations of *S. granarius, S. oryzae*, *T. confusum*, *T. castaneum* and *R. dominica*, reared in an insectary, were used in the testing, and procedures described by Harein and Soderstrom (1966), and Davis and Bry (1985) were employed. *S. granarius* and *S. oryzae* were reared in 2.5 L glass jars containing whole-grain soft wheat with moisture content below 12%, while coarse ground wheat was added for *R. dominica* and *T. confusum,* and *T. castaneum* was reared on white wheat flour with 5% yeast. Air temperature in the insectary was 25±1°C, and relative humidity 60±5 %. Unsexed 2-4 week old adults of all tested species were used in the experiment.

The following commercial products were used in the experiment: Laser 240 SC containing 240 g/L spinosad, and Delegate 250 WP containing 250 g/kg spinetoram (Dow AgroSciences, Austria).

Bioassays

Investigation was conducted in the laboratory under high relative humidity conditions of 75±5% and 25±1°C temperature (both parameters were measured by a data logger Kestrel 4000, USA). Moisture content in wheat grain, variety 'Simonida', was 12.3±0.1 % and it was measured by a Dickey–John Mini GAC (Dickey–John Co., USA) device before the experiment.

Two standard solutions were prepared for both insecticide and diluted into dose series of 0.5, 1.0 and 2.0 mg a.i./kg, so that each insecticide dose was used for two treatments of 500 g lots. Each 1000 mL glass jar was filled with 500 g of wheat grain and treated with 5 mL of water solution of one of the insecticides, or 5 mL of water for control grain. After hand shaking the treated wheat for 30 s, each jar was placed on a mechanical roller for 15 minutes. For each tested species, six 50 g samples (three per treatment), representing each dose and insecticide, were placed into 200 mL plastic vessels. The next day, 25 adults of each tested species were released into each vessel, which was then covered with cotton cloth and fixed with rubber band. Adult mortality of the tested species was determined 2, 7, 14 and 21 days after the beginning of their exposure to treated wheat grain.

After the last assessment, dead and living adults were removed and the vessels were retrieved to the laboratory (25±1°C and 75±5% r.h.) for additional periods of 5 weeks for *Sitophilus* species, 7 weeks for *R. dominica* and 9 weeks for *Tribolium* species. Progeny emergence/suppression was determined by counting adults (for *Tribolium* species the total number included larvae, pupae and adults).

When the progeny were counted, damage caused by the weevils and *R. dominica* were also assessed on 100 randomly selected kernels per vessel.

Data analysis

Before analysis, percentage mortality was transformed using *arcsine* and progeny counts were transformed by *log(x+1)*. All data were submitted to a one-way ANOVA and the means were separated by Fisher's LSD test at P=0.05. Progeny reduction (IR%) in wheat grain was determined using a formula recommended by Tapondjou et al. (2002).

3. Results

All application rates of spinosad and spinetoram caused low mortality (0-16%) of all tested species after 2 days of exposure, except of *R. dominica*, whose mortality was 18.0-62.7% and 32.7-53.3%,

respectively. Seven to 21 days exposure to both insecticides at all application rates caused high mortality of *R. dominica*, 98-100%. The 7 days exposure period to all rates of spinosad and spinetoram caused *S. granarius* mortality that ranged from 18.0-81.3% and from 62.0-86.0%, considerably lower mortality of *S. oryzae* (8.7-72.0% and 24.0-87.3%), and the least (<12%) in *T. confusum* and *T. castaneum*. After 14 and 21 days, spinosad and spinetoram caused high mortality (92-100%) of *S. granarius* and *S. oryzae* in contact with 1.0 and 2.0 mg/kg, and 2.0 mg/kg of both insecticides, respectively, while the highest mortality of *T. confusum* and *T. castaneum* was recorded after 21 days of contact with 2.0 mg/kg of both insecticides, 54-55.3% and 25.3-31.3%, respectively (Table 1).

All application rates of both insecticides caused high progeny reduction: 98.6-100% of *R. dominica*, 90-100% of *T. confusum* and 94.5% of *T. castaneum* (only with 2.0 mg/kg). The highest *S. granarius* progeny reduction (90.2-95.3%) was found in wheat treated with 2 mg/kg spinosad and 1-2 mg/kg spinetoram, while *S. oryzae* progeny reduction was the greatest (94.5%) in wheat treated with 2 mg/kg spinetoram (Table 2).

No grain damage caused by *R. dominica* was detected in wheat treated with any rate of spinosad or spinetoram other than grain treated with the lowest doses of the insecticides, and even that dose caused only a very small damage of up to 0.2%. After *S. granarius* and *S. oryzae* progeny were counted in all treated wheat, grain damage was detected, peaking with 42.2-77.2% in wheat treated with 0.5 mg/kg spinosad, while the lowest was 3.0-5.2%, found in wheat treated with 2 mg/kg spinetoram (Table 2).

4. Discussion

The results in our present study show that the efficacy of spinosad and spinetoram depend on the rate, exposure interval and target species, which is consistent with previous results (Fang et al., 2002; Nayak et al., 2005; Subramanyam et al., 2007; Athanassiou et al., 2008; Vassilakos et al., 2012; Vassilakos and Athanassiou, 2013). For example, both insecticides were highly effective at the rate of 0.5 mg/kg against *R. dominica* after 7 days, at the rate of 1-2 mg/kg against *S. granarius*, and 2 mg/kg rate against *S. oryzae* after 14 days, while the 2 mg/kg rate achieved its highest efficacy against *T. confusum* and *T. castaneum* after 21 days.

In a recent study Athanassiou and Kavallieratos (2014) concluded that spinetoram was equally and in some cases even more effective than spinosad against stored-product beetle species. Based on these results, we can similarly conclude that no significant difference emerged in our experiment between spinosad and spinetoram effectiveness against the most susceptible *R. dominica* and least susceptible *Tribolium* species.

Regarding *Sitophilus* species, however, spinetoram was significantly more effective than spinosad. For example, spinetoram applied at the rates of 0.5 and 1 mg/kg was significantly more effective than spinosad after 7-21 days of exposure of *S. granarius* and *S. oryzae*, as well as considering the average progeny counts and percentage of damaged grain, which was significantly lower for both species in wheat treated with spinetoram.

A number of previous studies (Fang et al., 2002; Nayak et al., 2005; Subramanyam et al., 2007; Athanassiou et al., 2008; Vayias et al., 2009, 2010; Vassilakos et al., 2012, 2015; Athanassiou and Kavallieratos, 2014; Rumbos et al., 2018) agreed that *R. dominica* was the most susceptible of stored-product beetle species, while *Sitophilus* species were significantly less susceptible, and *Tribolium* species the least susceptible to spinosad and spinetoram, which was further confirmed in our present research under high relative humidity conditions. Furthermore, our results clearly show that *S. granarius* is significantly more susceptible than *S. oryzae* to both insecticides, while *T. confusum* is significantly more susceptible than *T. castaneum*. Differences between *Sitophilus* species were greatest when 0.5 mg/kg rate was applied, and after exposure periods of 7 and 14 days, as well as between *Tribolium* species after the application of 2 mg/kg spinosad and spinetoram and exposure for 21 days.

Tab. 1 Mean (% ± SE) mortality of *S. granarius*, *S. oryzae*, *R. dominica*, *T. confusum* and *T. castaneum* adults exposed for 2, 7, 14 and 21 days to wheat treated with spinosad or spinetoram (for each species/exposure separately, means within columns marked by the same letter are not significantly, Fisher's LSD test at $P>0.05$)

Vassilakos et al. (2012) reported a 1.5 times lower efficacy of 0.5 mg/kg rate of spinetoram in wheat against *S. oryzae* than *S. granarius*. Our study showed even greater differences, so that spinetoram rate of 0.5 mg/kg after 7 days and spinosad rate of 0.5 mg/kg after 14 days were 2.6 times less effective against *S. oryzae* than against *S. granarius*. After 21 days of contact with 2 mg/kg rate of spinosad and spinetoram, efficacy was 1.8 and 2.1 times lower against *T. castaneum* than against *T. confusum*.

Data from some earlier studies show that increasing relative humidity mostly leads to lower efficacy of spinosad and spinetoram (Athanassiou et al., 2008; Vassilakos and Athanassiou, 2013). Comparing efficacy data for spinosad under high humidity of 75% in the present study and our earlier findings (Andrić et al., 2011) in experiments conducted under 60% r.h., similar conclusions were drawn. For example, spinosad applied in our present study at 0.5, 1 and 2 mg/kg rates resulted in *S. oryzae* mortality of 18, 60 and 92% after 14 days, while the respective data from earlier experiments were 59, 77 and 100%. Similarly, progeny reduction of *S. oryzae* in wheat treated with 0.5, 1 and 2 mg/kg spinosad was 2.5, 34.1 and 82.2% at 75% r.h., which is significantly less than progeny reduction at 60% r.h, which was 42.2, 80,8 and 91%.

Tab. 2 Progeny emergence (adults/vessel ± SE), progeny reduction (%) and kernel damage (mean % ± SE) of *S. granarius*, *S. oryzae*, *R. dominica*, *T. confusum* and *T. castaneum* in wheat treated with spinosad or spinetoram (for each species separately, means within columns followed by the same letter are not significantly different, Fisher's LSD test at *P*>0.05)

As data from tests of the effectiveness of insecticides as grain protectants may vary, it is very important to determine their effects on progeny production of storage insects, as well as on grain damage (Subramanyam and Roesli 2000; Subramanyam et al., 2007). In the present study, all spinosad and spinetoram doses caused high progeny reduction (98.6-100%) only for *R. dominica*, accompanied by almost no grain damage at all (≤0.2%), as well as high progeny reduction (90-100%) for *T. confusum*, which is consistent with earlier reports (Fang et al., 2002; Vayias et al., 2009; Subramanyam et al., 2007; Athanassiou and Kavallieratos, 2014). Regarding both *Sitophilus* species, however, only the 2 mg/kg rate of spinosad and spinetoram caused high progeny reduction of 82.2-90.2% and 94.5-95.3%, respectively, while the percentage of grain damage ranged 3-14.7% and 3-5.2%, respectively. These results are inconsistent with several earlier studies (Vayias et al., 2009; Subramanyam et al., 2007; Athanassiou and Kavallieratos, 2014) in which 1 mg/kg rate of spinosad or spinetoram applied to various types of grain resulted in high or maximum reduction of progeny of maize weevil *Sitophilus zeamais* (Motsch.), *S. granarius* and *S. oryzae*, and no maize grain damage was caused by *S. zeamais* and *S. oryzae*. Besides the lower effiacy that was observed in this study and

population origin, the observed differences may also be attributed to the high relative humidity that made wheat grain softer in our experiment (Gaines et al., 1996). It enabled progeny production of *Sitophilus* species, and consequent grain damage, as well as progeny production of *T. castaneum* even after wheat grain treatment with 2 mg/kg spinosad or spinetoram. Supporting these findings are data on grain damage caused by *S. granrius* and *S. oryzae* in control of 58.7 and 76.0%, respectively.

Based on all results in this study, we concluded that the minimum effective dose of spinosad and spinetoram for *R. dominica* and *S. granarius* control in wheat grain under high humidity conditions (75% r.h.) is 0.5 and 2.0 mg/kg, respectively, and only 2 mg/kg of spinetoram for *S. oryzae* control, while successful control of *T. confusum* requires 0.5 mg/kg of spinosad or spinetoram, and *T. castaneum* 2.0 mg/kg of either spinosad or spinetoram.

Abstract

Although seldom considered, sublethal insecticide exposure may lead to harmful, neutral, or even beneficial responses that may affect (or not) the behavior and fitness of the exposed insects. Intriguingly, little is known about such effects on stored product insect pests and even less is available regarding the bioinsecticide, spinosad. Thus, we assessed the sublethal effects of spinosad on walking, feeding, drinking and mating behaviors of maize weevils (*Sitophilus zeamais*), also assessing their survival, reproductive output, and grain loss compared with maize weevils exposed to the pyrethroid deltamethrin (as positive control), and water only (negative control). Both spinosad and deltamethrin were able to effectively control the insects, although the latter caused a faster mortality than the former. Behavioral pattern changes were caused by both insecticides, especially deltamethrin, triggering irritability (i.e., avoidance after contact). Different feeding and drinking responses were also detected with significant avoidance to deltamethrin, but not to spinosad. Maize weevil couples sublethally exposed to deltamethrin and spinosad exhibited altered reproductive behavior, a likely consequence of their altered activity, but deltamethrin caused greater behavioral changes. Curiously, higher progeny emergence and grain loss were observed in deltamethrin-exposed insects, suggesting that this pyrethroid insecticide elicits hormesis in maize weevils that may compromise control efficacy by this compound. In contrast, such effect was not detected with spinosad, which did not elicit avoidance allowing the intended weevil exposure and control.

Keywords: biopesticide, hormesis, insecticide avoidance, sublethal exposure, progeny production

Introduction

Insecticides are a familiar class of pest control agents, understandable due to their broad use since the 1940's across many sectors, including stored product protection. Although insecticides are technically defined as "*any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any insect pest*" (e.g., US Federal Insecticide, Fungicide, and Rodenticide Act), these compounds are popularly defined as substances that kills insects. The blame probably lays with the old Romans and the Latin origin of the suffix *cide* (from *cīda*; = a killer of), which is rather popular and frequent in several nouns of different languages. Regardless, the emphasis of the popular definition of insecticide is on the *killing* of insects, not managing or controlling them, as

advocated by the technical definition. Such fact leads to an important bias on dealing with insecticides – the emphasis and reliance on their mortality effect, while largely neglecting their sublethal consequences (Hardin et al., 1995; Guedes et al., 2016).

Lethal effects of insecticides are certainly important, and the primary intent of most users is indeed to quickly kill the pest species. Importantly, however, sublethal exposures can cause population suppression without necessarily causing death; reproductive impairment, for instance, can be as effective, or even more effective, for pest control. It is critical to understand the issues that contribute to a sublethal exposure. Initial insecticide deposits degrade over time, lowering residue levels, eventually to the sublethal range for a length of time that is a complex function of toxicological and environmental factors. Another contributor is that the lethal concentration applied to target a given pest is potentially sublethal to other species, particularly co-occurring species.

Sublethal insecticide exposure is known to affect arthropod development, longevity, reproduction, and even the genetic make-up of the population (Lee, 2000; Guedes et al., 2016, 2017). Sublethal exposures may lead to shifts in species prevalence (or dominance) (Cordeiro et al., 2014) creating unforeseen pest outbreaks, as well as inadvertent selection(s) for insecticide resistance in non-targeted pest species (Haddi et al., 2015; Guedes et al., 2017). Behavioral changes are also among the potential consequences of sublethal insecticide exposure. These changes may involve general activity, mobility, feeding, mating and egg-laying, among others, all potentially affecting the maintenance and growth of the arthropod pest population (Haynes, 1988; Lee, 2000; Guedes et al., 2016). Therefore, a range of responses may accrue from sublethal insecticide exposure. In fact, novel insecticidal chemistries have increasingly relied on secondary and behavioral effects (Casida and Durkin, 2013; Guedes et al., 2016). Curiously, sublethal insecticide exposure is rarely scrutinized in stored product scenarios, where it is common for pest species co-occur with finite resource (Guedes et al., 2011, 2014).

Another conceptual bias that commonly plagues the general public perception of insecticides, and also influences pest research and management, is the deeply-rooted notion that natural compounds are safer than synthetic ones. While this may be valid in certain cases, the notion in based on the false premise that origin is a determinant of toxicity, and safety (Coats, 1994; Isman and Grieneisen, 2014; Guedes et al., 2016). The selection of a "natural" insecticide, including biopesticides, reduced-risk pesticides, biorational compounds, insecticidal proteins, and an increasing variety of neologism, pleonasms, and/or misnomers should be considered based not on semantic qualification, but on the chemistry that dictates toxicity and safety.

Spinosad is an insecticide of natural origin, or bioinsectide, with recent use in stored product protection, not yet subjected to comprehensive sublethal studies. The technical active ingredient (a.i.) is a mixture of spinosyns A and D, fermentation products of the soil actynomycete *Saccharopolyspora spinose* Mertz and Yao (Thompson et al., 2000; Sparks et al., 2001). Earlier launched for field crop use, its market was more recently extended to stored products as a grain protectant efficient against a range of pest species (Toews and Subramanyam, 2003; Huang and Subramanyam, 2007; Athanassiou et al., 2008; Athaniassiou and Kavallieratus, 2014), including the grain weevils (Coleoptera: Curculionidae) (Athaniassiou and Kavallieratus, 2014). In warmer climates, particularly Neotropical America, the maize weevil *Sitophilus zeamais* Motsch is a key pest, and virtually nothing is known about (sublethal) effects of spinosad, despite its potential usefulness for conventional and organic production and storage systems.

We assessed the sublethal effects of spinosad on the overall activity, walking, feeding, drinking and mating behaviors of maize weevils (*Sitophilus zeamais*), and evaluated results relative to conspecifics exposed to the pyrethroid deltamethrin (as positive control), and water only (negative control). Differences in the sublethal effects of the two insecticides were suspected, as the mechanism and modes of neurotoxic action are distinct; deltamethrin is a Na-channel modulator of the axon of neurons (i.e., nerve cells) with quick activity, in contrast with spinosad, which is a disruptor of

nicotinic acetylcholine receptors (nAChRs) in synapses of the insect nervous system with potentially slower activity (Sparks et al., 2001; Casida and Durkin, 2013).

1. Material and Methods

1.1. Insects and insecticides

The maize weevil population used in the study was originally collected in Sete Lagoas county (State of Minas Gerais, Brazil). This population is used as a susceptible standard population in studies of insecticide resistance and has been maintained on maize grains free of insecticide residues under controlled conditions of 27 ± 2°C, 70 ± 10% r.h., and 12:12 h photoperiod (L:D).

The insecticides were used in their respective commercial formulations available in Brazil for stored product protection and at the recommended label rates, as follows: deltamethrin (K-Obiol 25 CE; emulsifiable concentrate at 25 g a.i./L; Bayer, São Paulo, SP, Brazil), and spinosad (Tracer 480 SC; suspension concentrate at 480 g a.i./L, Dow, Mogi-Mirim, SP, Brazil). The insecticides were diluted in distilled and deionized water at the concentrations of 0.25 and 0.50 mf a.i./L of deltamethrin and spinosad, respectively. The insecticide solutions were sprayed in batches of 400 g of maize grains at 0.5 and 1.0 mg a.i./kg grain using an artist air brush (Saguma SW440A, Yamar, São, SP, Brazil) connected to an air compressor (model 131 type 2VC, Primatec, Itu, SP, Brazil) at 3 bar pressure. The maize grains were sprayed within a stainless-steel container coupled to a revolving rotor to homogenize the grain coverage until the residues dried. The air brush and revolving container were cleaned with acetone; distilled and deionized water was used as negative control treatment.

1.2. Survival bioassay

Time-mortality bioassays were conducted using 3- to 7-days old adults (unsexed). Individual insects were placed inside 30-mL glass vials containing 10 g of treated maize (i.e., deltamethrin, spinosad, or water (control)). Twenty insects were used in each insecticidal treatment and their respective survival was monitored at 30 min (for first two hours) and 1 h intervals for deltamethrin, and at 1 h (first 8 hs) and 6 h-interval afterwards for spinosad and water. The insects were considered as dead if unable to respond when prodded with a fine hair brush.

1.3. Overall group activity

Adult weevils subjected to either 30 min (deltamethrin) or a 10-h exposure (spinosad and water), the duration corresponding to non-observed effect levels as determined in the survival bioassays, were clustered in groups of 10 individuals within Petri dish arenas (9-cm diameter) lined at the bottom with filter paper and coated with Teflon® to prevent insect escape (Guedes et al., 2009b). The overall group activity within each arena was recorded for 15 min and digitally transferred to a computer using an automated video-tracking system equipped with a CCD camera (ViewPoint LifeSciences, Montreal, Canada). Overall activity was digitally recognized as changes in pixels in two successive frames taken every 10^{-2} s from each other representing any change of position and posture of the insects. The bioassays were carried out under the same conditions as previously described and during daytime.

1.4. Walking bioassays

Walking bioassays in half-treated arenas were performed to assess insecticide behavioral avoidance by means of irritability (i.e., with contact with insecticide) and repellence (i.e., without direct contact with insecticide). Unexposed insects were released alone in individual Petri dish arenas lined with filter paper half-treated with either deltamethrin or spinosad and their movement was digitally recorded for 15 min with the tracking system described above (Cordeiro et al., 2010; Morales et al., 2013). Again, 20 replicates were used for each dichotomous bioassay with either deltamethrin or spinosad vs water (control).

1.5. Feeding and drinking preference

A free-choice test modified from Guedes et al. (2009a) was performed using white plastic trays (30 x 18 x 6 cm) with 200 g of water- and insecticide-sprayed grains placed in opposite sides. The inner walls of the trays were covered with Teflon® to prevent insect escape and 25 unsexed adult weevils (1-2 weeks old) were released in the center of the arena. Insect preference was recorded after one hour and the bioassays were replicated five times.

A dichotomous bioassay of water drinking preference was carried out as described by Guedes et al. (2014) providing a choice between 50-µL droplets of water uncontaminated ,or insecticide-contaminated (deltamethrin or spinosad), after maintaining the insects under 30-40% relative humidity for 24 hs. The insecticide contaminations were used at the same rates from previous bioassays, and each droplet was stained with either artificial blue or red dye (Mix Industries, São Bernardo do Campo, SP, Brazil). The choice of water droplets was provided in 9-cm Petri dish arenas and the insects were observed for 5 min. Water intake was confirmed by dissecting the insects and examining evidence of the dye coloration in the insect gut diverticula, what was performed under stereomicroscope (Stemi 2000; Zeiss, Göttingen, Germany).

1.6. Female mate-searching

Virgin weevil females (< one week old) were treated with insecticides (except in the control) as previously described, and transferred to 9-cm Petri dish arenas containing a male weevil caged in its center (Guedes et al. 2017; Cordeiro et al. 2017). The searching activity of the females was recorded again using the ViewPoint tracking system recording search time and velocity for up to 2 hours under the same conditions of the previous experiments.

1.7. Progeny emergence and grain consumption

Three groups of 35 virgin weevil couples (one week old) were treated with insecticide as previously described and subsequently released in 140-mL jars containing 50 g maize free of insecticide residues. The insects were removed after 30 days and progeny production and grain loss were recorded. Progeny production was daily assessed until emergence of the last adult, and grain loss was determined in sequence with eventual correction for humidity change, if necessary.

1.8. Statistical analyses

Time-mortality data was subjected to survival analyses using Kaplan-Meyer estimators allowing determination of the respective median survival times (LT_{50})(PROC LIFETEST; SAS, SAS Institute, Cary, NC, USA). The curves were compared using Bonferroni's method. Individual and overall group activity, irritability, repellence, and feeding and drinking preferences were subjected to general linear model and contrasted by χ^2 test (PROC GENMOD; SAS). Female searching time, progeny production and grain loss were subjected to analyses of variance and Tukey's HSD test ($P < 0.05$), when appropriate (PROC GLM; SAS).

2. Results

3.1. Survival time

The survival curves of weevils exposed to either insecticide, deltamethrin or spinosad, and the control were significantly different ($\chi^2 = 409.37$, df = 2, $P < 0.001$). Natural (i.e., control) mortality was negligible for up to 15 days, in contrast with insecticide-exposed weevils (Fig. 1). Deltamethrin led to quick mortality among the exposed adult weevils with median survival time of 3.5 hs, while median mortality by spinosad took significantly longer (i.e., 76.5 hs) (Fig. 1).

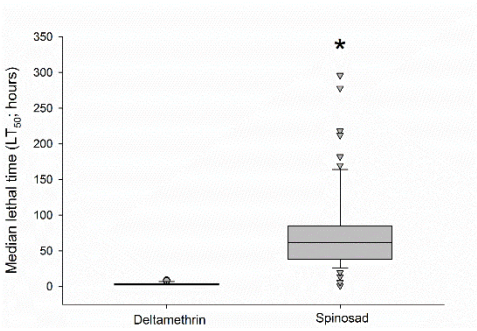

Fig. 1. Median lethal times (TL_{50}) of insecticide-exposed adult maize weevils (*Sitophilus zeamais*). The box plots indicate the median and dispersion (lower and upper quartiles, and outliers) of the median lethal times. The asterisk indicate significant difference between insects exposed to the insecticides using Bonferroni's method ($P < 0.05$).

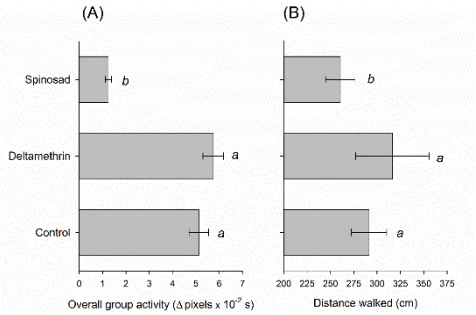

Fig. 2. Overall group activity (A) and distance walked by individual weevils (B) (± SE) subjected to insecticide exposure (except control with unexposed insects). Different low case letters in the bars indicate significant differences by χ^2 test ($P < 0.05$).

3.2. Activity

The overall group activity also significantly differed among treatments with spinosad-exposed adult weevils exhibiting significant less activity than unexposed and deltamethrin-exposed weevils ($\chi^2 = 181.45$, df = 2, $P < 0.001$) (Fig. 2A). When distance walked by individual insects was considered as a proxy of individual activity, a similar trend was observed. Again spinosad compromised activity and led to the lowest distance walked compared with deltamethrin and unexposed insects, which provided similar results ($\chi^2 = 55.68$, df = 2, $P < 0.001$) (Fig. 2B).

3.3. Feeding and drinking preference

Behavioral avoidance among insecticide-exposed weevils indicated significant irritability ($\chi^2 = 4.73$, df = 2, $P = 0.03$), or avoidance after contact with contaminated surface, but no repellence (i.e., avoidance without contact with contaminated surface). Most insects did not respond to spinosad though, in contrast to deltamethrin against which 40% of the insects exhibited avoidance by irritability (Fig. 3A).

Feeding preference also differed between insecticides when given a choice between uncontaminated and contaminated maize grains. Weevils did not exhibit feeding preference when offered uncontaminated and spinosad-contaminated grains, but the insects significantly avoided deltamethrin-contaminated grains in favor of uncontaminated maize kernels ($\chi^2 = 25.53$, df = 1, $P = 0.0004$) (Fig. 3B). Such a trend was also observed when water was provided for drinking with weevils avoiding deltamethrin-contaminated water ($\chi^2 = 39.32$, df = 1, $P < 0.001$), but no avoidance was detected with spinosad-contaminated water ($\chi^2 = 2.91$, df = 1, $P = 0.10$) (Fig. 3C).

3.4. Female-mate searching, progeny production and grain loss

The female searching for suitable male partner was significantly affected by insecticide exposure ($F_{2,57} = 39.63$, $P < 0.001$). Unexposed females were able to find their mates relatively quicker, while spinosad and particularly deltamethrin significantly extended such searching time (Fig. 4A). Nonetheless, the differences in mate searching time did not significantly affect the total progeny produced by each female weevil ($F_{2,102} = 0.35$, $P = 0.70$) (Fig. 4B), but deltamethrin-exposed weevil led to higher grain loss than those unexposed or exposed to spinosad ($F_{2,102} = 13.93$, $P < 0.001$) (Fig. 4C).

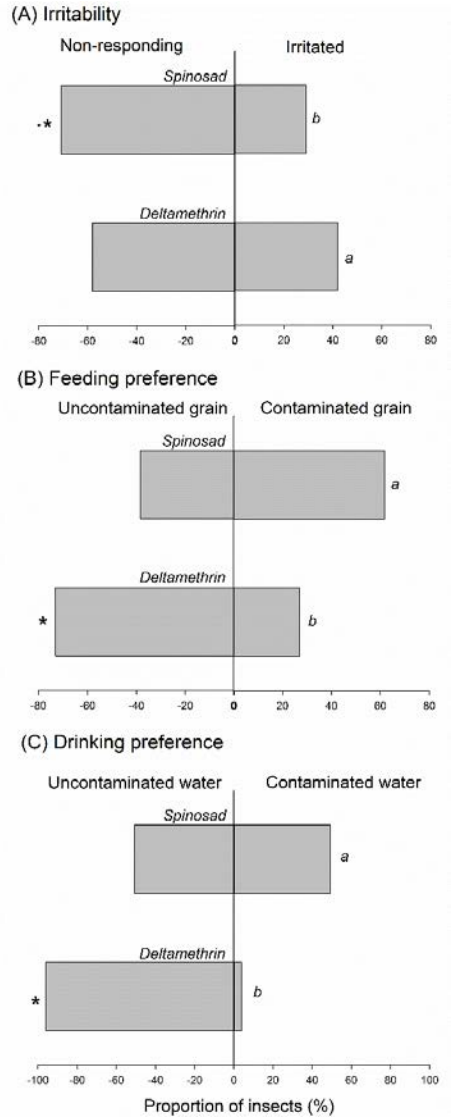

Fig. 3. Proportion of adult weevils showing irritability to insecticide-contaminated surfaces (A), and exhibiting feeding (B) and drinking preferences (C) with choice of uncontaminated and insecticide-contaminated grains and water. Different letters in each bar indicate significant differences between treatments and asterisk indicates significant difference between proportion of uncontaminated and insecticide-contaminated material (i.e., surface, grain, or water). All differences were detected with χ^2 test ($P < 0.05$).

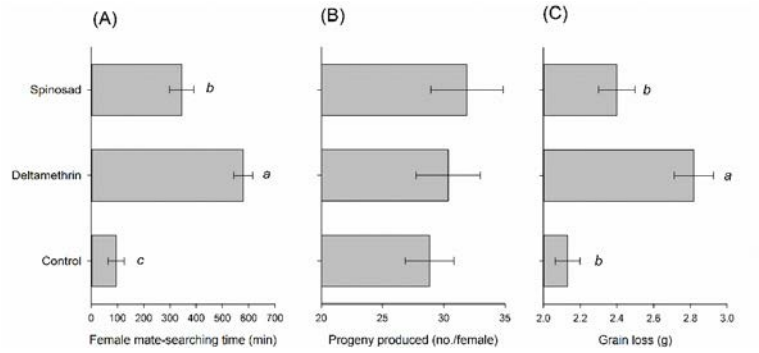

Fig. 4. Female mate-searching time (A), total progeny produced per female (B), and total grain loss (C) (± SE) by weevils subjected to insecticide exposure (except control with unexposed insects). Different lower case letters in the bars indicate significant differences by χ^2 test ($P < 0.05$).

3. Discussion

The lack of information regarding the sublethal effects of the bioinsecticide spinosad led us to evaluate its impact on walking, feeding, drinking and mating behaviors of maize weevils (*Sitophilus zeamais*), also assessing their survival and reproductive output compared with maize weevils exposed to the pyrethroid deltamethrin (as positive control), and water only (negative control). Interference of both neurotoxic compounds with weevil activity were expected with potential consequences for mating, reproduction and grain (weight) loss. Indeed behavioral changes were induced by both insecticides although the effects of deltamethrin were stronger, but unexpectedly enhancing grain loss instead of reducing it.

Both deltamethrin and spinosad were effective against adult maize weevils exposed to contaminated grains at their respective recommended label rates as grain protectants, although deltamethrin exhibits faster activity, as previously been shown (Athanassiou et al., 2008; Athaniassiou and Kavallieratus, 2014). Nonetheless, the impact of both compounds go beyond mortality. Sublethal effects of deltamethrin and spinosad have been reported in other species (Elliott et al., 1978; Huang and Subramanyam, 2007; Amakware et al., 2014; Velki et al., 2014). Overall group activity and walking activity were both significantly reduced by spinosad, a likely consequence of its mode of action modulating nicotinic acetylcholine receptors (nAChR) and interfering with receptors of γ-aminobutiric acid (GABA) at synapses of the nervous system (Sparks et al., 2001; Casida and Durkin, 2013).

Among the two different types of insecticide avoidance behavior reported among insects, repellence (i.e., avoidance with little or no contact) and irritability (i.e., avoidance after contact), only the latter was observed in weevils and sole with deltamethrin, not with spinosad. Weevils exhibited significant irritability to deltamethrin and avoided feeding on deltamethrin-contaminated grains and water, which may potentially reduce exposure to, and targeted-efficacy of this compound. Irritability and associated behavioral responses toward pyrethroids, such as deltamethrin, were already reported among other arthropod species (Quisenberry et al., 1984; Vatandoost, 2001; Pekar and Hadda, 2005; Guedes et al., 2009ab, 2014). In contrast, spinosad avoidance was reported only in a couple of species of predatory stink bugs (Castro et al., 2013).

Insecticides may also interfere with insect communication (Guedes et al., 2016, 2017), which may potentially disrupt mating and reproduction (Lürling and Scheffer, 2007; Guedes et al., 2016). Indeed, spinosad and deltamethrin extended the mate searching time in exposed female weevils, but without significant effect on progeny production. In fact, the trend was of increased progeny production with insecticide exposure, which was reinforced by the higher grain loss obtained, particularly for deltamethrin. With sublethal insecticide exposure, we expected a decrease in progeny production and an extension of the time spent searching for a mate. However, the opposite

was observed in our study, suggesting that the longer searching time may have favored the selection of better quality male partners, potentially leading to higher (and/or better quality) progeny production and more feeding leading to heavier grain losses. The lack of significant difference in the total progeny produced is a likely reflex of not accounting for the time of 1st reproduction in our assessment, and not assessing progeny quality. The former condition shortens generation time, leading to higher population growth and progeny numbers with time, conditions that were beyond the scope fo this investigation. The consequence of higher population growth is more feeding, and ultimately higher grain loss, as was observed to a greater extent for deltamethrin, relative to spinosad.

Higher grain losses resulting from sublethal insecticide exposure is a counter-intuitive outcome. However, this outcome takes place when insecticide-induced hormesis is present. Hormesis is a biphasic dose-response phenomenon that takes place when a stimulatory effect is observed from the low dose of a compound demonstrated to be toxic at higher doses (Guedes and Cutler, 2014; Guedes et al., 2016, 2017). Deltamethrin-induced hormesis has already been reported in the maize weevil (Guedes et al., 2010), and the same likely occurred in our study. The pyrethroid effective against the exposed parental population may have induced higher reproductive output of the better-quality (surviving) parents, leading to higher and/or better-quality progeny. Although the final progeny population was not significantly higher with deltamethrin, the grain loss observed provides at least partial support for this contention. Hormesis, in this case, was probably the result of a trade-off where energy resources for the parent self-maintenance are diverted to offspring production (Guedes and Cutler, 2014), which are of better quality and/or in higher numbers leading to higher grain loss.

Insecticide behavioral avoidance and hormesis are two management concerns for pest species in general, and the maize weevil in particular. The former potentially minimizes exposure to the insecticide, while the latter favors population growth with exposure. Evidence for both phenomena was observed in our study with the maize weevil, but only with the insecticide deltamethrin, not spinosad. Therefore, deltamethrin use deserves particular attention and spinosad, although not as quick in leading to adult mortality, is also a very effective insecticide against the maize weevil and without apparent risk of minimizing exposure or leading to hormesis, at least at the label rate conditions used in our study. Thus, spinosad is an attractive alternative for weevil management, not due to its natural origin, but due to its insecticidal activity. The natural origin of spinosad however, makes it an enticing alternative for organic production and storage systems, a condition in which the origin, rather than chemistry, receives emphasis.

Abstract

As part of on-going efforts to use eco-friendly alternatives to chemical pesticides, leaf powder of *Hemizygia welwitschii* was sequentially extracted in hexane, acetone and methanol. Bioassays were carried out to establish the most active fraction(s) against *Sitophilus zeamais* in maize. Maize grains (50 g) were treated with concentrations within the range 2, 4, 6, and 10 g/kg of extract and *Azadirachta indica* seed oil (positive control) in the laboratory. The total number of progeny emerging from grains infested separately with *S. zeamais* eggs, larvae and pupae were recorded. Adult mortality counts were carried out 1, 3, 7 and 14 d post-exposure. Acetone extract was more toxic to the eggs, larvae and pupae than the other extracts, inhibiting progeny production by 90.90%, 88.10% and 100%, respectively, at the concentration 10 g/kg. For the same concentration, *A. indica* seed oil reduced progeny production by 100% for eggs, 96.08% for larvae and 70.93% for pupae. Hexane extract was more potent to the adult weevil than the other extracts, recording 100% mortality for the concentration 10 g/kg within 14 d. LC_{50} values were 0.78 (Hexane), 5.52 (acetone) and 1.69 g/kg (methanol). Extracts of *H. welwitschii* leaves had sufficient efficacy to be a component of storage pest management package for *S. zeamais*.

Key words: Leaf powder, Mortality, Grain damage, Pest management

1. Introduction

Maize (Zea mays L.) is a staple food for a large proportion of the world with significant economic importance. It is currently the third most-cultivated and traded cereal after wheat and rice (FAO, 2006). The highest amounts of maize consumed as food are found in Southern Africa at 85 kg/capita/year as compared to 27% in East Africa and 25% in West and Central Africa (Smale *et al.,* 2011). The crop is characterized by the diversity of its consumption forms: fresh, boiled, roasted, and "foufou" (Ndjouenkeu *et al.,* 2010). A world challenge is to increase the global maize production to feed nine billion people by 2050 (Godfray *et al.,* 2010).

The production and storage of maize have faced many constraints throughout developing countries such as scarcity of rain, diseases and lack of inputs (Brisibe *et al.,* 2011), and most important constraint being the field-to- store infestations of maize weevil *Sitophilus zeamais* (Coleoptera: Curculionidae) (Akob and Ewete, 2007). This insect inflicts severe damages leading to weight loss and reduction of the economic value, grain viability and nutritive value of maize (Akunne *et al.,* 2013). According to Obeng-Ofori and Amiteye, (2005) and Yuya *et al.,* (2009), about 20 to 40% of

maize grain is lost due to the attack of *S. zeamais*. The control of insect pests of stored products in general, relies mainly on the use of residual synthetic chemical insecticides. This practice, although effective in the fight against insects, is toxic to consumers, pollutes the environment and induces resistance in pests (Arnaud *et al.,* 2001). The use of increasing amounts of pesticides represents a real danger since it leads to the stage where the insecticide is completely ineffective against the pest. Also, obsolete synthetic chemicals are found in our local markets, which cause serious health hazards (Bambara and Tiemtoré, 2008).

Alternative solutions to the application of synthetic chemicals is the use of phytochemicals (reduced-risk insecticides of plant origin) which is presently being encouraged in stored grain protection because there are more biodegradable, and thus may pose less environmental hazards. *Hemizygia welwitschii* Rolfe Ashby (syn. *Orthosiphon welwitschii* Rolfe) (Lamiaceae) is a bushy aromatic perennial herb, widely available in the Adamawa region of Cameroon, and used in folk medicine for the treatment of skin diseases (Ngassoum *et al.,* 1999). The essential oil is known to possess antibacterial properties and repellence activity against mosquitoes (Oyedele *et al.,* 1992, 2000). The chemical composition of the essential oil from the powdered leaf of *H. welwitschii* harvested in Ngaoundere, Cameroon, were mainly 1-octen-3-01 (14.1%), 3-octanol (4.5%) and linalool (2.6%) (Ngassoum *et al.,* 1999). To date, no scientific publication has reported the efficiency of *H. welwitschii* leaf extracts on stored product insect pests. The study was therefore aimed at determining the most active fraction of *H. welwitschii* against the eggs, larvae, pupae and adults of *S. zeamais*.

2. Materials and Methods

2.1. Collection and extraction of *Hemizygia welwitschii*

Fresh leaves of *H. welwitschii* were collected from the surroundings of University of Ngaoundere in the Vina Division, Adamawa region, Cameroon between August and November 2016 and shade-dried naturally at the room temperature for five days where they became crisp dry. The identity of the plant was confirmed at the Cameroon National Herbarium in Yaounde, where a voucher specimen (Serial number: 6910/SRFK) was deposited. The dried leaves were crushed in a mortar until the powder passed through a 0.4 mm mesh sieve. The powder was stored in a deep-freezer at the temperature of -18°C until needed for bioassay.

Two thousand three hundred grams of *H. welwitschii* powder were mixed with 7.5 L of hexane and stirred for 30 min and allowed to stand for 24 hours in the laboratory of the Institute of Medical and Medicinal Plant Research (IMPM), Yaounde, Cameroon, and then re-stirred again. After 48 hours the mixture was then filtered with a filter paper (Whatman no. 1). The residue obtained after filtration was put through the process above again and the filtrate was admixed with the one obtained initially. After the hexane extraction was done, the paste left was dried for 10 h at room temperature in the laboratory and then used for Acetone extraction and followed by methanol extraction. The filtrates obtained with hexane, acetone and methanol were then separately concentrated in a Rotavapor at 70°C, 60°C and 65°C, respectively at 120 rpm. Extracts were stored in a refrigerator at 4 °C until needed for bioassay. *Azadirachta indica* seed oil from the study of Tofel *et al.,* (2016), which was stored in a deep freezer at -18°C, was used as a positive control.

2.2. Insects

The parent adults of *S. zeamais* for the adult toxicity test were obtained from colonies maintained at the Applied Zoology laboratory of the University of Ngaoundere while those for the immature stages toxicity were taken from colonies maintained at JKI, Institute for Ecological Chemistry, Plant Analysis and Stored Products Protection, Berlin since 2007 and 1968, respectively. In Ngaoundere, *S. zeamais* were reared on Shaba maize variety while in Berlin they were reared on Ricardino variety.

2.3. Bioassays

For the adult mortality bioassay, four different masses of 0.1, 0.2, 0.3 and 0.5 g each of the hexane, acetone and methanol extracts were separately mixed with 50 g grains in glass jars, which corresponded to the concentrations of 2, 4, 6 and 10 g/kg, respectively. The negative controls consisted of grains with solvent alone. The content of each jar was hand-shaken properly to ensure complete coating of the grains with the extracts. The grains were then air-dried for 2 hours to evaporate the solvent. Groups of 20 *S. zeamais* were added to glass jars containing treated or untreated maize. Glass jars were securely covered with muslin cloth and were tightly held in place with rubber bands to ensure adequate ventilation. All treatments were arranged in a completely randomized design on shelves under fluctuating laboratory condition in Ngaoundere, Cameroon and each treatment had four replications. Mortality was recorded 1, 3, 7 and 14 days after treatment. Insects were considered dead when no movement was observed after touching them with forceps twice within two or three minutes.

Concerning the toxicity test on immature stages, individual lots of 50 g maize grains in 250 ml glass jars, containing eggs, different larval stages or pupae of *S. zeamais* were coated with *A. indica* seed oil (positive control) or the hexane, acetone and methanol extracts at the rates 1, 4 and 10 g/kg, with the aid of a rotatory shaker. The jars were closed with perforated metal lids. The negative controls consisted of grains with solvent alone. The grains were then dried for 10 min in a ventilated fume chamber to evaporate the solvent. The treated and untreated grains, which were replicated four times were keep in a controlled environment at 25 ± 1°C and 65 – 70% r.h. in a complete randomized design in Berlin, Germany for F_1 progeny emergence. All the F_1 progeny were counted.

2.4. Data analysis

Data on % cumulative corrected mortality and % reduction in F_1 progeny, were arcsine [(square root(x/100)] transformed to homogenise the variance. The transformed data were subjected to the ANOVA procedure using the Statistical Analysis System (version 9.2). Tukey (HSD) test (P = 0.05) was applied for mean separation**.** Probit analysis (Finney, 1971) was applied to determine lethal concentrations causing 50% (LC_{50}) mortality of *S. zeamais* at 1 and 7 days, after treatment application. Abbott's formula (Abbott, 1925) were used to correct for control mortality before probit analysis and ANOVA.

3. Results

3.1. Toxicity to adult

All the *H. welwitschii* extract fractions generally caused significant mortality to adult *S. zeamais* compared to the control. Mortality increased with ascending content levels and time exposure, irrespective of extract fractions. Overall, significant difference was observed among the fractions. Hexane extract was more potent to the adult weevil than the other extracts, recording the maximum 100% mortality for the concentration 10 g/kg within 14 days post infestation. Within the same time and at the same dosage, acetone and methanol extracts recorded respectively 64.87 and 75.98% adult mortality. Within 1day after infestation the methanol extract caused higher mortality of 16.25% at the dose of 10 g/kg. The lowest tested dose (2 g/kg) achieved 63.32, 51.91 and 83.14% *S. zeamais* adult mortality respectively for the methanol, acetone and hexane fractions within14 days post-exposure.

The results of the evaluation of toxicity of the different extract fractions of *H. welwitschii* s are shown in Table 1. All the extracts proved to be toxic to adult *S. zeamais* although the acetone fraction was less effective with the LC_{50} of 410.18 g/kg one day after treatment. Adult S. *zeamais* was more susceptible to the hexane fraction with LC_{50} of 0.78 g/kg (7 day) followed by the methanol fraction with LC_{50} of 1.69 g/kg (7 day). At day one, the slope of the hexane extract (4.55 ± 0.74) was steeper than that of methanol (1.89± 0.24) and acetone (0.83 ± 0.21) extracts while they seemed similar at seven

days. In general, the coefficients of determination (R^2) of the extracts were between 0.60 and 0.94. The values of chi-square (Chi^2) were not significant for all the extracts except the methanolic fraction after day one exposure.

Tab. 1 Toxicity of leaf extracts from *Hemizygia welwitschii* to adult *Sitophilus zeamais* in maize grains at different exposure periods

Extract	Slope ± S.E.	R^2	LC_{50} (g/kg)	Chi^2
Day 1				
Hexane	4.55 ± 0.74	0.70	19.04	17.31ns

3.2. Inhibition of offspring production from eggs and immature stages

Table 2 shows the result of ability of *H. welwitschii* extract to inhibit the emergence of progeny in grains containing eggs, larvae and pupae of *S. zeamais*. All the extracts significantly influenced the production of the weevil ($P < 0.05$). Overall, the bioefficacy of these extracts on the eggs and immature stages was dose-dependent. *A. indica* seed oil was more efficient in inhibiting the development of eggs at all doses (100% inhibition). Acetone extract was more toxic to the eggs, larvae and pupae than the other extracts, inhibiting progeny production by 90.90%, 88.10% and 100%, respectively, at the concentration 10 g/kg. Contrariwise, hexane fraction had less affects the eggs, larvae and pupae development, reducing them by only 25%, 33.75% and 52%, respectively, at the concentration 10 g/kg. Methanol extract was most effective on pupal stage (73.50% inhibition) at its lowest dose (1 g/kg) than at its highest content of 10 g/kg with 58.50 % emergence reduction.

4. Discussion

Plant products and their secondary metabolites are receiving increasing attention in stored product management (Zettler and Arther, 2000). Several researchers have evaluated the insecticidal, repellent or antifeedant and development inhibiting effects of various plant parts and plant extracts on *S. zeamais* with varying degrees of success (Arannilewa et *al.,* 2006). Boulogne *et al.,* (2012) mentioned that, 656 plant species worldwide, distributed into 110 families, were identified to have a significant insecticidal activity. The most cited family is the Lamiaceae in which *H. welwitschii* belongs, with 181 species distributed into 48 genera, counting for 28 % of the plant families with an insecticidal activity. In the present study, the different extracts of *H. welwitschii* which caused significant mortality to *S. zeamais* suggests that they contain insecticidal compounds. Compounds like linalool known for insecticidal activity and present in the leaves as reported by Ngassoum *et al.* (1999) may have played a significant role. The hexane extract was the most effective against adult *S. zeamais*. This could be speculated that the fraction may possess compound with high insecticidal potency. Kosini *et al.* (2015) reported similar results with *Ocimum canun,* plant of the same family. They mentioned that the high mortality caused by hexane extract may be partially related to the gummy aspect of the hexane extract, which acetone and methanol extracts lacked. The extract may be glued to the insect's wing cover and legs and hindered mobility. The insect thus lost vigor by trying to get loose and when combined with the toxic effects of compounds in the leaf extracts, may lead to the death of *S. zeamais*. The essential oil of the studied plant was repellent against mosquitoes preventing them from feeding (Oyedele *et al.,* 2000). This repellency property may have averted the maize weevils in the present study from food intake and death occurred by starvation since mortality was time dependent. More studies are needed to elucidate the active ingredients in each fraction and to understand the mode of action of these against insect pests of stored products. Also, microscopic observations will help to clarify how and where the glue of the extract fixes on the insect.

One of the basic characteristics of an effective phytochemical is its ability to reduce progeny emergence in treated grains (Khoshnoud et al., 2008). Results of inhibition of progeny production showed that extract fractions from *H. welwitschii* inhibited adult emergence of *S. zeamais,* showing their ability to control the development of the insect. The fractions might have acted physically by asphyxiation or chemically on eggs or immature stages, depending on the compounds present in each extract. The coating of the grains with extracts might have prevented the eggs from adhering unto the grains. Afful *et al.,* (2012) indicated that the methanol extract of root of *Securidaca longipendonculata* inhibited the development of eggs and larvae of the maize weevil. This reduction in emergence is an indication of the presence of ovicidal and larvacidal compounds which need to be determined.

The results of the present investigation based on the laboratory experiments, revealed that the extracts of *H. welwitschii* leaves had sufficient efficacy to be a component of storage pest management package for *S. zeamais,* especially for low income farmers since the plant species are cheap and widely available.

Abstract

Common control strategies to manage stored product pests are mainly based on the use of synthetic insecticides and fumigants. Consumer's demand for pesticide-free food, and the increasing resistance of pests to traditional insecticides, dictate the need to evaluate alternative control methods. For this purpose, many sustainable techniques have been tested for the control of stored product pests. Among them, Citrus essential oils can represent a valid alternative to synthetic insecticides. The effects of Sweet Orange essential oil (EO) nanoemulsion applied as cold aerosol were evaluated against adults of *Tribolium confusum* du Val (Coleoptera: Tenebrionidae) and *Cryptolestes ferrugineus* Stephens (Coleoptera: Cucujidae). Both chemical and physical characterization of the EO-based formulation was carried out. The developed formulation had an average size belonging to the nanometer scale and a low polydispersity index. The relatively high zeta potential value confirms the stability over time of the developed formulation. The efficacy of the tested formulation showed a dose-dependent response and the cumulated mortality of the exposed insects increaseduntil 24h of exposure for *C. ferrugineus* and until 120h for *T. confusum*. The tested formulation was more effective against *T. confusum* adults (LD50= 86.30 ppm) than *C. ferrugineus* ones (LD50= 36.79 ppm). The results of this study coupled with the large availability at reasonable costs of Sweet orange EO, are promising for the potential development of new tools against stored product pests.

Keywords: Citrus, essential oil, Tribolium confusum, Cryptolestes ferrugineus, control, fumigation

Introduction

Although their high toxicity and non-biodegradable nature have already been acknowledged worldwide, the use of synthetic pesticides is still increasing (Koul et al. 2008). However, the environmental consequences, the negative impact on non-target species and the development of resistance have stimulated the interest in alternative control strategies, such as the use of naturally derived chemical compounds (biopesticides), which have selective toxicity and are easily biodegradable (Kordali et al. 2006; Regnault-Roger et al. 2012).

Among botanicals, essential oils (EOs) are effective biopesticides, due to their promising laboratory results in term of toxicity against insect pests, bacteria and other pathogens (Romeo et al. 2008; Ali et al. 2012; Russo et al. 2013; Campolo et al. 2014).; Essential oils are volatile natural compounds, synthesized by many species of plants as secondary metabolites (Bakkali et al. 2008), which may act against insects as larvicidal, antifeedant, growth inhibitor, adulticidal, fertility reducer, oviposition deterrent and repellent (Cardiet et al. 2012; Ibrahim et al. 2001; Werdin-Gonzáles et al. 2011; Licciardello et al. 2013). Furthermore, EO toxic activity against mammalians is quite reduced (rat oral LD50 = 2–5 g × kg-1) (Regnault-Roger et al. 2012), guaranteeing product specificity and safety. Although most essential oils are exempt from registration, standardization and quality control are key issues for registration (Isman 2000; Koul et al. 2008). Moreover, EO chemical composition can negatively affect their application in operative conditions, since EO-based insecticides generally show high volatility and poor solubility in water (Moretti et al. 2002).

In this context, the development of a stable formulations containing EOs is a pivotal requisite for the application of these technique in field conditions. Nanoemulsions are defined as emulsions (i.e. mixtures of two or more liquids that are normally immiscible) in which the micelles of the dispersed phase show nanometric dimensions. In this study, we developed and characterized a nanoemulsion oil in water (i.e. the dispersed phase was EO and the dispersion medium was water) of sweet orange (SOR) [*Citrus sinensis* (L.)] essential oil. Thus, the aim of this study was to assess the insecticidal activity of SOR-EO against two stored product pests, *Tribolium confusum* du Val and *Cryptolestes ferrugineus* Stephens, testing its toxicity as cold aerosol (i.e. cold fumigation) against adult insects.

2. Materials and Methods

2.1. Insects

The confused flour beetle *T. confusum* and the rusty grain beetle *C. ferrugineus* were reared for several generations in the Stored Products Laboratory of the Department of Agriculture on wheat flour mixed with yeast (10:1, w: w). The rearing conditions were: 25 ± 1°C, 65±5% r.h., with a

photoperiod of 16h:8h (L: D). To obtain adults of the same age, about 100 unsexed adults were placed inside 5 l glass containers each provided with 500 g of non-infested rearing medium. After 2 days the specimens were removed and the newly emerged adults (2–8 days old) were used in the trials. Insects were collected from cultures using a 450-µm sieve (Technotest; Modena, Italy) and a mouth aspirator.

2.2. EO extraction

SOR-EO was extracted from the fruit peels, pesticide-free certified (Capua SRL, Campo Calabro Italy). The essential oil was extracted with the cold pressing technique (Citroflor, Condofuri Marina, Italy) (Lahlou 2004), from fruits cultivated in Calabria (Italy) and harvested from November to March following the harvest calendar for the species.

2.3. Nanoemulsion formulation and characterization

TWEEN 80 (Polyoxyethylene (20) sorbitan monooleate) was purchased from Sigma-Aldrich (Italy). The EO-NPs were prepared following Werdin-González et al. (2011), with some modifications. In brief, EO was mixed with Tween 80 and stirred for 30 min. Then, nanoemulsion was realized using the mechanism of spontaneous emulsification that is created between an organic phase and an aqueous phase when they are mixed. Double-distilled water was added to the homogeneous solution of citrus essential oil and a hydrophilic surfactant and then stirred for 60 min. The oil in water nanoemulsion was composed by 5% Tween 80®, 15% essential oil and 80% water. Lastly, to reduce micelles, the formulation was sonicated using an ultrasonic immersion homogenizer, stored at 25±0.5 °C in an airtight container and used for the bioassay within the following 48h. In order to measure the characteristics of the realized nanoemulsion, qualitative analyses such as particle size, polydispersion and emulsion stability were measuredusing the Zetasizer Nano (Malvern®) instrument. The dimensional and polydispersion analyses were carried out in cuvettes, model DTS0012 in polystyrene latex at 25°C. The nanoemulsion was diluted in double-distilled water in a ratio of 1/200 and 1 ml of the diluted solution was inserted into the cuvette. The measurement of each sample involved 3 replicas of 14 cycles. Three samples were tested as replicates. The stability analysis (potential ζ) was carried out by inserting 730 µl of the diluted solution in DTS1070 polystyrene latex cuvettes and tested at 25°C. The measurement of each sample involved 3 replicas of 14 cycles. Three samples were tested as replicates.

2.4. Cold aerosol trials

Toxicity trials were carried out in laboratory conditions at 25 ± 1°C, 65 ± 5% r.h. with a photoperiod of 16h:8h (L:D). Test specimens were placed inside a Perspex cage (25 x 25 x 25 cm), presenting a hole on one side (highness from the bottom 20 cm; diameter 14 mm) where was allocated an aerosol glass ampule. A known quantity of SOR-EO nanoemulsion (2 mL for *C. ferrugineus* and 4 mL for *T. confusum*) was put inside the aerosol ampule, which was connected to an air delivery system blowing purified air at 2 L min−1 constant flow. The air flow was turned off when the ampule was empty. Tested insects were maintained inside the cage for an exposure time of 24 h. After exposure time, specimens were removed from the cage and gently placed in a clean glass Petri dish, in which was added a plastic container containing 1g of wheat flour mixed with yeast (10:1, w: w). The dosages tested against *C. ferrugineus* were: 300, 150, 75, 37.5, 18.75 and 9.38 ppm of SOR-EO. For every dose 3 replicates (i.e. 15 insects each) were performed. The mortality was recorded after 24 from the beginning of the cold aerosol treatment. The dosages employed against *T. confusum* were: 600, 300, 150, 75 and 37.5 ppm of SOR-EO. For every dose 3 replicates (i.e. 10 insects each) were performed. For T. *confusum*, the mortality was counted after 24 48, 72, 96 and 120h.

To exclude the impact of surfactant on insect mortality, control trials were carried out using formulations of Tween in water at the same concentrations tested as EO-nanoemulsions. In addition, additional control trials using only distilled water were performed for both *T. confusum* and *C. ferrugineus*.

2.5. Data analysis

Statistics were carried out using SPSS® V. 20 (IBM). The efficacy of the tested formulations was corrected for control mortality using Abbott's formula (Abbott 1987). Probit analysis was performed in order to estimate the median lethal concentrations for both tested insect species (LD50 and LD99).

3. Results

The average size of the developed formulation belonged to the nanometer scale (average size ± standard error= 230.3 ± 14.65 nm) (Figure 1), with low polydispersity index (Pdi 0.274). The stability over time of the tested formulation was confirmed by the relatively high zeta potential value obtained (ζ= 26.93) (Figure 2).

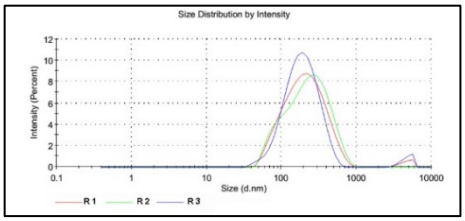

Fig. 1 Size and PdI values for the SOR-EO nanoemulsion

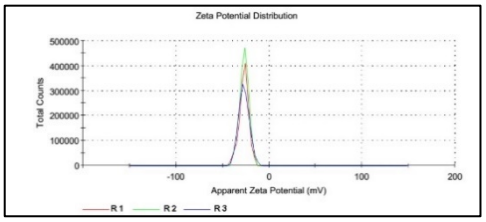

Fig. 2 ζ potential of the SOR-EO nanoemulsion

The efficacy of the tested formulation showed a dose-dependent response and the cumulated mortality of the exposed insects increased until 24h of exposure for *C. ferrugineus* (Figure 3) and until 120h for *T. confusum* (Figure 4). No mortality was recorded for control with distilled water, while little toxic activity was recorded for Tween solutions. From statistical analyses *T. confusum* adults proved less susceptible to the tested formulation than *C. ferrugineus* specimens. Lethal dose values for *C. ferrugineus* were LD50= 36.79 ppm and LD99= 209.7 ppm after 24h from the exposure. In contrast, the LD50 and LD99 values recorded for *T. confusum* at 24h from the exposure were 86.30 ppm and 631.14 ppm, respectively.

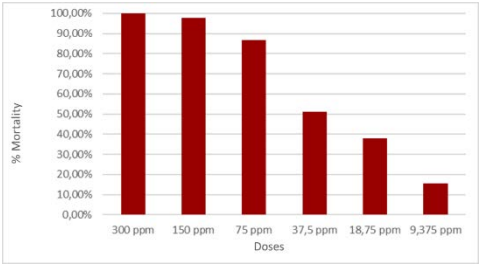

Fig. 3 Insecticidal activity of SOR-EO nan emulsion as cold aerosol against *C. ferrugineus* adults after 24h from the exposure.

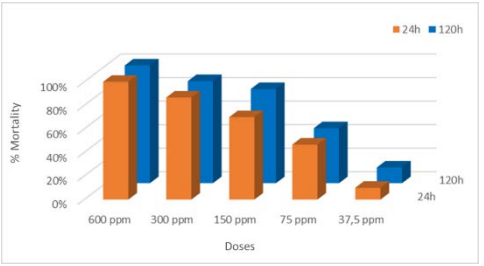

Fig. 4 Insecticidal activity of SOR-EO nanoemulsion as cold aerosol against *T. confusum* adults after 24h and 120h from the exposure.

4. Discussion

Several studies had demonstrated the fumigant activity of essential oils to several stored product pests (Polatoğlu and Karakoç 2016), highlighting higher susceptibility of adults than of pre-imaginal stages (Koul et al. 2008). Terpenes are key compounds for the bioactivity against insects, bacteria and fungi, acting as contact, fumigant and ingestion insecticides (Malacrinò et al. 2016; Prates et al. 1998). The formulation of EOs as nanoemulsions improves both the stability and effectiveness of botanical insecticides. Indeed, nano-formulations can solve problems related to EO volatility, poor water solubility, and the tendency to oxidize (Campolo et al. 2017; Werdin-González et al. 2014). Furthermore, these formulations are able to release the active compounds at the site of action

gradually (de Oliveira et al. 2014), and concurrently minimize the toxic effects on non-target organisms (Gogos et al. 2012).

Both the size and the polydispersion index obtained in our study are adequate for nanoemulsion and the zeta potential obtained can be considered an indicator of the extent of EO loading in the emulsion. Furthermore, our results highlighted the good insecticidal activity of the citrus peel essential oils against the stored product pests *T. confusum* and *C. ferrugineus*. In this study, we also tested a novel administration method of EOs, using cold fumigation as aerosol. Indeed, this promising technique may allow the development of efficient and effective control strategies based on the application of plant-derived compounds to protect stored products in the food industries. The results obtained in these trials, together with the availability of SOR-EO at reasonable cost, are promising for the potential development of new tools against stored product pests.

Abstract

Contact insecticides are commonly applied as fogs to disinfest and disinfect spaces. Recently, these fogs have been adapted to treat commodity within the spaces, and much has been learned regarding the efficacy of this process. When considering fresh citrus in California, fogs are applied to control both insects and microbes. One insect pest, the Asian citrus psyllid (ACP), *Diaphorina citri*, is a quarantine pest in California and limiting its geographic distribution is a major goal of the California citrus industry. While a variety of phytosanitary measures can be used to control adult ACP once fruit is at a packing house, ultimately, a treatment must be developed to disinfest field-run fruit prior to its exiting the grove. High-pressure fogging with 1,100-L of an aqueous mixture containing 0.2% Evergreen® (6% pyrethrins & 60% piperonyl butoxide) and 0.5% (v/v) BreakThru® (polysiloxane surfactant) was explored in laboratory-, pilot-, and commercial-scale trials as an approach to disinfest a 48-bin trailer load of fresh citrus. Laboratory-scale studies were conducted to quantify, and subsequently model, insecticidal coverage as a function of temperature, surface area, droplet size, and fog volume. Results are discussed in the context of experimental variability across confirmatory trials and continued efforts to optimize the technical and economic feasibility of fogging as a postharvest control strategy.

Keywords: food security, food safety, pyrethrins, postharvest fogging

1. Introduction

Asian citrus psyllid (ACP), *Diaphorina citri*), which transmits citrus greening disease (Huanglongbing or HLB)-associated liberibacter ('*Candidatus* Liberibacter asiaticus; Las), has the potential to devistate the production of fresh citrus in California (Grafton-Cardwell et al. 2016). Moreover, the presence of ACP in the marketing channel can create a phytosanitary barrier for exports, which are key to the industries profitability. While ACP adults are removed from fresh citrus that has been subjected to cleaning and packing procedures standard to commercial production and distribution, State and Federal quaratines often restrict movement of fruit from ACP infested orchards to packhouses (CDFA, 2018).

Accordingly, a treatment must be developed to disinfest field-run fruit prior to its exiting the grove to control any incidental transportation of ACP and potential spreading of the insect and its associated disease. This work describes the development of a high-pressure fogging system using Evergreen® to control ACP in trailer loads of field-run fruit. The proposed treatment will reduce the number of psyllids in bulk citrus and reduce the insecticides applied to the grove, which will in turn improve worker safety, reduce environmental impacts, and improve IPM of ACP and other pests.

2. Materials and Methods

2.1. Chemicals

Evergreen® Pro 60-6 (McLaughlin Gormley King (MGK) Company, Minneapolis, MN), an aqueous mixture of 6% pyrethrins & 60% piperonyl butoxide, was sourced from Fruit Growers Supply (Exeter, CA) (EPA Reg. No. 1021-1770). BreakThru® S240, a polysiloxane surfactant (CA REGISTRATION #1051059-50001-AA), was sourced from Evonik Corporation (Hopewell, VA). Prior to dilution of the active and the surfactant, water was deionized using a Portable Deionizing System (ion exchange resin).

2.2. Insects, rearing, and infestation

The Asian citrus psyllid (ACP), *Diaphorina citri*, were reared on potted *Murraya koenigii* (L.) plants contained within ca. 0.5-m^3 rearing enclosures housed in an environmental room at the UC Riverside Insectary & Quarantine Facility set to 85 ± 2°C, 65% RH, and 16: 8 (L: D). Movement of the psyllids from the quarantine facility was permitted by CDFA (Permit # 3280)

To obtain an aliquot of adult ACP for efficacy studies, 10 specimens were consecutively aspirated into mesh cages using a customized arrangement of the aspirator and cage (Fig. 1). With respect to the commercial-scale trial conducted on 23 October 2017, two cage types were used. Cylindrical ~8-mL stainless-steel cages (30-mesh), as shown in Figure 1, were fabricated and following aspiration of the specimens, these cages were capped with a cork. Nylon mesh cages (3/4" diameter and 2.5" height) were fabricated by shrouding (Fig. 2A & 2B) – a wire cylinder (1/2" diameter and 2" height) with a square of nylon hardware cloth. After aspiration, the open end of the nylon cage was closed using a binder clip.

2.3. Commercial-scale fogging

At 07:00 PST on 23 October 2017 a 48-bin trailer load of field-run fresh navel oranges (ca. 56 to 88 size), sourced from Gless Ranch (Riverside, CA) arrived at Blue Banner Citrus in Riverside, California. Bins were off-loaded, numbered, and ACP specimens, which were caged ca. 0.5- to 1.5-h earlier, were buried throughout the bins at locations that were previously shown to have the relatively lowest piperonyl butoxide residues following a treatment (Fig. 3A). A total of 140 nylon cages were buried, 78 and 14 at low- and high-corner positions, respectively, and, 48 at the center of respective bins. To quantify residues throughout the load, and particularly those in proximity to nylon-caged specimens, nylon cages containing glass microfiber filter papers (1.6μm, 95 ± 1 mg, ~20 m^2/g, 4.7-cm diameter, 53 g/m^2 weight basis Whatman GF/A) were place next to nylon-caged specimens at each location. A stainless-steel cage containing ACP (used in previous experiments) was also placed at the center of respective bins. A total of 22 aliquots of ACP specimens and 12 nylon mesh cages as well as 10 "cage-less" 7-dram clear plastic aspirator vials, each of which contained a host leaf and a snap cap with an 8-mm diameter stainless-steel 100 wire mesh gas-portal, were buried throughout separate container of sourced fruit to serve as non-treated controls (Fig. 3B).

Within a de-greening room (V = 753.6 m^3; 21.3 l x 5.8 w x 6.1 h meters) at ca. 70°F, infested bins of fruit were re-oriented into the geometry of the truck load, two bins wide by two bins stacked, with a ca. 3-ft span between the 6th and 7th rows of bins (Fig. 4). The container of non-treated controls was transferred to an adjacent de-greening room, also set to ca. 70°F. The high-pressure spray system, designed and fabricated by Valley PackLine Solutions (Reedley, CA) was then situated around the load. Industrial Air Circulating Fans (34"- Fan Blade Dia, 17000 cfm Max Air Flow) were alternately arranged, directed laterally toward the center of each of the six 8-bin cubes comprising the load. An aqueous mixture (1,100-L) of ca. 0.1% Evergreen® (6% pyrethrins & 60% piperonyl butoxide) and 0.5% (v/v) BreakThru® (polysiloxane surfactant) was prepared in the reservoir of the spray system (note: Max label is 914mL per 290 gallons). The fans were turned on, and the aqueous solution was directed at 1000 psi to each of the six fans, outfitted respectively with a ¾"- steel manifold and a 45° fan nozzle that discharged into the airflow, ~ 6" below from the front of the fan. The de-greening room doors were shut, which marked the start of the treatment.

After the solution was delivered, the fans were turned off, 10 minutes elapsed to let the fog settle, and the de-greening room door was opened. The treated specimens were retrieved from the bins, along with the caged filter papers. Treated as well as non-treated control specimens were placed in bin- and location-specific Ziploc bags (separate from the caged filter papers that were organized similarly). Bagged-specimens were placed in a cooler and returned to the UC Riverside Insectary & Quarantine Facility for mortality evaluations (vide infra), which occurred at ca. 3-h following treatment.

2.4. Mortality evaluation

After returning the specimens, both treated and non-treated, to UC Riverside Insectary & Quarantine Facility the treatment, preparations were immediately made to evaluate mortality that resulted from the treatment. All specimens, less the non-treated controls specimens already in 7-dram snap cap vials, were transferred from nylon and stainless-steel cages into7-dram clear plastic "snap cap" cage modified with 8-mm diameter stainless-steel 100 wire mesh gas-portals on the cap (Fig. 5). A fresh lemon leaf was introduced into all plastic cages. Approximately 3 h following the treatment, all cages were visually inspected. Mortality was diagnosed by lack of motion and was calculated by subtracting the number of survivors from the number of treated specimens. Mortality of non-treated control specimens was treated numerically using Abbott's method (Abbott, 1925). Mortality, calculated as a percentage of the response per treatment, was expressed as a function of the number of specimens treated via probit analysis of Finney (1944 & 1977) at the 95% confidence level (CL), as further derived in Couey and Chew (1986) as well as Liquido and Griffin (2010).

3. Results

3.1. Commercial-scale fogging

The fogging process commenced at 10:30 AM and terminated at 12:10 PM. All but five non-treated control specimens survived, a single specimen did not survive in the plastic vial, while four did not survive in the nylon mesh. Only 2 specimens survived from 1,968 total treated, one specimen each from a stainless-steel and nylon mesh cage, both situated in the middle of the same bin on the top row, opposite the nearest fan. Using the statistical methods described above, the treatment resulted in 99.778% mortality (probit 7.85 at the 95% CL).

These results provide evidence to support the conclusion that adult ACP will be controlled in 48-bin trailer loads of fresh citrus subject to the high-pressure fogging treatment, at least when the volume of the load is ≥ 10% of the fogging enclosure. Although the 23 October 2017 commercial-scale trails were conducted in a de-greening room, analogues trials have been conducted on 48-bin trailer loads that were driven into a tent structure, as shown in Figure 6, methodology that is consistent with the need to disinfest field-run fruit prior to its exiting the grove.

Fig. 1 Method of collecting adult Asian citrus psyllid (ACP), *Diaphorina citri*, into 30-mesh stainless-steel cages using a standard mouth aspirator apparatus.

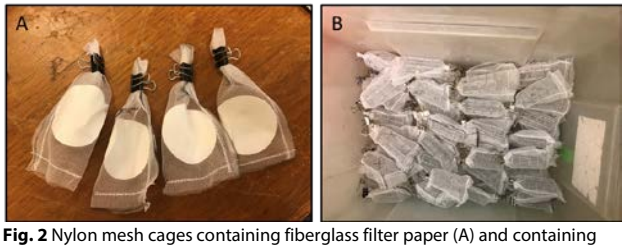

Fig. 2 Nylon mesh cages containing fiberglass filter paper (A) and containing ACP (B). Note that the open end of the nylon cage was closed using a binder clip.

Fig. 3 A bin filled with field run fruit showing placement of caged specimens in the middle position (A), a container filled with the same fruit that was used to analogously burry the non-treated, control ACP in the nylon mesh cages (B), the fruit were carefully positioned back atop the caged specimens (C), and the geometry of the trailer load was reconfigured within the degreening room (D).

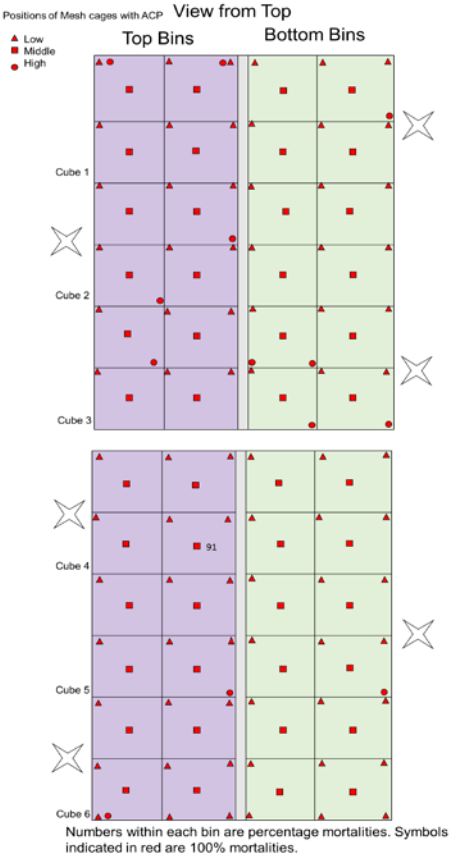

Fig. 4 Layout of 48-bin trailer loads of fresh citrus. Purple and green color indicate top- and bottom-stack positioning, respectively. Different shapes show location of cages within the bin (middle positon had both nylon and stainless-steel mesh cages). Note that the two survivors were found in the 8th row (top to bottom), one specimen each from a stainless-steel and nylon mesh cage, both situated in the middle of the same bin on the top row, opposite the nearest fan (denoted by stars).

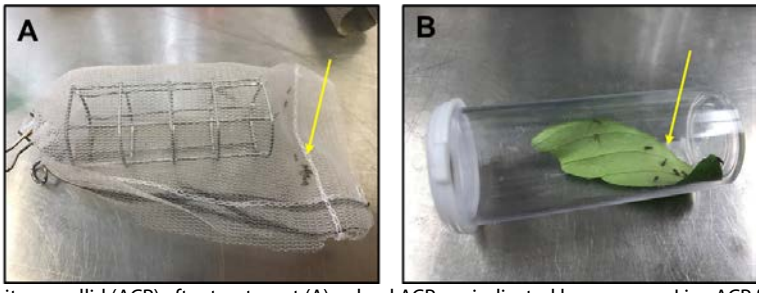

Fig. 5 Asian citrus psyllid (ACP) after treatment (A) – dead ACPs as indicated by an arrow. Live ACP feeding on lemon leaf in the non-treated controls caged in a plastic vial (B).

Fig. 6 The high-pressure fogging with an aqueous mixture containing 0.1% Evergreen® (6% pyrethrins & 60% piperonyl butoxide) and 0.5% (v/v) BreakThru® (polysiloxane surfactant) can be conducted on a 48-bin trailer load driven into a tent structure, methodology that is consistent with the need to disinfest field-run fruit prior to its exiting the grove.

4. Discussion

Future research effort will focus on minimizing the amount of fogging material required for efficacy, which will likely involve a transition to low-volume applicatiors, such as ultrasonic and thermal fogging technologies. Additionaly, treatment withina curtain-sided truck will be persued to further minimize the infrastructural requirement to tent the truck, while still remaining "mobile", within the grove. From a regulatory prespective, the proposed treatment represents a shift in paradign from the familiar pre- and post-harvest designations, and this divergence must be addressed at both the State and Federal levels. Considered a preharvest treatment, the application of Evergreen® is excempt from residue tolerance (USEPA and CA), has a 0-h postharvest interval, and a 12-h re-entry period for workers (CA). It is critical to note, however, workers will not be reuired to touch treated fruit after treatment, as it is already in field bins. While postharvest space foggings and direct applications to binned fruit on trucks are permitted postharvest treatments, with corresponding Personal Protective Equipment (PPE) and re-entry requirments, the proposed treatment occurs prior to washing and packing, which remove residues, contradicting the reationale for a postharvest tolerance. Regardless of the ultimate regulatory categorization, the proposed treatment could reduce the amount of insecticides applied to the grove, which will in turn improve worker safety, reduce environmental impacts, and improve IPM of ACP and other pests.

Acknowledgement

This work was funded by the California Citrus Research Board (Project 5300-184). We would like to acknowledge substantial contributions of David Sorenson and Dirk Hartley during the trials. We would also like to thank the UC Riverside Insectary and Quarantine staff for providing ACP samples, Alan Washburn for providing fruit, Dr. Joseph Morse, UCR staff (Nastaran Tofangsazi, Imon Riabi, Brandon Skylar Rogers, Tobias Moyneur) and USDA-ARS staff (Matthew Rodriguez, Stephen Corbett, Erik Rivera) for technical assistance, and especially thank co-operating packinghouses, namely, Blue Banner Co., Corona-College Heights Orange and Lemon Association, Valley PackLine Solutions, and Harding and Leggett.

Toxicity of fine powders, filter cake and Triplex against *Sitophilus zeamais* adults

Tesfaye M. Tadesse[1], Bhadriraju Subramanyam[1]

[1]Department of Grain Science and Industry, Kansas State University, Manhattan, Kansas 66506, USA, tesfayet@ksu.edu

DOI 10.5073/jka.2018.463.170

Abstract

Filter cake and Triplex are powdered by-products of aluminum sulfate and soap factories, respectively. There is limited data about the use of these powders as grain protectants. This study was aimed at determining contact toxicity of both powders against *Sitophilus zeamais*, a common pest of stored grains. Lethal concentration of both powders to *S. zeamais* was determined by exposing 10 adults for 12 h in 9 cm diameter concrete arenas inside Petri dishes dusted with filter cake (0 - 8 g/m^2) or Triplex (0 - 9 g/m^2). Lethal time was determined by exposing adults to 3 g/m^2 filter cake and 9 g/m^2 Triplex for 1 to 24 h. Each treatment was replicated 3 times. At the intended exposure time, adults were transferred to 150-ml round plastic containers with 30 g of wheat and held at 28 degree Celsius and 65% r.h. for 14 d to determine mortality. Adult progeny production was determined after 42 d. A 50% mortality of adults was obtained at 0.61 g/m^2 of filter cake and 1.61 g/m^2 of Triplex concentrations with a 12 h exposure. The corresponding effective concentrations for 50% reduction of progeny production were 0.18 g/m^2 of filter cake and 2.66 g/m^2 of Triplex. Lethal times for 50% mortality of adults after exposure to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex were 4.42 and 4.29 h, respectively. The corresponding effective times for 50% reduction of progeny production after exposure to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex were 1.74 and 2.34 h respectively. The overall result indicated that filter cake was highly toxic to *S. zeamais* than Triplex. Therefore, filter cake is a potential powder to be included in the integrated pest management practice in small holder farmers' storage structures after tested under real field conditions.

Keywords: Filter cake; Triplex; *Sitophilus zeamais*; Toxicity

1. Introduction

Grain losses due to insect pests in sub-Saharan Africa are very high, and the magnitudes of losses vary from country to country and from region to region (Abate et al., 2015). In countries like Ethiopia, about 80% of all grain produced is estimated to be stored at the farm or village level (Tadesse and Eticha, 2000). Grain storage losses in Ethiopia due to insect pests were estimated to be in the range of 10 to 21% (Abraham et al., 2008). A number of chemical insecticides used by Ethiopian small holder farmers to protect their grain in storage have been reported by several researchers (Abraham et al., 2008; Girma et al., 2008a,b; Hengsdijk and De Boer, 2017; Mengistie et al, 2017; Dessalegn et al., 2017). Recently, chemical pesticides, regardless of their inherent hazards, are used extensively in the fast changing agricultural sector of Ethiopia (Nigatu et al., 2016). However, Ethiopia is confronted with a number of problems related to unsafe handling of pesticide distribution and use, such as use of unsafe storage facilities, improper training on safe use of pesticides, and inadequate infrastructure to regulate safe use of pesticides (Mengistie et al., 2017). A survey done by Nigatu et al. (2016) on knowledge, attitude, and practices of farmers and farm workers in Ethiopia reported that 85% of farm workers (pesticide mixers/loaders, sprayers, and application supervisors) (n = 601) and 100% of female re-entry farm workers (harvesters, pesticide assessors, irrigation workers, irrigation supervisors, packing and sorting workers, transport/push car workers), (n = 275) did not receive pesticide-related training. In addition, 62% of farm workers did not shower after pesticide application, and none of the small-scale farm workers (n = 258) used personal protective equipment. A considerable increment in chemical pesticide usage intensity, illegitimate usage of DDT and Endosulfan on food crops, and direct import of pesticides without the formal Ethiopian registration process were also reported by Nigatu et al. (2016).

Therefore, there is a need to explore products that are safe and effective in controlling insects in smallholder farmers' traditional storages in Ethiopia. Two such products are filter cake and Triplex (Girma et al., 2008a,b; Tadesse and Subramanyam, 2018). Filter cake is a by-product of aluminum sulfate factory (Awash Melkassa Aluminium Sulphate & Sulfuric Acid Share Company, Melkassa Awash, Ethiopia (AMASSASC)). Triplex is a by-product of Mohammed International Development Research and Organization Companies (MIDROC) soap factory (Star Soap and Detergent Industries (SSDI Private Limited Company), Addis Ababa, Ethiopia). A study on elemental composition of both powders using energy-dispersive X-ray spectroscopy indicated that silicon and oxygen were dominant elements (Tadesse and Subramanyam, 2018). The same study showed 100% mortality when adults of *Sitophilus zeamais* Motschulsky were exposed to 7.5 g/m^2 of filter cake and 10 g/m^2 of both powders for 24 h on treated concrete arenas. Girma et al. (2008a) reported 92% mortality 3 d after *S. zeamais* were exposed to three genotypes of maize treated with 1, 2.5, and 5% (w/w) of filter cake. Similarly, a 0.25% (w/w) Triplex treated maize showed no significant mean percentage mortality of *S. zeamais* (93%) when compared with that of a synthetic insecticide, pirimiphos-methyl (100%), 7 months after treatment (Girma et al., 2008b). However, the toxicity of both products on multiple range of concentration and time was not known. Toxicity study is the investigation of either short or long-term toxic effects of a drug or chemical on animals (Saganuwan, 2017). Short-term toxic effect is determined using median lethal dose (LD_{50}), the dose required to kill half the members of a tested population after a specified test duration which was first introduced by Trevan in 1927 (Trevan, 1927) and revised many times (Saganuwan, 2017). It is frequently used as a general indicator of a substance's acute toxicity and lower LC_{50} is indicative of higher toxicity (Criswell and Campbell, 2013). Therefore, knowing the toxicity of filter cake and Triplex will help to use both products at the safer and effective level. This study was designed to determine the LC_{50}, lethal time (LT_{50}), effective concentration (EC_{50}) and effective time (ET_{50}) of filter cake and Triplex against *S. zeamais* economically, an important stored grain pest in Ethiopia (Abraham et al., 2008; Girma et al., 2008a,b; Tilahun and Hussen, 2014).

2. Materials and methods

2.1. Concrete-poured Petri dishes

Rockite®, a ready-to-mix concrete product (Hartline Products Co., Inc., Cleveland, Ohio, USA), was mixed with tap water in 2:1 ratio (grams to milliliter) to make a slurry. The slurry was poured into 9 cm diameter and 1.5 cm high plastic Petri dishes (Fisher Scientific, Denver, Colorado, USA). Slurry was poured to cover one half of the Petri dish's height. Slurry filled Petri dishes were allowed to dry on a laboratory bench for 24 h. Polytetrafluoroethylene (Insecta-a-Slip, Bio Quip Products, Inc., Rancho Dominguez, California, USA) was used to coat the inside walls of Petri dishes to prevent insects from crawling on sides of dishes.

2.2. Application of powders to concrete arenas and insect exposure

Brass frame, stainless steel wire cloth sieve with #80 mesh size (Seedburo Equipment Company, Des Plaines, Illinois, USA) were used to sift filter cake and Triplex powders. Concrete arenas of dishes were treated with the fines (particle size < 177 microns) at the following concentrations: 0 (untreated control), 0.5, 1, 2, 3, 4, 5, 6, 7 and 8 g/m^2 of filter cake or 0, 1, 2, 3, 4, 5, 6, 7, 8, and 9 g/m^2 of Triplex. A laboratory strain of *S. zeamais* was reared at 28 °C and 65% r.h. on organic hard red winter wheat (Heartland Mills, Marienthal, Kansas, USA) of 12.5% moisture content (wet basis) at the department of Grain Science and Industry, Kansas State University. Adults of *S. zeamais* were separated from wheat using a 2.38 mm diameter round-holed aluminum sieve (Seedburo Equipment Company, Des Plaines, Illinois, USA). Ten unsexed newly emerged two weeks old adults were exposed to untreated concrete arenas (control) and arenas receiving each of the 9 concentrations of filter cake or Triplex for 12 and 24 h in an environmental chamber with 28 °C and 65% r.h. A separate set of experiment, 10 adults from the same culture were exposed to 3 g/m^2 of

filter cake or 9 g/m^2 of Triplex separately for 1,2,4,6, 8, 10,12, 14, 16, 18, 20, 22, 24 h to determine the lethal times of both powders. Each powder-concentration-time combination was replicated three times. After the intended exposure time period insects were transferred carefully with a camel's hair brush to 150 ml round plastic containers holding 30 g of cleaned, organic hard red winter wheat (Heartland Mills) of ~12.5% moisture content (wet basis). The plastic containers had perforated lids with wire-mesh screens to facilitate air diffusion. Containers were incubated on the same chamber at 28 °C and 65% r.h. After 14 d, wheat from each container was sifted using a 2.38 mm circular round-holed aluminum sieve to separate insects from wheat. Insects that did not respond when gently prodded by a camel's hair brush were considered dead. A third set of experiment with same concentrations and exposure times was set to determine adult progeny production 42 d, after exposure to filter cake or Triplex. Adult progeny produced was counted from each container and the 10 starting adults were subtracted.

2.5. Data analysis

The mean ± SE mortality of *S. zeamais* on untreated (control) (n = 3) arenas at all exposure times ranged from 0.0 to 0.33 ± 0.33 and 0.0 to 0.67 ± 0.33 for filter cake and Triplex, respectively. Therefore, mortality data of *S. zeamais* exposed to filter cake or Triplex were corrected for responses in the control treatment (Abbott, 1925). Probit analysis was used to generate probit regression estimates and lethal concentration (LC) or lethal time (LT) producing 50 and 99% mortality. Similarly, probit analysis was used to generate effective concentrations (EC) and effective times (ET) for the 50 and 99% reduction of progeny production. The LC_{50}, LT_{50}, EC_{50} and ET_{50} values of filter cake were compared to the corresponding values of Triplex using ratio tests (Robertson et al., 2007). All the data were analyzed using SAS software (SAS Institute, 2012). Differences between any two LC_{50} or LT_{50}, EC_{50} or ET_{50} values were considered to be significantly different ($P < 0.05$) if the 95% CL for the ratio did not include 1 (Robertson et al., 2007).

3. Results

3.1. Concentration and corrected mortality responses of S. zeamais

Mean ± SE percentage corrected mortality of *S. zeamais* adults exposed to 0.5, 1, 2, 3, 4, 5, 6, 7 and 8 g/m^2 concentrations of filter cake at 12 h ranged from 41.58 ± 6.87 to 100 ± 0.00%. For 1, 2, 3, 4, 5, 6, 7, 8 and 9 g/m^2 concentrations of Triplex, the mortalities ranged from 20.96 ± 9.09 to 96.56 ± 3.44%. The corresponding mortalities of *S. zeamais* adults after exposure to 3 g/m^2 of filter cake or 9 g/m^2 of Triplex for 1,2,4,6, 8, 10,12, 14, 16, 18, 20, 22, 24 h ranged from 20.96 ± 6.87 to 100 ± 0.00% and 24.40 ± 3.44 to 96.56 ± 3.44%, respectively.

Table 1. Probit estimates and concentrations required for 50 and 99% mortality for *S. zeamais* of adults based on mortality assessment made 14 d after exposure to filter cake and Triplex for 12 h

Powder	*N*[a]	Mean ± SE		LC (95%CL) (g/m^2)		x^2(df)[b]
		Intercept	Slop	LC_{50}	LC_{99}	
Filter cake	180	0.63 ± 0.03	0.56 ± 0.07	0.61 (0.37 – 0.82)	7.54 (4.65 – 18.60)	11.01 (16)
Triplex	270	0.13 ± 0.05	0.84 ± 0.07	2.63 (2.12 – 3.11)	23.46 (15.88 – 44.05)	18.88 (25)

[a] N = total number of adults used to generate the probit regression estimates
[b] x^2- values for goodness-of-fit of model to data were not significant ($P > 0.05$)

Table 2. Probit estimates and times required for 50 and 99% mortality for *S. zeamais* of adults based on mortality assessment made 14 d after exposure to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex

Powder	*N*[a]	Mean ± SE		LC (95%CL) (g/m^2)		x^2(df)[b]
		Intercept	Slop	LC_{50}	LC_{99}	
Filter cake	240	-2.12 ± 0.32	2.72 ± 0.35	4.42 (3.47 – 5.26)	21.92 (16.74 – 33.56)	23.49 (22)
Triplex	390	-1.61 ± 0.24	2.00 ± 0.22	4.29 (3.14 – 5.34)	39.62 (29.87 – 60.30)	23.28 (37)

[a] *N* = total number of adults used to generate the probit regression estimates
[b] x^2- values for goodness-of-fit of model to data were not significant ($P > 0.05$)

The x^2 values for goodness-of-fit of the model to corrected mortality data were not significant ($P > 0.05$) (Table 1 and 2) indicating good fit of model to data. The lethal concentrations to kill 50% of *S. zeamais* adults exposed to filter cake and Triplex were 0.61 g/m^2 and 2.63 g/m^2, respectively. Triplex had significantly higher LC_{50} value than filter cake (ratio [95% CI] = 4.33 (2.85 – 6.57). The lethal times to kill 50% of adults exposed to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex were 4.42 and 4.29 h respectively. There was no significant differences between the LT_{50} value of Filter cake and Triplex (ratio [95% CI] = 0.97 (0.70 – 1.35).

Mean number of adult progeny produced ± SE by *S. zeamais* adults 42 days after exposure to 0.5, 1, 2, 3, 4, 5, 6, 7 and 8 g/m^2 concentrations of filter cake at 12 h ranged from 0.00 ± 0.00 to 135.00 ± 27.78. The corresponding mean number of adult progenies produced ± SE were ranged from 1.00 ± 0.58 to 123.67 ± 34.76 for Triplex at 1, 2, 3, 4, 5, 6, 7, 8 and 9 g/m^2 concentrations. Similarly, Mean number of adult progeny produced ± SE by *S. zeamais* adults after exposure to 3 g/m^2 of filter cake or 9 g/m^2 of Triplex for 1,2,4,6, 8, 10,12, 14, 16, 18, 20, 22, 24 h ranged from 0.00 ± 0.00 to 111.33 ± 7.62 and 24.40 ± 3.44 to 96.56 ± 3.44%, respectively. The percentage reduction of adult progeny produced relative to the control treatment was used to fit the model.

Table 3. Probit estimates and concentrations required for 50 and 99% mortality for *S. zeamais* of adults based on mortality assessment made 7 d after exposure to filter cake and Triplex for 12 h

Powder	*N*[a]	Mean ± SE		LC (95%CL) (g/m^2)		x^2(df)
		Intercept	Slop	LC_{50}	LC_{99}	
Filter cake	180	1.41 ± 0.07	1.93 ± 0.28	0.18 (0.10 – 0.26)	3.00 (2.15 – 5.19)	6.31 (7)[b]
Triplex	270	-1.17 ± 0.28	2.76 ± 0.44	2.66 (1.98 – 3.30)	18.59 (11.91– 43.60)	470 (25)

[a] *N* = total number of adults used to generate the probit regression estimates
[b] x^2- values for goodness-of-fit of model to data were not significant ($P > 0.05$)

Table 4. Probit estimates and times required for 50 and 99% mortality for *S. zeamais* of adults based on mortality assessment made 7 d after exposure to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex

Powder	*N*[a]	Mean ± SE		LC (95%CL) (g/m^2)		x^2(df)[c]
		Intercept	Slop	LC_{50}	LC_{99}	
Filter cake	210	-0.82 ± 0.19	1.89 ± 0.25	1.74 (1.10 – 2.32)	17.49 (12.50 – 30.42)	132.51 (19)
Triplex	390	-1.08 ± 0.16	1.93 ± 0.16	2.34 (1.75 – 2.91)	22.31 (18.23 – 29.12)	200.52 (37)

[a] *N* = total number of adults used to generate the probit regression estimates
[c] x^2- values for goodness-of-fit of model to data were significant ($P < 0.05$)

The x^2 for goodness of fit of the model to percentage adult progeny reduction data collected 42 d after exposure to filter cake and Triplex were not significant (P > 0.05) (Table 3). The effective concentration to decrease 50% of adult progeny production for *S. zeamais* 42 d after exposure to filter cake and Triplex were 0.18 and 2.66 g/m^2, respectively. Triplex had significantly higher EC_{50} value than filter cake (ratio [95% CI] = 14.41 (8.83 – 23.51). The x^2 for goodness-of fit of the model to adult progeny reduction data collected 42 d after exposure to 3 g/m^2 of filter cake and 9 g/m^2 of Triplex were significant ($P < 0.05$) (Table 4), indicating poor fit of model to data. The corresponding effective times to reduce 50% of adult progeny production of *S. zeamais* after 42 d were 1.74 and 2.34 h for filter cake and Triplex, respectively. Triplex had significantly higher ET_{50} value than filter cake (ratio [95% CI] = 1.81 (1.12 – 2.92).

4. Discussion

Contact insecticides have been used to protect stored commodities from pests for a long period of time (Ebling, 1971; Headlee, 1924). Such products have large proportion of silica which has high capacity to absorb epicuticular lipid from insects' body (Ebling, 1971; Malia et al., 2016; Subramanyam and Roseli, 2000). Silicon and oxygen are the major components of filter cake and Triplex (Tadesse and Subramanyam, 2018) which makes them similar to other inert dusts.

Our data demonstrated contact toxicity of filter cake and Triplex through concentration and exposure time responses of *S. zeamais* adults. The mortality of *S. zeamais* increased with increasing concentration of filter cake and Triplex. Accumulation of powder over insect's body is directly proportional to concentration of the powder (Le Patourel et al., 1989), and insect behavior such as mobility. These factors cause adverse effects to exposed insects (Malia et al., 2016). A positive correlation between oil absorption and silicon dioxide concentration was reported by Filipović et al. (2010) after testing oil absorption capacity of silica powders prepared from sodium silicate solution with different concentration of silicon dioxide. This is supported in our study where adult mortality tended to increase with increasing concentration of filter cake and Triplex. The same phenomenon was reported by Tesfaye and Subramanyam (2018) after unsifted filter cake and Triplex were tested at 2.5, 3.75, 5, 7, 7.5 and 10 g/m^2 concentrations of filter cake or Triplex against *S. zeamais*.

The x^2 values for goodness-of fit of the model to our data to determine LT_{50} and ET_{50} was significant. These heterogeneous responses could be related to sex as unsexed adults were used in the experiment. Heterogeneous responses of insects were reported by several researchers when exposed to temperature (Mahroof et al., 2003), Spinosad and Chlorpyrifos-Methyl Plus Deltamethrin (Seghal et al., 2013), spinosad (Subramanyam et al., 2014) and chlorine-dioxide (Xinyi et al., 2017). The LC_{50}, EC_{50} and ET_{50} values of filter cake were three time less than that of Triplex. This was confirmed by the ratio test which showed significantly higher toxicity of filter cake to *s. zeamais* than Triplex. A 7.54 g/m^2 concentration of filter cake was effective to kill 99% of s. zeamais adults within 12 hours and 21.92 hours were required to get the same mortality when 3 g/m^2 concentration of filter cake was used. A similar concentration (7.5 g/m^2) of filter cake was reported by Tadesse and Subramanyam (2018) to kill 100% of *s. zeamais* adults exposed for 24 h. However, more than three times the concentration of filter cake was required to kill *s. zeamais* adults after exposure to Triplex for 12 h. This could be related to the carbon content (atomic percent = 39.43 ± 12.63) of filter cake in the form of calcium carbonate (Tadesse and Subramanyam, 2018). Calcium carbonate at 1 and 2% (w/w) applied to maize caused 70.2 and 84.2% mortality of *s. zeamais* adults, respectively, 15 d after treatment (Silva et al., 2004). Filter cake was also effective in suppression of progeny production with more than 3 times less concentration than Triplex.

In conclusion, 7.54 g/m^2 of filter cake was effective in killing adults of *s. zeamais*, an economically important species. It also completely suppressed adult progeny production, indicating adults were killed before they lay eggs into the kernel. Three-fold higher concentration was required to get similar result on Triplex treatments. This indicated that filter cake was highly efficacious to *s. zeamais* than Triplex. This work was done under laboratory conditions. Therefore, it needs to be confirmed under practical field conditions such as traditional storage structures of smallholder farmers.

5. Acknowledgement

We thank Dr. Dereje Ayalew, Mr. Karta Kalsa, Bahir Dar University, Ethiopia, and Dr. Girma Dimissie, Ethiopian Institute of Agricultural Research, Bako, Ethiopia for providing the filter cake and Triplex powders for this research. Research reported here was made possible by the generous support of the American people through the United States Agency for International Development (USAID) under the Feed the Future initiative (www.feedthefuture.gov). Silica dusts have a long history of use in agriculture for insect control. But the product has several problems that limit its overall use and effectiveness. The present study is investigating a form of silica that has not been used in agriculture to date. The study has been comparing both hydrophilic and hydrophobic forms of the silica against traditional silica products such as Dryacide. The study

has focused on the key grain pest the red flour beetle (*Tribolium castaneum*) and explored the ability of the new form of silica to control the various beetle life stages. The results show that the efficacy of the new silica against larvae was nearly two-to threefold higher than that of adults. The results also show a clear difference in performance between hydrophilic and hydrophobic forms of the silica with hydrophobic forms outperforming the hydrophilic forms for the control of the red flour beetle.

Susceptibility of Stored Grain Insects to the Insect Growth Regulator Methoprene

Frank H. Arthur

USDA-Agricultural Research Service, Center for Grain and Animal Health Research, 1515 College Avenue, Manhattan, KS, USA, 66502, Email: frank.arthur@ars.usda.gov
DOI 10.5073/jka.2018.463.172

Abstract

The insect growth regulator (IGR) methoprene is labeled in the United States (US) for direct application to stored grain commodities, and as a residual surface treatment to empty grain bins and flooring surfaces inside indoor structures. Methoprene is also labeled in the US as an aerosol for use in indoor areas. One of the challenges in research with methoprene and stored product insects is through design of experiments that mimic how methoprene would be used in practical applications. Recent research with methoprene will be used to describe experimental designs to examine efficacy of methoprene when used as a grain protectant.

Keywords: stored products, IGRs, management, efficacy

1. Introduction

Insect pests can cause economic damage to stored grain commodities, especially in warm temperature areas and in the tropics. One of the components of integrated pest management (IPM) for stored grains is the use of protectant insecticides, which are applied as raw commodities are loaded into grain bins or elevator silos. Historically organophosphate insecticides were the primary protectants used by grain managers, but due to concerns with insecticide resistance, along with new regulations, some products in developed countries have been removed from the market (Daglish, 2008; Arthur, 2012). Today there is more emphasis today on using reduced-risk insecticides, including but not limited to pyrethrins, pyrethroids, insect growth regulators (IGRs) (Arthur, 2012), and biological insecticides such as spinosad (Hertlein et al, 2011, Nayak and Daglish, 2017).

Other components of IPM programs for stored grains include the use of aeration, which involves using low airflow rates to cool and modify a grain bin, thus limiting the growth of insect pests Arthur and Casada, 2016). It is not to be confused with grain drying, which utilizes much higher airflow rates to remove excess moisture from grains before they are stored (Navarro et al., 2012). Pre-binning cleaning and sanitation is also important, as the environment in and around grain storage sites can contain residual pockets of grain residues and spillages that will support insect pest development (see references in Arthur, 2018). Finally, the primary component for controlling stored grain insects is the fumigant phosphine. Concerns regarding the development of phosphine resistance (Lorini et al., 2007, Nayak et al., 2015, 2017, Afful et al., 2018) could lead to more extensive use of grain protectants. Thus, when designing experiments to evaluate efficacy of grain protectants, including reduced-risk adulticides and IGRs, there are multiple factors that must be considered

One IGR that is being used in the US as a grain protectant is methoprene, which is also labeled as a residual surface treatment and as an aerosol inside structures to control stored product insects. As an IGR, it does not kill adults, and it has limited efficacy against *Sitophilus species* (Lui et al, 2016). Methoprene can be used alone, or combined with other strategies, including the use of aeration (Arthur, 2016; Lui et al., 2016) and with the pyrethroid deltamethrin (Kavallieratos et al., 2015). Multiple factors should be considered when planning experiments utilizing methoprene as a grain protectant. This paper presents a review and discussion of some of those factors as they relate to

the use of methoprene alone and in combination with other strategies, and will not necessarily follow the standard format of a research paper, though data will be presented to illustrate specific concepts and ideas.

2. Three Simulated field trials

Here at the USDA-ARS Center for Grain and Animal Health Research (CGAHR), we have grain bins of different storage capacities that can be used for studies. These bins are equipped with aeration systems that operate when temperatures fall below set thresholds, using a controller that operates as a thermostat when outside ambient temperatures fall below specified levels (Arthur and Casada, 2005, 2010, 2016). We have also conducted studies with university cooperators that also have small-scale storage bins equipped with similar aeration systems (Lui et al., 2016).

3. Field Trial One: Pitfalls with inconsistent natural populations

One of the problems with field trials involving methoprene is the difficulty assessing treatment effects by examining natural insect populations in treatment and control bins. The first example is a test in which wheat was treated with a target application rate of 2.5 ppm as it was loaded into each of two 110-metric ton (MT) capacity metal grain bins at the CGAHR, using a commercial application system. Two untreated bins served as controls. All bins had aeration systems that were set to operate at an approximate rate 0.206 m^3/min/MT when temperatures fell below 23.9, 15.6, or 7.2 °C (Arthur and Casada, 2005; 2010). After the bin was cooled to the desired temperature the aeration fans were turned off until the next cycle.

The treated and untreated wheat was loaded into the bins the first week of August. After the bins were filled, HOBO temperature cables (Onset Computers, Pocasset, MA, USA) were put into the bins at the North, South, and Center positions, at depths of 0.3, 0.9, and 1.8 m. In mid-August and at the end of the month, each bin was artificially infested with 500 adults each of *Rhyzopertha dominica* (F.), *Tribolium castaneum* (Herbst), and *Cryptolestes ferrigineus* (Stephens) to supplement natural populations. In late August insect pest populations in the bins were assessed by placing five plastic pitfall traps, at each cardinal position and in the center, left for one week, and then removed from the bin. Samples for bioassays, using only *R. dominica*, were also taken as well. Thereafter bins were sampled monthly during autumn except in December, and in January, February, March, and April of the following year (eight total). Data for live adult insects collected in pitfall traps were totaled for all five traps in the two untreated bins. This was also done for all traps in the treated bins as well. Data were compared by a t-test (Statistical Analysis System version 9.2, Cary, NC, USA). Temperatures in the bins were plotted using Sigma-Plot (Systat Software, Version 11, San Jose, CA, USA).

The only species collected in the pitfall traps were *C. ferrugineous*, *Ahasverus advena* (Waltl), *Typhea stercoria* (L.), and *T. castaneum* (Fig. 1). Insects were collected in early autumn, but populations in treated and untreated bins declined during the Winter and except for *C. ferrigineous* did not increase in the Spring. However, there were several sample points were populations were greater ($P < 0.05$) in untreated wheat versus the treated wheat. Temperatures for most of the storage period were below 15 °C, the lower developmental limit for most stored product beetles (Howe, 1965; Fields, 1991) (Fig 2.).

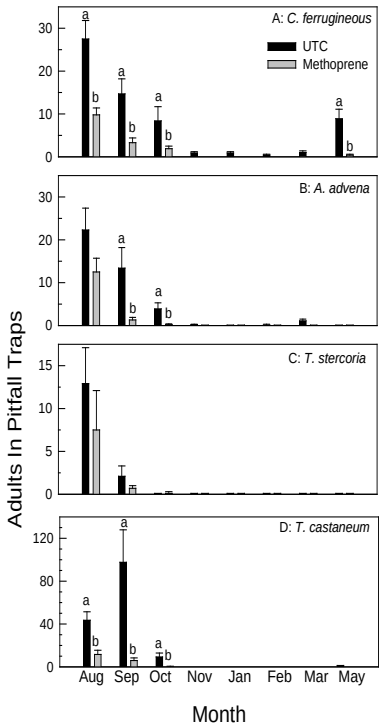

Fig. 1. Average number of adults of four insect species (A-D) collected from probe traps placed in bins with aeration alone (dark bar) versus bins with aeration + methoprene (grey barr), means denoted with different letters indicate significant differences ($P < 0.05$, Proc *t*-test, SAS). The sample in May was taken after aeration monitoring ceased.

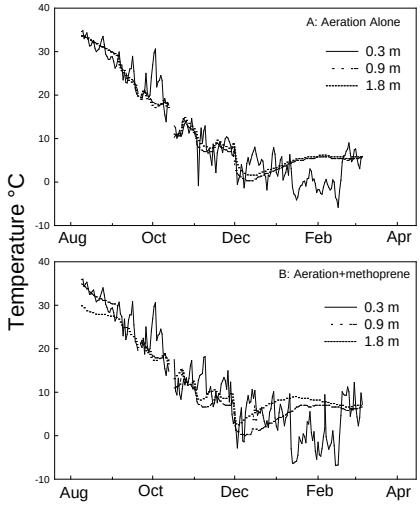

Fig. 2. Temperature at depths of 0.3, 0.9. and 1.8 m in wheat mass in 110 MT bins in wheat with aeration alone (A) and in wheat with aeration + 2.5 ppm methoprene (B).

The bioassay data gave a clearer picture of methoprene efficacy. These bioassays were conducted by placing 20 mixed-sex 1 to 2-week old adults on ca. 30 grams of wheat in a 37-ml capacity vial for two weeks, then removing the adults and holding the wheat in an incubator at about 27°C and 60% r.h. for about 6 weeks. At each sample point five 250-g samples were taken from each bin, and then subdivided into 30-gram lots for each of 5 vials. The remainder of the wheat was discarded. The wheat in the vials was warmed in the laboratory for several days before the parental adults were introduced. Thus, there were a total of 10 treated and 10 untreated samples. Average progeny production over all sample months was 99.9 ± 23.5, while progeny production in the methoprene bioassays averaged less than 0.1. This test indicated that strict reliance on natural populations of stored product insects may not be an appropriate method for assessing residual efficacy of grain protectants.

4. Field Trial Two: Supplemental introductions and sampling with traps and trier samples combined with bioassays

This test was conducted in sixteen 13.6 MT capacity metal bins, equipped with aeration systems, at the SPREC Research Center (Oklahoma State University, Stillwater, OK, USA). The test has been reported previously (Lui et al., 2016), so only the essential details will be summarized here. There were four treatments with four replications each: wheat with aeration alone at about 0.206 m^3/min/MT with no methoprene treatment, 1.0 ppm methoprene applied to the entire grain mass

with no aeration, aeration + methoprene applied to the entire grain mass, and aeration + 1.0 ppm methoprene applied only to the top 50-cm of the grain mass. For this test, grain temperatures were monitored and recorded hourly using an aeration control system from OPI Systems Inc. (Calgary, Alberta, CA). Fans were set to operate when outside air temperatures were 5°C lower than the grain temperature at 30 cm below the grain surface. This is different from the test above, where discreet aeration cycles were used.

Wheat was loaded into the bins in July. At 7, 14, 21, and 28 days after bins were filled, 100 mixed sex adults of each of the species described above were introduced into the bins. The bins were sampled at every two months after bins were filled, by placing one probe trap in each bin for seven days, then removing the trap and counting and separating adults by species. Grain samples of about 1 to 2 kg were also taken at the same time from the bins using a grain trier. Samples were also taken at 0.25, 4, and 10 months post-treatment for bioassays of *T. castaneum*, *R. dominica*, and *Plodia interpunctella* (Hübner). For the bioassays of beetles, 50 adults of each species were placed into 240-ml jars with about 100 g of wheat, then held in an incubator at 28°C and 60% r.h. *For P. interpunctella*, 20 eggs were placed on a mixture of ground and whole wheat (20 g each). The test ended after 10 months.

Total numbers of *T. castaneum*, *R. dominica*, and *C. ferrugineous* collected in the probe traps during the entire storage period are listed in Table 1 (complete data for bi-monthly bioassays given in Lui et al., 2016). Data were compared using Chi-Square analysis (SAS Institute). It is apparent that the most optimal treatment was the combination of the entire wheat mass treated with methoprene combined with aeration. Also, far more adults of the three species were collected in probe traps versus trier samples (Table 2). The probe traps provided a measure of relative abundance, and gave an indication of relative species susceptibility: *R. dominica* < *C. ferrugineous* < *T. castaneum*. However, it should be emphasized that the four separate introductions of the beetles helped to establish the populations, and strict reliance on natural populations may not have yielded successful results. Bioassay data for beetles (Table 3) and *P. interpunctella* (Table 4) also showed the residual efficacy of methoprene.

Table 1. Total numbers of three species collected from pitfall traps in wheat held under four treatment regimens from July to May in Stillwater, OK, USA (n=6). Sum totals within columns followed by different lower-case letters are significantly different (Chi Square, $P< 0.05$)

Treatment	*T. castaneum*	*R. dominica*	*C. ferrugineous*

Methoprene total-no aeration	0
Methoprene total+aeration	0

5. Field Trial Three: Assessing residual efficacy assessed only with bioassays

Given the difficulty of determining methoprene efficacy based on actual infestation, another option for collecting data, and for determining species susceptibility, is to rely on bioassay data. This approach was utilized in Arthur (2016), a two-year study in which wheat, corn, rough rice, and brown rice was treated with 1.25 and 2.5 ppm methoprene, and stored for two years under natural conditions on the floor of a grain bin. The commodities were bioassayed every two months, using different insect species depending on the commodity. Data for rough rice and brown rice highlight the differences between grain commodities, in terms of assessing insecticidal efficacy. Data also show differences in susceptibility between two internal feeders, *R. dominica* and *Sitotroga cereaella* (Oliver). Adult females of both species lay eggs on the interior of the grain kernel, and the neonate larva bores inside the kernel, and completes development. Adult *R. dominica* chew their way out of the kernel, while adult *S. cereallella* push their way out through the feeding holes created by the larva. While *R. dominica* causes physical damage to the kernel, and *S. cerealella* does very little feeding, high populations of *S. cereallella* may still present a contamination issue.

The rough rice and brown rice was treated in August by treating four individual replicate lots of 11 kg with either 1.25 or 2.5 ppm methoprene, then storing the replicate lots in buckets held on the floor of an empty grain bin at the CGAHR. Every two months two aliquot samples of about 80 g each were taken from an individual replicate bucket, placed in a 120-ml capacity plastic vial and 10 parental adults of either *R. dominica* or *S. cerealla* was exposed on the aliquots from each treatment and on companion sets of untreated controls. The individual vials were held for 3 months at 27°C and 60% r.h. to determine progeny production.

There was very little development of *R. dominica* even on untreated rough rice, presumably because the husk offers protection from larval penetration. There was some development of *S. cerealla* on rough rice treated with the two methoprene rates, but far less compared to untreated controls. On brown rice, there was extensive progeny production of *R. dominica* in untreated controls, but none in treatments. As with rough rice, there was some progeny production in the treatments, but far less than the controls. The bioassay data were then used to compare percentage weight loss of samples, of *R. dominica* and *S. cerealella* feeding damage on brown rice. Progeny production was correlated with feeding damage for *R. dominica* but not for *S. cerealella*.

6. Conclusions

Data for these studies show there are multiple methods for assessing residual efficacy of methoprene, and other contact insecticides, when used as grain protectants. IPM in stored grains could be considered more as a multi-component management strategy, and grain protectants, especially reduced-risk products, could play a more important role in the future. However, when conducting experiments, many factors should be considered. In actual or simulated field tests, bioassays must be paired with grain sampling through probe traps and pheromone traps, as natural infestations may be inconsistent. Even seeding experimental bins with insects may not yield reliable results, as the introductions may not be successful, or the populations could decline and die out during winter months, especially in temperate climates. Bioassays offer the best option for evaluation of residual efficacy of methoprene. Relating progeny production to physical grain

damage, such as weight loss, frass production, and presence of insect-damaged kernels, should also be done as well. **8.**

Post-harvesting losses is a critical component for filling the demands of ever increasing population. Because a large number of food security issues can be facing in the future. Current study was planned to probe the comparative insecticidal, growth inhibitory and feeding detterent activities of spinetoram, chlorfenapyr, cypermethrin and beta-cyfluthrin against *Trogoderma granarium* (Everts) and *Tribolium castaneum* (Herbst) under laboratory conditions. The insecticides were used at three different concentrations i.e., 5, 7 and 9ppm. Results revealed that maximum adult mean percent mortality of *T. castaneum* was recorded at highest concentration (9ppm) was 78.08% followed by 69.41% at 7ppm and 61.41% at 5ppm. In case of *T. granarium* at highest concentration (9ppm) the mortality was 72.58% followed by 64.08% at 7ppm and 55.33% at 5ppm. Results regarding growth inhibition showed that cypermethrin and chlorfenapyr gave highest values 28.77 and 23.78% for larval emergence inhibition. While beta-cyfluthrin gave lowest larval emergence inhibition against the *T. castaneum*, beta cyfluthrin gave 53.02% pupae inhibition. 50.26%, 48.66% and 46.48% pupae inhibition values were given by spinetoram, chlorfenapyr and cypermethrin, respectively. Adult emergence inhibition was highest 40.17% in case of cypermethrin followed by chlorfenapyr (30.60%). Similarly, the efficacy of all tested insecticides in term of feeding deterrence for both insects was cypermethrin > chlorfenapyr > spinetoram > beta-cyfluthrin.

Toxicity of four Cuban botanical derivatives against two stored-products coleopteran pests

Abstract

Plants are a source of substances for protection of stored products. The Cuban flora has not yet been fully studied as a source of pesticides for postharvest protection, partly due to its great diversity. The toxicity of four Cuban plant derivatives against *Lasioderma serricorne* (F.) and *Sitophilus zeamais* Motschulsky was investigated. The anti-insect activity of the powders and the essential oil from plants belonging to Asteraceae, Fabaceae and Piperaceae was tested. Mortality and emergence of adult insects and the repellent effect of products were evaluated. Two products derived from *Piper aduncum* subsp. *ossanum*, caused high mortality (81,6 and 100%), reduced emergence (27,9 and 0,4%) and exhibited strong repellent activity on *L. serricorne*. Against *S. zeamais*, treatments with the highest mortality values were stems of *Lonchocarpus punctatus* (72,4%), seeds and stems of *Canavalia ensiformis* (64,9 and 69,9%), and leaves of *Tithonia diversifolia* (67,2%). The progeny production of *S. zeamais* was inhibited by powders of *L. punctatus* stems (31,8%), *C. ensiformis* seeds (40,5%), leaves (43,7%) and stems (30,6%), and *T. diversifolia* leaves (38,7%). The stems of *C. ensiformis*, leaves of *T. diversifolia* and *L. punctatus* had the highest repellent effect. These products have potential for small-scale treatments of grains for protection against both insects, and *P. aduncum* subsp. *ossanum*-based products to control *L. serricorne* infestation in tobacco. Identification of local candidates to develop effective and safe pesticides offers new alternatives to the Cuban agriculture in the control of storage pests.

Keywords: *Lasioderma serricorne*, *Sitophilus zeamais*, Fabaceae, Asteraceae, Piperaceae.

Introduction

Stored products of agricultural and animal origin are attacked by many species of insect pests causing quantitative and qualitative losses and insect contamination in food commodities is an important quality control problem of concern for food industries (Rajendran and Sriranjini, 2008). Storage insects cause significant losses for grain and legume producers, due to the reduction of the quantity and quality of food for domestic consumption and the value of the grain for sale in the

market (Jones et al., 2018). Concerns over the harmful effects of synthetic insecticides have stimulated interest in alternative pest management tactics including the use of botanical insecticides that provide novel modes of action against pests that have developed resistance against synthetic insecticides (Amoabeng et al., 2018).

Plants are a source of substances for protection of stored products (Ogendo et al., 2012). Plant parts and botanical derived products have gained importance because flora biodiversity has provided an excellent source of biologically active constituents or allelochemicals for use in traditional crop protection. In the tropics, plant biodiversity has provided an excellent source of allelochemicals for crop protection in traditional agriculture for centuries and crude local products were applied to crops and stored food grains to protect them from an array of pest species (Gahukar, 2014).

Cuba is considered as one of the most biodiverse countries in the world in terms of sheer numbers of species and has the richest plant biodiversity of all the islands in America, with an estimated 6,600 plant species of which 50% are endemic (González-Torres et al., 2013). The Cuban flora has not yet been fully studied as a source of pesticides for postharvest protection, partly due to its great diversity. To date, only a small fraction of the plant species has undergone systematic phytochemical or biochemical research, leaving valuable sources for commercial products undiscovered (Pino et al., 2013). The toxicity of four Cuban plant derivatives, *Tithonia diversifolia* (Hemsl.), *Lonchocarpus punctatus* Kunth, *Canavalia ensiformis* L. and *Piper aduncum* subsp. *ossanum* (C.DC.) Saralegui, against *Lasioderma serricorne* (F.) and *Sitophilus zeamais* Motschulsky was investigated.

Materials and Methods

Plant derived products (powders and essential oil)

Raw plant materials were collected from four botanical species belonging to Asteraceae, Fabaceae and Piperaceae in Mayabeque, Cuba (Table 1).

Tab. 1 Plant Material.

Plant Family	Plant species		Part of the plant
	Scientific name	Common name	
Asteraceae	*Tithonia diversifolia* (Hemsl.)	tree marigold, Mexican tournesol, Mexican sunflower, Japanese sunflower or Nitobe chrysanthemum	Leaf, stem, root
Fabaceae	*Lonchocarpus punctatus* Kunth	dotted lancepod	Leaf, stem, fruit
Fabaceae	*Canavalia ensiformis* L.	jack-bean	Leaf, stem, seed
Piperaceae	*Piper aduncum* subsp. *ossanum* (C.DC.) Saralegui	spiked pepper, canilla de muerto, guayuyo or platanillo de Cuba	Leaf

Asteraceae and Fabaceae plant materials were dried in an oven at 45 °C, then grounded into powder (< 1 mm) and sieved (250 µm). They were kept at room temperature in nylon bags and were identified according to the plant structures until use for bioassays. The essential oil of *P. aduncum* subsp. *ossanum* was extracted by hydrodistillation using a Clevenger type apparatus. After extraction, the essential oil was dried over anhydrous sodium sulphate and stored in a refrigerator at 4 °C. Two powder formulations, PAO-1 and PAO-2, were obtained from the fresh leaf powder and the essential oil of *P. aduncum* subsp. *ossanum*, respectively. The anti-insect effect of products from *P. aduncum* subsp. *ossanum* (PAO-1, PAO-2) and zeolite, as an inert material, was tested against *L. serricorne* on chickpea. The biological activity of the nine powders from the different parts of *L. punctatus*, *C. ensiformis* and *T. diversifolia* (Table 1) was evaluated against *S. zeamais* on maize. Mortality and emergence of adult insects and the repellent effect of products were evaluated.

Insects

Sitophilus zeamais Motschulsky (Coleoptera: Curculionidae) was reared on maize (*Zea mays* cv. Manitou) in controlled conditions (25 ± 2 ºC, 70 ± 5 % of relative humidity and 12:12 light/dark photoperiod) in the Institute of Animal Science, Mayabeque, Cuba. *Lasioderma serricorne* (F.) (Coleoptera: Anobiidae) was maintained on chickpea (*Cicer arietinum* L.), at 25,7 ± 1,95°C and 76,4 ± 9,18% r.h. under a 16:8 light/dark photoperiod, at the Entomology Laboratory, Agricultural Pests Group, National Centre of Animal and Plant Health, Mayabeque, Cuba. Experiments were conducted using emerged adults (age < 10 days old) from laboratory colonies.

Effect on adult mortality and F1 adult *emergence*

The effect of the derived plant products on adult mortality and F1 adult emergence was evaluated by grain treatment test (Silva et al., 2003). The grains of chickpea or maize (100 g) were mixed thoroughly with the products (plant powder (1g), PAO-1 (1g), PAO-2 (2g) or zeolite (2g)) in 1L glass jars. Twenty couples of adult beetles (*L. serricorne* or *S. zeamais*) were introduced into each glass jars containing the different treatments. Untreated grains in glass jars, where twenty insects were also placed, acted as the controls.

Adult mortality was evaluated 15 days after jar infestation for both insects. They were considered dead when no movement was observed after carefully touching them with a dissection needle. The live and dead *L. serricorne* adults were also counted after 3, 6, 9, and 12 days.
The number of emerged F1 adults (F1 progeny) were counted 58 days and 55 days after infestation with *L. serricorne* and *S. zeamais,* respectively. The percentage of insect emergence was calculated..

Repellent effect of plant products to the two betle species

The effect of the tested materials applied to the grains on the behaviour of the insects was established by using an arena formed by five circular plastic boxes (8,5 cm of diameter, 1.5 cm of height). The central box was connected with the rest using plastic tubes disposed diagonally. The boxes with treated grains (the same concentration used in previos bioassay) and the control (untreated grain), were distributed in two symmetrically opposed boxes. In the central container, 50 adults of *L serricorne* or S. zeamais were released. After 24 hours, the number of insects was counted in each box and the index of repellence (IR) was calculated (Mazzonetto and Vendramim, 2003):
IR = 2G/(G + P)
Where,
G =percentage of insects in the treatment
P = percentage of insects in the control
The effect of the product was clasified: neutral if IR=1, attractive if IR>1 and repellent if IR<1.

Experimental design and statistical analysis

For both bioassays, all treatments were arranged in a completely randomized design in the laboratory and kept at the same conditions asthe colonies. Each treatment was replicated four (adult mortality and emergence bioassay) or three (repellency bioassay) times.

The mortality counts were corrected with Abbott's formula (Abbott, 1925). All data were subjected to analysis of variance (ANOVA) and the means of treatments were compared by Duncan's Multiple Range Test at p < 0,05. The Statistical Analysis System (SAS Version 9.2) was used.

Results

The two products derived from *P. aduncum* subsp. *ossanum* caused high mortality and reduced F1 emergence of *L. serricorne* (Table 2). The highest values of mortality and reduction of adult emergence were observed with PAO-2; although, in the variable mortality, no significant differences were found with the other treatments.

Tab. 2 Effect of products from *Piper aduncum* subsp. *ossanum* on mortality and F1 emergence of the *Lasioderma serricorne* adults.

Treatment	Mortality (%)*	No. of emerged insects (Mean ± EE)*	Emergence (%)
PAO-1	81,58[a]	87,25 ± 37,7[b]	27,88
PAO-2	100[a]	1,25 ± 0,75[a]	0,40
Zeolite	94,74[a]	50 ± 21,46[b]	15,97
Control		313 ± 25,89[c]	100

*15 days, four replicates of 20 insects in each replication, means in the same column with letters in common do not differ significantly (Duncan's Multiple Range Test, p > 0.05)

Contact toxicity assayed by coating chickpea grains showed that both products caused mortality of *L. serricorne* and it was time of exposure dependent (Figure 1). PAO-2 had the fastest action, causing the highest number of deaths (43.33%) after three days. Treatment with PAO-1 induced death to increase from the ninth day (46%). Mortality due to the zeolite increased from the sixth day, with values higher than those obtained with the other treatments after nine days.

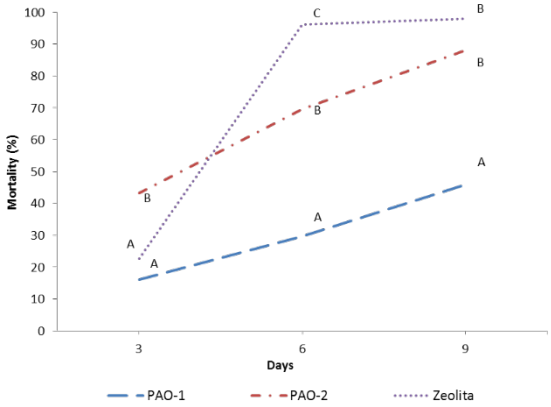

Fig. 1 Mortality of *Lasioderma serricorne* produced by products of *Piper aduncum* subsp. *ossanum* and zeolite after different periods of treatment.

All the products tested on *L. serricorne* showed a repellent effect, with IR values less than one (Table. 3). The best result was obtained applying PAO-1 with a value of 0.27.

Out of the nine treatments tested against *S. zeamais*, six surpassed 40% of mortality and five presented values below 50% of emergence from F1 in comparison to the control (Table 4).

Tab. 3 Effect of products from *Piper aduncum* subsp. *ossanum* on behavior of the *Lasioderma serricorne* adults.

Treatments	Index of repellence (IR)	Classification
PAO-1	0,27	Repellent
PAO-2	0,80	Repellent
Zeolite	0,68	Repellent

The treatments with the highest mortality values were stems of *Lonchocarpus punctatus*, seeds and stems of *Canavalia ensiformis*, and leaves of *Tithonia diversifolia*. Regarding the percent of F1 reduction, the best treatments were powders of: *L. punctatus* stems, *C. ensiformis* seeds, leaves and stems, and *T. diversifolia* leaves.

Tab. 4 Effect of powders from *Tithonia diversifolia, Lonchocarpus punctatus* and *Canavalia ensiformis* on mortality, F1 emergence and behavior of the *Sitophilus zeamais* adults.

Treatment	Mortality (%)*	Emergence (%)	Index of repellence (IR)**

T. diversifolia (leaf)	67,20[a]	38,7[fe]	0,47
T. diversifolia (stem)	45,87[b]	50,8[de]	0,72
T. diversifolia (root)	22,10[cd]	78,6[b]	1,12
L. punctatus (leaf)	25,16[cd]	60,12[cde]	0,48
L. punctatus (stem)	72,36[a]	31,79[f]	0,71
L. punctatus (fruit)	19,49[ed]	82,12[b]	0,82
C. ensiformis (leaf)	46,81[b]	43,75[fde]	0,84
C. ensiformis (stem)	69,93[a]	30,56[f]	0,67
C. ensiformis (seed)	64,93[a]	40,48[fde]	0,93

15 days, four replicates of 20 insects in each replication, means in the same column with letters incommon do not differ significantly (Duncan's Multiple Range Test, $p > 0.05$)
[**]Classification neutral if IR=1, attractive if IR>1 and repellent if IR<1

The index of repellence attained values below the unit for all of tested materials against *S. zeamais*, except for roots from *T. diversifolia* (Table 4). The leaves of *T. diversifolia* and *L. punctatus* and the stems of *C. ensiformis* had the highest repellent effect.

Discussion

Botanical derivatives, with biological activity against insects, include compounds with behavioral actions – those causing repellence, feeding deterrence or oviposition deterrence – and those with physiological actions – those causing acute toxicity, developmental disruption or growth inhibition. It is not uncommon for a plant secondary compound to have both behavioral and physiological effects in one insect species, or different effects in different species (Isman, 2014).

The products of *P. aduncum* subsp *ossanum* demonstrated the anti-insect properties of the plants of the Piperaceae family. According to Silva et al., (2003), 40% mortality must be achieved to consider a treatment promising. The activity of the *P. aduncum* essential oil was studied against *Tenebrio molitor* L and *Callosobruchus maculatus* (F.), it showed insecticidal activity against both insects (Fazolin et al., 2007, Pereira et al., 2008). The *P. aduncum* subsp. *ossanum* is an endemic subspecie, whose production of secondary metabolites is different from that of the plants of this species growing in other geographical regions, even in the same country (Pino et al., 2011). To the best of our knowledge, the toxicity of its products against *L. serricorne* has not been previously reported.

From a chemical point of view, the *P. aduncum* subsp. *ossanum* essential oil (active ingredient of PAO-2) is composed mainly of sesquiterpenes, monoterpenes and oxygenated compounds; the main components of this oil were camphene, camphor, piperitone and viridiflorol (Pino et al., 2011). These compounds and some essential oils containing them were toxic to stored-product insect pests; for instance, *Sitophilus granarius* L and *Rhyzopertha dominica* F. showed very high susceptibility to camphor (Pérez et al., 2010). This monoterpenoid may be one of the components responsible for the observed biological activity of PAO-2 on *L. serricorne*.

Against *S. zeamais*, treatments that caused at least 40% mortality of adults or at least 50% reduction of the F1 emergence in relation to the untreated control were considered promissory (Silva et al., 2003).

Our results confirmed the findings of other workers that reported the Asteraceae family as a promising source of metabolites, with insecticidal activity against *S. zeamais*. Grainge and Ahmed (1988) reported the contact toxicity of the compounds present in leaves of *T. diversifolia* against *S. zeamais*. Mortality by the leaves was higher than the rest of the structures (stems and roots). These results were in agreement with those obtained in other studies, which reported substances with insecticidal activity in leaves of this plant against *Dysdercus cingulatus* (Fab.), *Plutella xylostella* L., *Spodoptera exempta* (Walker) and *Tribolium castaneum* Herbst (Grainge and Ahmed 1988). The highest value of insect mortality, reached with the powders of the leaves, could be due to the higher concentration of α-amino groups, which was made evident by the more intense color observed for this plant structure sample in the phytochemical screening (González et al., 2010). Other groups of compounds responsible for this effect could be phenols, tannins and triterpenes (González et al.,

2010). The *T. diversifolia* appears among the plants from which crude preparations are recommended for insect control in different tropical regions (Isman, 2014).

No references of the effect of *L. punctatus* on *S. zeamais* were found according to the reviewed literature. The insecticide effect observed with the powders from the stems of *L. punctatus*, could be associated to the action of compounds or mixture of compounds belonging to the groups found in the phytochemical screening of this material, such as the α-amino groups, phenols, tannins, triterpenes/steroids, and alkaloids (González et al., 2011). The insecticidal effect of the raw meal of seeds of *C. ensiformis* against *Sitophilus oryzae* L. was reported by Zamora (2005), but no information was found regarding the effect of the powder of the seeds and the other studied parts of this plant against *S. zeamais*.

The Fabaceae family, represented in this research by *L. punctatus* and *C ensiformis,* comprises a wide group of species with insecticide activity. Among them, the most popular belong to the genera *Lonchocarpus*, *Derris* and *Tephrosia* (Gahukar, 2014; Isman, 2014). The substances from these genera act topically and by ingestion; besides, they are characterized by exerting their insecticide effect through the inhibition of the mitochondrial respiration (Grainge and Ahmed 1988; Koona et al., 2007). There are several species of this family with insecticidal action in which the presence of alkaloids and tannins is reported (Grainge and Ahmed 1988). According to Pérez and Iannacone (2006), the alkaloids is a group of very active compounds that block the transmission of the motor nerve, causing relaxation and flaccid paralysis of the skeletic muscle in the body of some insects, indicating that these compounds could be related to the insecticide action observed. In this family of plants, the non-protein amino acids are also reported (Udedibie, 2001) and they have a double function: defense and storage of nitrogen. Probably, the mortality produced by the seed powder of *C. ensiformis* was due to the presence of these compounds. The toxic effect is produced by their structural analogy with the essential amino acids, when they are misincorporated in the formation of enzymatic proteins or neurotransmitters (Ramos et al., 1998).

Besides, the acute insecticide effect on adults of *L. serricorne* and *S. zeamais*, it was necessary to assess the effect of the powders on the F1 emergence because of the high rate of their reproduction. The tested treatments that had the highest mortality in the adult insect of *L. serricorne* and *S. zeamais* also provoked the lowest emergence; the decrease of the adult emergence could be a method of effective control. The results obtained in the reduction of the emergence could be due to different causes; it could be related to an initial insecticidal effect and/or to deletorius physiological changes that affect reproduction or growth (Napoleão et al., 2013, Gahukar, 2014, Isman, 2014). The immediate death of the females and/or males may disrupt mating and thus the egg laying is reduced. A female may die before ovipositing the normal number of eggs, may survive treatment and become sterile or lay eggs that do not hatch. Other aspects that could affect reproduction are associated with the behavior. These active compounds could hamper the movement and encounter of the male with the female by occupying the space between the grains affecting the mating, or that the female by finding the grain covered with the powder does not receive the stimulus necessary for egg laying, a situation that could be caused by the allomones of the plant that are released to the environment where the grains are found (Shenk and Kogan 2003). Also, the death of the insects in the immature stages hampers the insect emergence. Other studies are required to determine the actual factors involved in the reduction of the F1 progeny by the evaluated products.

Additionally, all the botanical derivatives, tested on *L. serricorne* or *S. zeamais*, showed a repellent effect, except *T. diversifolia* roots. The results suggested that PAO-1 would have greater application in pest control for its effect on insect behavior to prevent grain infestation. The repellent effect could be determined by the presence of secondary metabolites, volatile substances that may be present in the plant parts studied (Regnault-Roger et al., 2004). When the insects detect these substances, they cause an effect on their behavior and evoke them to move away from product (Pérez et al., 2007). The attractive action of *T. diversifolia* root powder could be explained by the diversity of groups of secondary metabolites detected in the different tissues of this species under the conditions in which it was collected (González et al., 2010).

No available information was found about the repellent effect of the studied plants against *S. zeamais* or *L. serricorne*. But it is known that farmers sow *C. ensiformis* plants as intercrop and barrier to avoid the attack of pests (Arim et al., 2006; González et al., 2009). Also, *T. diversifolia* repellent action on the herbivorous *Atta* sp has been reported (Medina et al., 2009).

Further work is in progress to isolate and identify the insecticidal and repellent constituents of the plants studied. The sustainable use of these plants in the storage pest management is possible; they are cultivated or abundant wild species in Cuba. However, their practical application will require subsequent environmental and economic assessment. These products have potential for small-scale treatments of grains for protection against both insects. The *P. aduncum* subsp. *ossanum*-based products may also be used to control *L. serricorne* infestation in tobacco. The identification of local candidates to develop effective and safe pesticides offers new alternatives to the Cuban agriculture in the control of storage pests.

Abstract

Several methods are used to control stored product insects. The spraying of empty structures with insecticides, prior to the introduction of produce, is an important method for preventing development of insects. It is known that insecticide activity varies according to the various sprayed surfaces. In this study, the activity of deltamethrin was examined on concrete and plastic surfaces. Deltamethrin is a synthetic pyrethroid, active by contact against a variety of insects; applied in Israel in two formulations: KESHET 2.5% EC and BUNGY 1.5% SC (ADAMA Makhteshim Ltd.). Adults of the rice weevil, *Sitophilus oryzae* (L.), served as target insect in all experiments. The research was carried out in plastic Petri dishes and in Petri dishes with layer of concrete. Deltamethrin (KESHET 2.5% EC) was applied in water solution in doses of 0.02, 0.1, 0.5 g/m^2. Without concrete, complete mortality of *S. oryzae* was obtained at a concentration of 0.02 g/m^2, whereas in concrete plates, no mortality was found in all 3 concentrations. In contrast, deltamethrin (BUNGY 1.5% SC) in doses of 0.1 g/m^2, caused 100% mortality with and without concrete layer. The same results were found in the commercial warehouse. No difference in efficiency was found between the spraying methods: airbrush (Sparmax DH-125) or dripping by pipette. The results show that the efficacy of warehouse spraying by deltamethrin depends on its formulation.

Keywords: deltamethrin, stored product insects, treated surfaces, concrete, suspension, emulsion.

1. Introduction

The control of stored product insects, which cause serious damage to stored agricultural produce, is achieved by a combination of several methods. The use of protectants is an important and widespread method for preventing the development of stored product insects as an integral part of pest control practice. Protectants are applied by spraying incoming grains and empty warehouses, prior to produce introduction; in order to disinfest insect population on surface and cracks. Using residual materials can reduce and slow insects' infestation and reduce or eliminate the need for further control treatments. Surface treatments are applied as liquid contact insecticides on different types of surfaces (Arthur and Subramanyam, 2012). Floor and walls of grain warehouses are usually made of concrete. The surface of concrete is porous and alkaline, so when the insecticides are applied to concrete, hydrolysis and rapid degradation occur (Arthur, 1994; Jain and

Yadav, 1989). Hence, insecticides efficacy may depend on its formulation. Deltamethrin is synthetic pyrethroid, exceptionally potent against the whole spectrum of stored product pests (Snelson, 1987). Using deltamethrin can be effective as grain protectant or as surface treatment, singly or in combination with other insecticides, to control stored product insects. Contact toxicity of deltamethrin was found highly effective against *Tribolium castaneum* (Herbst), *Sitophilus oryzae* (L.), and *Rhyzopertha dominica* (Fab.) (Paudyal et al., 2016). Several studies which examined deltamethrin efficacy on various surfaces reported that wettable powder (WP) formulation was more effective than emulsifiable concentrate (EC) (Jain and Yadav, 1989). Deltamethrin is applied in Israel by two formulations: KESHET 2.5% EC and BUNGI 1.5% SC (ADAMA Makhteshim Ltd.). In this study, the activity of these two formulations was examined on concrete and smooth surfaces, under laboratory conditions and in commercial warehouses.

2. Materials and methods

Insects

Sitophilus oryzae (L.), *Rhyzopertha dominica* (Fab.) and *Tribolium castaneum* (Herbst) cultures have been reared under laboratory conditions for many years without any contact with insecticides. *S. oryzae* and *R. dominica* were reared on wheat grain, *T. castaneum* was reared on wheat flour. All these insects were maintained in 0.8L glass jars with paper covers and bred at 30±0.5^{0}C and 65±5% r.h. in dark.

Chemicals

The deltamethrin for the experiments was applied in two formulations: KESHET (2.5% EC, ADAMA Makhteshim Chemical Plants Ltd) and BUNGI (1.5% SC, ADAMA Makhteshim Chemical Plants Ltd).

Laboratory Experiment

In a laboratory experiment, deltamethrin formulations were examined in Petri dishes (diameter 9 cm). Plates without concrete (plastic) and plates with concrete were used. Individual concrete arenas in Petri dishes were made by mixing cement (42.5N II/A–LL) - sand - water (1:1:0.5). About 30 grams of the mixture was added in each Petri dish. Four days later, plates with concrete layers were ready to be used. The required concentrations of insecticides were obtained by dilution by tap water. About 0.62 ml of mixture (100 ml/m^2) was sprayed by airbrush (Sparmax DH-125), or dripping by pipette (approximately 40 drops per plate) to each Petri dish. Tap water was used as control.

For studying the effect of alkaline concrete, flush water from fresh concrete surface was used. 15 ml of tap water were added into each Petri dish with a concrete layer, and after one hour the water was removed from the dishes, with a pipette. About 10 ml of flush water was obtained from each Petri dish.

In all laboratory experiments, ten adults of *S. oryzae, R. dominica* or *T. castaneum* were exposed in Petri dishes with/without concrete layer, without food, in each probe. The plates were stored in the dark at 30±0.5^{0}C and 65±5% r.h. Insect mortality was recorded after 2 and 24 hours of exposure. Each treatment was replicated 3 times.

Warehouse experiments

For several years, local grains are stored in warehouses in the south of Israel. Before inserting the new wheat harvest, crop residue was removed from the warehouses and a mixture of ACTELLIC 50 EC, KESHET 2.5 EC and water was sprayed in the warehouses. The concentration of ACTELLIC 50 EC in the mixture was constant (1.0%), and the concentration of KESHET 2.5 EC increased from 1.0 to 3.0%. In a certain year, during commercial treatment, the warehouses were sprayed with only 4% KESHET 2.5 EC in water; working mixture consumption at 100 ml/m^2. A day after the spraying, the effectiveness of the treatment was tested. Adults *S. oryzae* (10 insects in each probe) were put on

various treated structures, and their movements were limited within lower part of Petri dishes which were attached to the surface with duct tape (14 probes). After 24 hours, the insects were transferred to Petri dishes which were put in incubator and their mortality was recorded the following day.

To test the efficiency of the spraying in storage facilities with two different deltamethrin formulations, 14×14cm squares (~0.02m^2) were marked on concrete walls and insecticides were sprayed by airbrush (Sparmax DH-125) on the marked squares. Ten adult *S. oryzae* were transferred onto the treated squares. The movement of insects was limited to a net that was attached with duct tape. After 24 hours, the insects were transferred from concrete walls to Petri dishes and their mortality was recorded. Each treatment was replicated 3 times.

Statistical analysis

A one-way analysis of variance (ANOVA) was used to compare percent of insect mortality. The Tukey Multiple Range test was used to compare mean values. (JMP Pro 13.0.0., 2016).

3. Results

Exposing stored product insects to KESHET 2.5% EC in concentration 20 mg/m^2, caused after 24 hours of exposure the following results: 100% mortality of *S. oryzae* and *T. castaneum*, and 23.3% mortality of *R. dominica*; and in concentration 100 mg/m^2 - 100% mortality of *S. oryzae, R. dominica* and *T. castaneum* (Tab. 1).

Tab. 1 Contact effect of 2.5 EC KESHET on plastic surface against stored product insects.

Spray*	Dose of deltamethrin g/m^2	Mortality (%), after 24 hours exposure		
		S. oryzae	*T. castaneum*	*R. dominica*
0.8% KESHET 2.5EC	0.02	100 A	100 A	23.3±8.8 B
4.0% KESHET 2.5EC	0.1	100 A	100 A	100 A
20.0% KESHET 2.5EC	0.5	100 A	100 A	100 A
Control	0	0 C	0 C	3.3±3.3 C

* - Tap water was used for dilution of commercial concentrates of deltamethrin and as control. 0.62ml of mixture (100 ml/m^2) was transferred at dripping by pipette (approximately 40 drops per plate) to each plastic Petri dish.

** - Ten adult insects were introduced in each sample. Each treatment was triplicate. Values are the means ± SEM. Values represented with the same letter are not significantly different one from the other.

In the commercial treatment in the warehouse, after 24 hours exposure, mortality of *S. oryzae* in KESHET 2.5EC depended on the surface type and on the location of treatment in the warehouse. Mortality on galvanized steel in all tests was 100%; mortality on concrete was 20 -100%. Control mortality in the untreated warehouse was 0 - 20%.

In the laboratory test on concrete surface, KESHET 2.5% EC was not effective, even in deltamethrin rate of 500 mg (AI)/m^2. In contrast, BUNGI (1.5% SC, ADAMA Makhteshim Chemical Plants Ltd), in concentration of 100 mg (AI)/m^2 caused 100% mortality of *S. oryzae, R. dominica* and *T. castaneum*. No significant difference in efficiency were found between the spraying methods: airbrush (Sparmax DH-125) or dripping by pipette (approximately 40 drops per plate) (Tab. 2).

In the warehouse test, on concrete surface, KESHET 2.5% EC in concentration 100 mg (AI)/m^2 was not effective. However, BUNGI (1.5% SC, ADAMA Makhteshim Chemical Plants Ltd) in same concentration caused 100% mortality of *S. oryzae* (Tab. 3).

*** - pH concrete flush water 12.5.

4. Discussion

Deltamethrin is a broad-spectrum synthetic pyrethroid insecticide with contact activity that is widely used to control stored product insects. In this study, emulsifiable concentrate of deltamethrin (KESHET 2.5% EC, ADAMA Makhteshim Chemical Plants Ltd), which were applied on Petri dishes, in concentration 20 mg/m^2, was very effective .

According to Paudyal et al. (2016), who used technical grade deltamethrin in ethanol on glass Petri dishes, LD_{95} for *S. oryzae* was 123.6 mg/m^2 (70.9–288.3), for *R. dominica* it was 121.3 mg/m^2 (74.4–233.6) and 57.8 mg/m^2 (43.2–83.0) for *T. castaneum*. The differences in the efficacy of deltamethrin are due probably to the fact that in our study we used a commercial product, rather than a technical grade deltamethrin, and insect's strains variability.

In our warehouse experiment, the efficacy of commercial treatment by spray KESHET 2.5% EC in rate of 100 mg (AI)/m^2 on concrete, against *S. oryzae*, varied in different parts of the warehouse.

Suspension concentrate formulation of deltamethrin (Centynal™) and chlorpyrifos-methyl + deltamethrin (Storcide™ II) are used in USA (Sehgal and Subramanyam, 2014, Sehgal et al., 2014); mix pirimiphos-methyl (ACTELLIC 50 EC) + deltamethrin (KESHET 2.5 EC) - are used in Israel.

In our laboratory experiments on concrete, KESHET 2.5% EC was not effective. In contrast, the new commercial formulation of deltamethrin, BUNGI (1.5% SC, ADAMA Makhteshim Chemical Plants Ltd), in concentration of 100 mg (AI)/m^2 caused 100% mortality of *S. oryzae, R. dominica* and *T. castaneum*. Similar results were obtained when testing the two formulations of deltamethrin in a warehouse.

It is a known fact that pyrethroid efficacy may be dependent on formulation. Jain and Yadav (1989) reported differences in efficacy of an emulsifiable concentrate (EC) and wettable powder (WP) formulations. In the same study, adult insects exposed to deltamethrin were applied at 10 mg (AI)/m^2 on various surfaces including concrete. WP formulation was more effective than the EC formulation on concrete.

According to Arthur (1997), 0.05% deltamethrin dust has potential to knockdown or kill *T. castaneum* and *R. dominica* after 24 h exposure on concrete, and has potential as a residual treatment in food storage facilities. However, use of dust and WP is inconvenient in practice. Suspension combines effectiveness of dust/WP and all the performance benefits of emulsions. Suspension concentrates of deltamethrin: Centynal (Wellmark Internatonal, Schaumburg, IL, 37mg (AI)/ml)) and Suspend® SC 4.75% AI, were effective against stored product insects. Centynal at 20 mg (AI)/m^2 on concrete was effective against adults of *R. dominica*, *T. castaneum* and *Oryzaephilus surinamensis* (L.) causing 100% mortality of laboratory strains (Sehgal and Subramanyam, 2014); Suspend® SC 4.75% AI at 24 mg (AI)/m^2 on concrete caused 100% mortality of adults and larvae of laboratory strains of *Trogoderma granarium* (Everts) (Ghimire et al., 2017).

Factors such as surface activity, surface pH, porosity and transfer from carrier to insect may play a role in the different effectiveness of two deltamethrin preparations on concrete. It was observed, that there was an influence of concrete alkaline on efficacy of 2.5EC KESHET. However, the decline in efficiency of KESHET 2.5% EC on concrete cannot be explained by basic pH only. The results show that the efficacy of deltamethrin treatment depends on its formulation and on the sprayed surfaces.

Extended Abstract

Diatomaceous earth (DE) is toxic to insects because it absorbs their cuticular waxes causing insects to die from desiccation. DEs are obtained from geological deposits around the world, are skeletons of diatoms, and are mainly made up of SiO_2, with very low mammalian toxicity They can be applied with approximately the same technology as other powder insecticides (Korunic, 1998; Subramanyam and Roesli, 2000). Several DEs are effective at doses of 500 ppm or higher. However, these doses cause unwanted effects on grain quality and flowability and their application for direct mixing with grain has limited acceptance by the grain industry (Korunic et al., 1996; Subramanyam and Roesli, 2000). Therefore, it is essential to develop formulations that are effective at lower doses of DE. One of the solutions is to combine DE with other substances, primary with botanicals (Athanassiou and Korunic, 2007; Athanassiou et al., 2009). Our objective was to develop effective insecticides using as much as possible Generally Recognized as Safe (GRAS) compounds that would not significantly reduce grain flow or test weight.

We developed two new insecticide formulations that combine: diatomaceous earth (DE), silica gel, pyrethrin, piperonyl butoxide (PBO) and dill essential oil (F2Z) or with these same ingredients and disodium octaborate tetrahydrate (F3DOTZ). Silica gel (Sipernat® 50 S) is synthetic amorphous silicon dioxide and, has similar mode of action as DE. Amorphous silicon dioxide is (GRAS) and, is used as a food additive. Pyrethrin is one of the most common botanical insecticides. To prevent the recovery of insects after the treatment, the pyrethrin formulations contain a synergist, most frequently piperonyl butoxide (PBO) (Ware and Whitacre, 2004). Dill essential oil is extracted from the seeds or leaves/stems of the dill (*Anethum sowa* and *A. graveolens*). Dill oil is known as a natural synergist for pyrethrin (Liu et al., 2014). Disodium octaborate tetrahydrate (DOT) is a naturally occurring mineral salt commonly called borate or sodium borate. It is used to treat lumber and other wood products to control fungi, termites, and other wood infesting pests (Ware and Whitacre, 2004). DOT is effective against *Sitophilus oryzae* (L.) and does not reduce bulk density as much as DE reduces bulk density (Korunic et al., 2017).

Sitophilus oryzae L., *S. granarius* (*L.*) (Coleoptera: Curculionidae*),* and *Rhyzopertha dominica* (F.) (Coleoptera: Bostrychidae) and one external feeder*, Tribolium castaneum* Herbst (Coleoptera: Tenebrionidae*)* were held on clean wheat (13.5% moisture) treated with different doses of the insecticides and held at 28 ± 1ºC and 60 ± 5 % RH for 3, 5 and 7 days, and then held for progeny emergence. In the series of three experiments both formulations were applied either as dusts or as wettable powders, F2Z at 150 ppm and F3DOTZ at 200 ppm.

After 3 days, with powders and wettable powder of F2Z and F3DOTZ formulations there was 100% mortality for *S. oryzae* and *R. dominica*. After 7 days, the mortality of *T. castaneum* was from 96 to

100%. All formulations completely reduced the progeny (100%). In another experiment, 75, 125, 175 and 225 ppm of F2Z and F3DOTZ formulations and 300, 400, 500 and 600 ppm of diatomaceous earth alone (Celatom MN 23) were tested. After 3 days, with 175 ppm of F2Z and F3DOTZ caused adult mortalities from 99 to 100%. The DE alone at 300 ppm after 3 days only caused 80% mortality of *S. oryzae*, 60% mortality of *R. dominica* and no mortality for *S. granarius* and *T. castaneum*, and the progeny of *S. granarius* was reduced by 77%, *S. oryzae* by 78%, *R. dominica* by 92% and *T. castaneum* by 100%.

The effective concentrations of 150 ppm of F2Z, 200 ppm of F3DOTZ and 300 ppm of DE reduced bulk densities by 4.9, 3.4 and 6.4 kg/hL, respectively.

These new formulations were effective at controlling insects better than DE alone, yet do not reduce the bulk density as much as DE alone. Further testing is required to determine if these formulations should be brought to market; duration of efficacy, cost of formulations, testing for their effect on non-target organisms, human safety and effect on end-use quality.

Abstract

Maize weevil (*Sitophilus zeamais*) is an important insect that affect the maize grain on the field and in storage. There are several ways of controlling this insect but the most commonly used is the use of chemicals. Although these chemicals are very effective, they are often expensive and not available to poor rural farmers resulting in high post-harvest losses of their harvested grains. In this study, the potential of using rice husk ash (RHA) as a protectant against maize weevil during storage was investigated. Cultured maize weevils were introduced into 400g of maize admixed with RHA at concentrations of 5g, 10g and 20g. A control set-up of both Actellic 50EC and no RHA was set-up to compare the effect of the ash treatments on weevil mortality, re-emergence and grain damage. The treatments were replicated and set-up in the lab at room temperature condition. Results showed that, 100% mortality was observed for the Actellic 50EC treatment 5days after application. However, there was no significant difference ($p>0.01$) after 60 days of storage between the 20g RHA application and the Actellic 50EC relative to weevil mortality, emergence and grain damage. With the 20g RHA admixture recording the highest mortality and suppression effect on adult weevil emergence as well as the lowest grain damage, the use of RHA can provide a significant economic advantage to farmers for storage of maize in tropical developing countries if reliable recommendations on application rate can be made for the protection of stored maize.

Introduction

Being an integral component of staples in Sub-Saharan Africa, maize is considered as an essential source of cash for farmers. It is well known to be one of the few crops that have profound effects on the livelihoods of people in Sub-Saharan Africa. There is no doubt that in Ghana, more than half of the area of land allocated for cereal production is being used for maize production (FAOSTAT, 2010). The adverse effect of climate change has led to the decrease in food output, of which maize constitute a significant part. This has caused a negative effect on the socio-economic lives of farmers. There is therefore, the need for innovative and well-adaptable methods for conserving the scarce food which is being produced by farmers from this part of the world.

In Ghana, maize like all other cereals, are stored in bags. In as much as initial pest infestation may occur in the field, the environmental conditions prevailing in traditional storage systems favour the survival and emergence of storage pests such as weevils. Indeed, weevils are often identified as one of the major problems causing loss of stored grain in Africa. An estimated percentage of 5 to 10 % maize is lost due to weevil attack (Booysen, 1983; Mashingaidze, 1994; Gadzirayi *et. al.,* 2006). This poses a risk to food security in Ghana and other developing countries in Sub-Saharan Africa.

The use of synthetic insecticides has proven to be effective as reported by Ogunleye and Adefemi (2007); Obeng-Ofori and Amiteye (2005) and Asawalam et al. (2007). In Ghana, two main chemicals: aluminium phosphide (phostixin) and actellic 50EC are used conventionally to treat/protect stored maize against the maize weevil. However, major drawbacks to the use of such insecticides such as the development of insect resistant strains and their toxic residues getting into food of animals and man are limiting their usage by farmers and other target customers. Again, the inimical macro-economy has resulted in high prices for these products and has therefore, sprouted the need for identifying other methods of preserving maize grains. Alternative methods such as the use of powdered plant parts and plant extracts have yielded positive results in comparison to the use of some synthetic insecticides (Cobbinah and Appiah-Kwarteng, 1989; Jembere *et al*., 1995; Lajide et al, 1998; Asawalam and Adesiyan, 2001; Asawalam *et al.,* 2007 and Udo, 2011). Aside these alternatives being eco-friendly, they are cheaper than chemical insecticides. Also, their availability for use is very easy since the materials used are readily available at farming areas.

The use of rice husk ash in storing maize for protection against storage pests is eminent in Ghana. However, information regarding its usage and effects on its protection of stored maize against *Sitophilus zeamais* attack is unknown. Therefore, there is the need for more study to be done in this direction. The present work therefore was designed to investigate the effectiveness of rice husk ash (RHA) in controlling *Sitophilus zeamais* in stored maize grain as compared to Actellic %0EC.

Materials and Methods

Culture of maize weevils

Species of *Sitophilus zeamais* was obtained from a sample of maize from the Ayigya market of Kumasi in Ashanti Region, Ghana. The insects were kept in Kilner jars at room temperature in the Entomology laboratory of the Agricultural faculty, Kwame Nkrumah University of Science and Technology (KNUST), Kumasi. The weevils were cultured for a period of 12 weeks.

Preparation of ash

Rice husk was collected from a rice farm at Besease, a rice farming community in Ashanti Region, Ghana. The husk was burnt into ash using a gasifier. On cooling, the ash was pulverized and kept in air tight bags at room temperature.

Moisture content determination

The maize variety, *Obaatampa*, was obtained from the Ministry of Food and Agriculture, MOFA, Kumasi at a moisture content of 13%. This was confirmed using the oven method (ISO 6540-1980).

Samples and treatments

Visual inspection was made to remove infested maize from the sample in use. 400g of uninfested maize was weighed into 15 plastic containers. Different concentrations (1.25%, 2.5% and 5% wt/wt maize grains) of rice husk ash were introduced in nine of the containers containing 400g of the maize samples. Each treatment, T5, T10, T20, TCH and TC representing 1.25 % of RHA, 2.5 % of RHA, 5% of RHA, Chemical (Actellic 50 EC) application and Control (no chemical/ash applied) respectively, were replicated three times. 20 species of the cultured *Sitophilus zeamais* (10 males and 10 females) were introduced into each container using forceps.

Experimental setup

The complete randomized design as shown in Tab. 1, with five treatments and three replicates were used in setting up experiment.

Tab. 1 Experimental setup in laboratory

1 **T5**	2 **T10**	3 **TCH**	4 **T20**	5 **TC**
6 **T10**	7 **TCH**	8 **T20**	9 **TC**	10 **T5**
11 **T20**	12 **TC**	13 **T5**	14 **T10**	15 **TCH**

Mortality, progeny and damage assessment

Number of dead weevils in each container was recorded after the first five days of set-up and for every other week for two months. Mortality rate was then calculated using Equation 1 by Asawalam (2007).

$M_r = \frac{d_w}{d_w} \times 100$ ..... Equation (1)

Where

M_r-mortality rate

D_w–total number of weevils

D_w-number of dead weevil

Percentage damage made on maize by the weevils was calculated using Equation 2 as used by Asawalam (2007).

$\text{Damage } (\%) = \frac{number\ of\ damage\ grains}{total\ number\ of\ grains\ in\ containe} \times 100$ ..... Equation (2)

Weevil Perforation Index (WPI) is a damage assessment in which the number of perforations in treated grains is compared to that of the control. Equation 3 was used to determine WPI during the experiment.

$WPI = \frac{Nps}{Npc} \times 100$ ..... Equation (3)

Where

WPI- Weevil Perforation Index

Nps - Number of perforated seeds with treatment.

Npc - Number of perforated seeds in the control.

WPI > 50 = negative protectant of plant material tested (i.e. enhancement of infestation by the weevil)

WPI < 50 = positive protectant (i.e. prevention of infestation by the weevil)

Data analysis

Using an analysis of variance, the number of dead weevils was investigated to determine whether there were any significant differences in the numbers of live and dead weevils as well as the quality

of maize grain used. A significance level of 1% was used for all analysis. A one-way ANOVA was set up for the investigation.

Results

Mortality and suppression of adult emergence

The comparison of the S. zeamais mortality in the four treatments plus the control is shown in Tab. 2. A significant difference ($p<0.01$) was recorded by the treatments on the average number of dead weevils monitored every other week in the storage containers for a period of 2 months. Apart from the control, all treatment recorded more than 80 % mortality. TCH had great effect of 100 % on the mortality of S. zeamais. This was followed by T20, T10 and T5 of mortality rates 98 %, 95 % and 90.9 % respectively. TC witnessed an uncontrollable emergence of adult weevils with a mortality of 52.9 %. Comparing the results from TCH to T20 and T10 treatments, it was observed that the effect on population growth of the weevils can be likened to that of TCH since there was no significant difference ($p>0.01$) between the two rice husk ash treatments and the chemical treatment.

Tab. 2 Mortality of S. zeamais from maize with different treatments

Treatment	Mortality*
TC	52.9a
TCH	100bc
T5	90.9d
T10	95c
T20	98c
L.S.D.	8.09

* Results are means of four replicates of twenty insects each. Mean values with same variabls indicates no significant difference ($p > 0.01$)

Damaged grains

The number of damaged grains recorded after the two months of storage is shown in Fig. 1. 100 grains sample was taken from each of the 15 containers for this analysis. TC had the greatest damage of 13 damaged grains. This was followed by T5, T10 and T20 with 8, 6.3, 4.3 and 2 damaged grains respectively. This shows that the ash as compared to the chemical also had an adverse effect on the weevils making them uncomfortable, hence less damage on grain. Similar results were witnessed by Mazarin et. al. (2016); Otitodun et. al., (2017) and Goudoungou et. at., (2018).

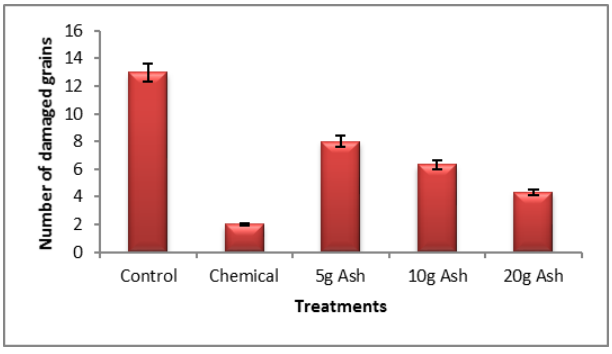

Fig. 1 Effect of different treatments on the number of damaged grains by *S. zeamais*

Weevil Perforation Index (WPI)

Weevil Perforation Index directly relates to weight loss and damage assessment. All treatments other than TC had WPI < 50 resulting in positive protectant of maize grains from *Sitophilus zeamais* attack. Hence, all tratments had the capabilities of preventing maize from the infestation by *S.*

zeamais. TCH had the least WPI of 15.38 followed by T20, T10 and T5 of 33.31, 40.69 and 58.54 WPI respectively. TC had WPI of 100 which means that it is ineffective or inefficient to store maize without any treatment (Asawalam et al., 2007).

Tab. 3 WPI of different treatments by S. zeamais

Treatment	WPI
TC	100
TCH	15.38
T5	48.54
T10	40.69
T20	33.31

Discussion

It is clear that the rice husk ash treatment used for the study gave positive results in terms of protecting maize grains from the attack of *S. zeamais*. Evidently, the rice husk ash treatments had an obvious effect on the population growth rate of the weevils, their re-emergence, WPI and the damage caused by *S. zeamais* to the maize grain. It was observed that, high application rate of 20g rice husk ash per 400g maize sample had a low mortality, low WPI and less damage to grains as it significantly suppressed the emergence of adult *S. zeamais* when compared to the control.

Results suggest that the weevils would prefer to avoid maize grains treated with the ash. The results showed that the ash had some degree of insecticidal activities. Insecticidal property of any plant material would depend on the active constituents of the plant material. Okonkwo and Okoye (1996); Ogban *et. al*. (2016) reported that *P. guineense* contains piperine and chavicine which are insecticidal. Idoko and Adesina (2012) also indicated that piperidine and alkaloids as the major active components in *P. guineense* seeds and suggested that *S. zeamais* development was adversely affected by grains treated with these powders than the control. The ability of these plant powders to cause mortality of *S. zeamais* adults on maize grains can be attributed to contact toxicity of the powders on the weevil. Though the lethal action of rice husk ash on maize weevils was not investigated, Otitodun et. al., (2017) reports that the main ingredient of rice husk ash which is silica (SiO_2) accounts for 87.1 % of the total content and has almost the same composition as diatomaceous earth which is effective in controlling pests of stored grain.

The rice husk ash is reported to contain large number of needle-like particles that are probably obtained from the setae covering the outer surface of the rice hull. These needle-like particles may have caused some skin irritations to the weevils which might cause death. It is believed that inert substances like the rice husk ash generally cause a loss in body moisture due to the presence of silica.

Conclusion

From this study, it can be concluded that rice husk ash has the potential in controlling the *S. Zeamais* in stored maize. It was observed that after the 120-125 days of storage, the incidence of weevils was lower in the containers with the higher concentration of ash (20g). This indicates that there is an increasing suppression on the population growth of the weevils with increasing concentration. This may be attributed to the toxic effect and unfavourable conditions created in the containers with the higher levels of rice husk ash. Hence, rice husk ash has the potential of controlling the damaging effects of *S. Zeamais* on maize grains in storage. Due to its eco-friendly and indigenous nature, rice husk ash can be adopted by small-scale farmers in rural communities in Ghana and some parts of Sub-Saharan Africa.

Abstract

Combinations of botanicals could enhance biological activity against insects. This in turn, will reduce amount of botanical used in storage protection. In this issue, the bioassay was carried out on *Sitophilus zeamais* to assess the effectiveness of binary combinations of *Hymenocardia acida* wood ash and *Plectranthus glandulosus* leaf powder regarding adult toxicity, progeny inhibition, and reduction of damage and germination ability. *Plectranthus glandulosus* leaf powder, *H. acida* wood ash and their binary combinations significantly induced mortality of *S. zeamais* adult (P< 0.0001). The higher mortality rate was achieved by the highest content (40 g/kg) of *H. acida* wood ash (94.66%) and 25PG75HA (94.59%) within 14 days of exposure. The combinations of *P.*

glandulosus leaf powder with *H. acida* at different proportions produced different interactions. The combination made up by 75% of *P. glandulosus* leaf powder with 25% of *H. acida* wood ash produced synergistic effect whereas that made up by 50% of each of two powders had antagonistic effect in weevil mortality. The three combinations of *H. acida* and *P. glandulosus* significantly reduced the progeny production. In term of inhibition of F_1, the combination 25PG75HA revealed more effective than the two other. The grain damage and population increase were significantly reduced. In general, the non-infested maize grain had a good germination rate than the infested ones. The treatments did not have negative effect on seed germination. From These results, the two powders and their binary combinations could be used to reduce grain infestation by insect while taking in account the proportions of insecticidal powders implied in the combination.

Keywords: *Sitophilus zeamais*, *Hymenocardia acida*, *Plectranthus glandulosus*, wood ash, leaf powder, binary combinations

Introduction

Cereals constitute the group of most consumed grain in Sub-Saharan African especially in sahelian zones. In these zones, cereals are very interesting according to its conservation ability. Cereals are easily conserved compared to the others food products, and also less demanding in term of storage technology, which can be self-made. The conserved and protected seeds permit availability of grains throughout the year thereby contributing to food security. Maize remains the most cultivated and most consumed cereal in Africa. The production of maize is done in the short period of the year whereas its commercialisation and consumption establish along the year. This makes imperative the storage and the protection of this grain. The insufficiencies of different storage methods in developing countries have not stopped to cause grain losses and this in unacceptable proportions (Gwinner etal., 1996).

During storage, maize grain is highly devastated by several pests, especially insect pests that are at the origin of the majority of damage occurring in the stored food products. Temperature and high humidity of the tropical climate favour proliferation of insects and micro-organisms which, in order to survive; devour the food products causing enormous damage (Ngamo and Hance, 2007). Maize grain does not escape to insect attack during storage. Among the insect, maize grain pest, *Sitophilus zeamais* is the most detrimental. This pest causes quantitative and qualitative damage on stored maize. In this condition, the protection of this grain according to its multiple uses becomes a major necessity for food security. Damage caused by *S. zeamais* on maize could be reduced through chemical, biological, physical control and host plant resistance, which are important components of integrated pest management strategies. However, the use of synthetic residual chemicals dominates in Cameroon and other African countries. These chemicals, although effective, cause many environmental problems such as pollution, diseases and resistance in pests (Subramanyam and Hagstrum, 1995; Park etal., 2003). Furthermore, most farmers in Africa are resource-poor and have neither the means nor the skills to obtain and handle pesticides appropriately. Therefore, an environmentally safe and economically feasible pest control practice needs to be available.

Botanicals are products based on parts, powders, extracts or purified substances of plant origin. They are generally assumed to be more biodegradable, leading to less environmental problems. *Plecthrantus glandulosus* Hook leaf (Ngamo etal., 2007a; Nukenine etal., 2007) and wood ash (Ntonifor etal., 2001, Mulungu etal., 2010; Moyin-Jesu, 2010; Singh, 2011.) could stand out as good candidates for environmentally friendly control of storage beetle pests under Cameroonian conditions. *P. glandulosus* is an annual, glandular and strongly aromatic herb, used in folk medicine for the treatment of colds and sore throat in the Adamawa region of Cameroon (Ngassoum etal., 2001). The insecticidal properties of products from *P. glandulosus* have shown good insecticidal properties against stored maize grain pests (Nukenine etal., 2007; 2010; Ngamo etal., 2007b; Goudoum etal., 2010). Many authors have reported the effectiveness of wood ash as a grain protectant (Golob etal., 1982; Firdissa and Abraham, 1999; Akob and Ewete, 2007; Oguntade and Adekunle, 2010; Gemu etal., 2013). The insecticidal efficacy of *Hymenocardia acida* wood ash needs to be determined since it is one of the plants which the wood is most used as firewood and charcoal in traditional kitchens in the northern part of Cameroon. Combinations of wood ash with *P.*

glandulosus leaf powder could enhance biological activity against insects. This in turn, will reduce both the amount of botanical and wood ash used in storage protection. Data concerning the effectiveness of the binary combinations between *H. acida* wood ash and *P. glandulosus* leaf powder are not available, although farmers mix dusts like wood ash with plant materials in stocks. As the stored grain in traditional facilities is used as seeds, the determination of the influence of grain protectant on seed germination is imperative.

Therefore, the objective of this study was to assess the effectiveness of binary combinations between *P. glanduosus* leaf powder and *H. acida* wood ash regarding adult toxicity, progeny production, population growth, grain damage and germination.

Materials and MethodsSource of maize grains

The variety of maize used during all experimentation was Shaba, this provided by IRAD Wakwa in the Adamaoua region of Cameroon. Before experimentation, broken grains, the pieces of stone, sand and others foreign materials were removed from the stock. Then the maize was kept in the freezer at –20°C for 14 days to allow its disinfestations. After disinfestations and 14 days of acclimatisation, the maize was ready for use as substrate for insect rearing and bioassays.

Insect rearing

Adults of *S. zeamais* were obtained from a colony maintained in rearing since 2005 in the Applied Chemistry Laboratory of the University of Ngaoundere. The weevils were reared on disinfested maize in 900 ml glass jars and kept under fluctuating laboratory conditions of 23.08 ± 2.05° C and 74.67 ± 14.36%). The culture was maintained and used as source of *S. zeamais* for bioassays.

Plants

Stems and branches of *H. acida* were collected in Ngaoundéré, Adamaoua region of Cameroon (latitude 7°25' North and longitude 13°35' East, altitude of 1151 m above sea level). The identity of the plant was confirmed at the Cameroon National Herbarium, where voucher samples were deposited. *H. acida* is registered on number 50114/HNC. Woods were air-dried until moisture was completely lost and burnt separately in a traditional kitchen normally used in the region. The obtained ash was sieved and packaged in glass jars, labelled and kept in a freezer (at – 4°C) until subsequent use in the bioassays.

Leaves of *P. glandulosus* were collected in July 2012 in Ngaoundere located inVina Division, Adamawa region of Cameroon (latitude 7°25' North and longitude 13°35' East, altitude of 1151 m above sea level). The identity of the plant was confirmed at the Cameroon National Herbarium on number 7656/SRF. The leaves were dried at room temperature for seven days, and then crushed until the powder passed through a 0.20 mm sieve. Wood ash and leaf powder of the two plants were mixed in the following proportions to constitute the different binary combinations:

25 % *P. glandulosus* leaf powder and 75% *H. acida* wood ash: 25PG75HA;
50% *P. glandulosus* leaf powder and 50% *H. acida* wood ash: 50PG50HA;
75 % *P. glandulosus* leaf powder and 25 % *H. acida* wood ash: 75PG25H

Toxicity and F_1 progeny bioassays

The toxicity bioassay was carried out under ambient laboratoryconditions. Four concentrations for each combination were considered. The masses of 0.25; 0.5; 1 and 2 g of *P. glandulosus* leaf powder and *H. acida* wood ash and their binary combinations were separately added to 50 g of maize in glass jars to constitute, respectively the contents of 5; 10; 20 and 40 g/kg. Then, the insecticidal materials plus grain were thoroughly mixed by manual shaking. The controls consisted of substrate without insecticidal products. A set of 20 insects of mixed sexes and 7 to 14-days-old were added into the jars containing the treated or untreated grains. All treatments were replicated four times. Mortality was recorded 1, 3, 7 and 14 days post-infestation.

The co-toxicity coefficient per *P. glandulosus* leaf powder–*H. acida* wood ash mixture was calculated according toSun and Johnson (1960). After the 14 days mortality recordings, all insects and products were discarded. The grains were left inside the bottles and the counting of F_1 adults was carried out once a week for 5 weeks (Nukenine etal., 2007).

Damage and germination tests

Four rates of the binary combinations (5, 10, 20 and 40 g/kg) were mixed with 150 g of maize grain as described above. Fifty unidentified sex weevils (7-14 days old) were introduced into each jar. Each treatment had four replications. After three months, the live weevils and dead ones were counted. Damage assessment was performed by counting and weighingthe number of damaged and undamaged grain using the method of Adams and Schulten (Adams and Schulten, 1987).

Seed germination was tested using 30 randomly picked grains from non-perforated grains after separation of the perforated from the non-perforated in each jar. Also, the non infested treated seeds were used to assess the effect of binary mixtures on germination ability. The number of germinated seeds was recorded after 10 days (Rao etal., 2006).

Data analysis

Abbott's formula (Zar, 1999) was used to correct for control mortality before Analysis Of Variance (ANOVA) and probit analysis. Data on cumulative corrected mortality, reduction in F_1 progeny, damage, weight loss and germination percentage were arcsine-transformed [(square root(x/100)] and the number of F_1 progeny was log-transformed (x + 1). The transformed data were subjected to the ANOVA procedure using the Statistical Analysis System (SAS Institute, 2003; Finney, 1971). Tukey's test (P = 0.05) was applied for mean separation. Probit analysis (Finney, 1971; Abbott, 1925) was conducted to determine lethal dosages causing 50% (LC_{50}) and 95% (LC_{95}) mortality of *S. zeamais* at 1, 3, 7 and 14 days after treatment application. The probit analysis was also used to determine the effective content causing 50% (EC_{50}) reduction of F_1 progeny.

Results

Plectranthus glandulosus leaf powder, *H. acida* wood ash and their binary combinations significantly induced mortality of *S. zeamais* adult. This mortality increased with content and exposure time (Tab. 1). Low variation in term of efficacy was observed amongst the five tested powders. In general, this variation became highly significant (P< 0.0001) within 7 and 14 days. The higher mortality rate was achieved by the highest content (40 g/kg) of *H. acida* wood ash (94.66%) and 25PG75HA (94.59%) within 14 days of exposure. *P. glandulosus* leaf powder induced low mortality compared to the other products at all exposure periods. The mortality rate of 57.24% was recorded with *P. glandulosus* leaf powder at its highest content (40 g/kg) within 14 days of exposure. Low mortality rate was recorded at 5 g/kg for the different powders. However, this lowest content (5 g/kg) induced significant mortality with increasing of exposure time. In term of induced mortality, the different products can be ranked as follows: *H. acida* wood ash > 25PG75HA > 50PG50HA > 75PG52HA > *P. glandulosus* leaf powder.

The lethal content of different powders and their combinations reduced; when the exposure period increased (Tab.2). The combinations of *P. glandulosus* leaf powder with *H. acida* at different proportions produced different interactions. The combination made up by 75% of *P. glandulosus* leaf with 25% of *H. acida* wood ash produced synergistic effect whereas that made up by 50% of each of two powders had antagonistic effect.

Tab. 1 Cumulative mortality of *Sitophilus zeamais* adult induced by *Plectranthus glandulosus* leaf powder and *Hymenocardia acida* wood ash and their binary combinations (t = 22.76 ± 2.02° C; r.h. = 69.87 ± 9.93%)

Means ± S.E. followed by the same capital letter in a line and the same lowercase letter in a column do not differ significantly at P< 0.05 (Tukey's test), Each datum represents the mean of four replicates of 20 insects each.

ns: P > 0.05, *: P < 0.05, **: P < 0.001, ***: P < 0.0001.

The three combinations of *H. acida* and *P. glandulosus* significantly reduced the production of progeny compared to the control (Tab. 3). From the application of 5 g/kg (lowest content), the number of emerging adults was highly reduced. The highest inhibition of emerging insects was recorded at the highest content (40 g/kg) of the three combinations made up by *P. glandulosus* leaf powder and *H. acida* wood ash; 25PG75HA, 50PG50HA and 75PG25HA inhibited adult F_1 progeny production by 95.49, 83.39 and 80.92, respectively. Generally, the combination 25PG75HA was revealed more effective than the two other (50PG50HA and 75PG25HA). This combination recorded the lowest EC_{50} (2.55 g/kg) whereas the highest EC_{50} was achieved by 75PG25HA (10.69 g/kg).

ns: P > 0.05; *: P <0.05, β : the LC values were obtained by extrapolation, # : the Fudicial limit values for LC could not be computed due to very low variations in mortality among the different contents of insecticidal material.

All the treatments significantly reduced grain damage and population increase, compared to the control (Tab. 4). And, the reductions of grain damage and population growth were dose-dependent. The number of insects, grain damage and weight loss decreased when the concentration of powders increased. Concerning the different parameters, a difference was observed in term of effectiveness according to the combination. The number of insects was also considerably reduced. Even at the lowest content (5 g/kg), the three combinations revealed very effective; the grain treated with 25P75HA recorded 21.92 % damaged grain and 3.22 % weight loss whereas the non-treated grain recorded 49.61 % damaged grain and 12.81 % weight loss. At their highest content level (40 g/kg), the damage was almost completely suppressed. 25PG75HA revealed more effective compared to the other combinations.

The germination rate varied with treatment. In general, the non-infested maize grain had a good germination rate than the infested ones (Tab. 5). In non-infested grain, the germination percentage was almost the same; it varied according neither to the combination nor to the content. But, with maize grain infested by *S. zeamais*, the germination rate increased with ascending the dosage. The germination percentage of infested maize grain was highest at the highest content (40 g/kg). Without insect, the germination was significantly higher even without insecticidal powder (94.33 %) whereas with insect the germination rate was the lowest one (21.67 %).

Discussion

The binary mixtures of *P. glandulosus* leaf powder and *H. acida* wood ash provoked significant mortality of *S. zeamais*. The combination of insecticidal materials has the advantages to increase efficacy by complementing the bio-efficacy of the individual products and simultaneously lowering their doses on the one hand, broadening the spectrum of activity and reducing the chance of resistance development, on the other hand (Das, 2014). However, with mixtures, negative effects

can also occur such as reduction of efficacy, phyto-toxicity and incompatibility problems between materials (Regupathy, 2004). The combinations of 75% of *P. glandulosus* leaf powder with 25% of *H. acida* on *S. zeamais* mortality produced synergistic effect, whereas combination made up by 50% of *P. glandulosus* leaf and 50% *H. acida* wood ash induced antagonistic effect within 14 days, it produced a significant synergism. In general, the mixtures composed by different insecticidal materials improved in efficacy. The additive effect was also observed, the effect of two materials is equal to the sum of each component given alone (1+3=4), which was observed in the present study by the combination 25PG75HA (25% *P. glandulosus* leaf powder and 75% *H. acida* wood ash) within 14 days of exposure.

The proportions of two products used in combinations can produce different performances according to the involved proportions. The combinations of 75PG25HA and 50PG50HA produced respectively synergistic and antagonistic effect. The same tendency concerning the variations in efficacy for different proportions of same products was observed by Ntonifor etal. (2010); these authors found that the combinations of *Syzygium aromaticum* (L.) (Myrtaceae) and *Cyperus aequelis* (Vahl) (Cyperaceae) at the proportions of 0:2, 0.5:1.5, 1:1, 2:0 (g:g) induced 36.3%, 93.8%, 98.8%, 100% mortality of *C. maculatus*, respectively, within 3 days of exposure.

The three binary combinations of *P. glandulosus* leaf powder and *H. acida* wood ash considerably inhibited the production of *S. zeamais* progeny. In addition to increasing mortality, the combinations of these products have an effect on *S. zeamais* development. The presence of *P. glandulosus* leaf powder in combinations may potentiate the effect of ash. There are physical and chemical action, which are the desiccation by ash and poisoning by the chemical compounds contained in *P. glandulosus* leaf. Mixtures can disturb or delay the development of larvae in adults. Karso and Al Mallah (2014) found that the mixture of soya oil and Acetamprid pesticide gave the highest average mortality of *Trogoderma granarium* larvae and which varied according to the proportions.

The combinations of insecticidal materials improve the protection of stored grain by reducing the qualitative and quantitative losses. The reduction of damage and the suppression of *S. zeamais* population growth were positively correlated. Combinations of *H. acida* wood ash with *P. glandulosus* leaf powder at different proportions considerably reduced damage, by lowering the number of perforated grains and weight loss, and at the same time by inhibiting the population increase. Hill (1990) reported that wood ash was useful as a physical barrier on the grain. However, it can also possess various chemical properties according to its botanical source. *P. glandulosus* leaf, thanks to its chemical compounds controlled the proliferation of insect, which explain the efficacy of combinations in short storage period. When the storage period increased, the efficacy decreased by loss of their volatile compounds which confer its toxicity against insects. Similar findings were reported by Mwangangi and Mutsiya (2013), who showed that the efficacy of *Ocimum basilicum* Linnaeus (Lamiaceae) powder deteriorated the fastest leading to 80, 77, 44, 20 and 15 % mortality over 0, 7, 14, 21 and 28 days of storage.

In many African countries, stored grains provide not only grains for food but also seeds for planting. The untreated maize in presence of insects recorded the week germination rate. In this case the seed loss their germination ability due to the high *S. zeamais* infestation that lays its eggs on grain. The larvae develop and feed inside the grain by consuming the germ of the seed, thus diminishing the viability of the seeds. Usha Rani and Devanand (2011) found that seed germination was significantly reduced when untreated maize seeds were exposed to *S. oryzae* and *T. castaneum*. Higher levels of the products improved their ability to protect grain, leading to a greater germination capacity. The different powders did not present any adverse effect on maize seed germination.

In the present study, no adverse effect was observed on germination ability. But, some findings reported the inhibiting effect of some plant extracts on seed germination (Chung and Miller, 1995; Bustos-Figueroa etal., 2009). The application of lower concentrations of *Murraya koenigii* Linnaeus (Rutaceae) and *Capsicum annuum* Linnaeus (Solanaceae) extracts caused a normal germination, but

the same plants at higher concentrations caused 30-35% inhibition of seed germination. Bustos-Figueroa etal. (2009) observed that the leaf powder of *Peumus boldus* used alone or mixed with lime did not affect the percentage of maize seed germination. This corroborates our findings about the germination rate recorded with the treatments. Higher germination rate recorded by the combinations 25% of *P. glandulosus* leaf powder with 75% of wood ash could be due to the higher content of ash in the combination. According to Philogène (1972), the ash does not affect germination but could enhance growth because of the cations that it contains. *H. acida* wood ash contains high quantity of Ca, K, P, Na, Fe, which are important for plant growth. Parimelazhagan and Francis (1999) found that leaf extracts of *Cerastium viscosum* Linnaeus (Caryophyllaceae) increased seed germination and improved seedling development of rice seeds. In general, grains in storage facilities lost their viability and germination chances as the post-harvest storage period increases (Hedimbi *et al.*, 2012). That could explain the loss of viability partly even when the seeds do not have damage. The combinations protected the maize grains against the destruction of their germination capacity by weevils and they did not influence negatively seed germination.

The binary combinations of *P. glandulosus* leaf powder and *H. acida* wood ash at different proportions effectively protect maize grain against infestation by *S. zeamais* in storage. The binary combinations permit to the maize grains to conserve their viability without affecting negatively germination rate. The beneficial effect of the combinations could be enhanced by using the appropriated proportions. Then, other proportions in combination of the two powders need to be tested in order to find out the most efficient combination. Further studies need to be carried out concerning mammalian toxicity that could be attributed to the use of these products in grain storage. Also, the investigations need to be undertaken in order to assess the effect of these powders on the organoleptic and technological properties of treated grains.

Abstract

Lethality of rice husk ash (RHA) and a diatomaceous earth (SilicoSec) (DE) to adults of *Sitophilus zeamais*, *S. granarius*, *Lasioderma serricorne* and *Callosobruchus maculatus* was investigated under controlled conditions of 25 ± 2° C and 60 ± 3% relative humidity. Each product was tested at 0.05 g to 0.5 g/20 g of grain respectively in glass Petri dishes against 20 adults of each beetle. Adult mortality was observed up to 10 days post treatment. RHA/DE mixtures (1:1, 3:1 and 1:3 ratios) were also tested at 2% of grain weight. Additionally, RHA and DE were tested at low dosages (0.01 g to 0.04 g/20 g) against adults of *C. maculatus* alone. The DE generally produced significantly higher mortality of all the adult storage beetles and at earlier observation times, than RHA at the lower dosages (< 0.2 g). Adult mortality produced by RHA and DE in *S. zeamais* and *S. granarius* increased with increase in dosage from 0.05 g to 0.5 g. The RHA/DE mixtures generally produced similar mortality of all the adult storage beetles irrespective of post-treatment exposure time. The *S. zeamais* and *S. granarius* were generally more tolerant to the DE and RHA treatments than *L. serricorne* and *C. maculatus*. Percentage mortality of *C. maculatus* adults when DE was applied at low dosages (0.01 g to 0.04 g) was generally higher than RHA applied at similar dosages, up to 3 days-post treatment. All treatments produced 100% mortality of *C. maculatus* adults 4 days-post treatment. The data further confirm the efficacy of DE and RHA as insecticidal dusts at the dosage rate of 0.5 g or more per kg of grain.

Keywords: Rice Husk Ash; diatomaceous earth (Silico Sec); lethality; storage beetles

1. Introduction

In developing countries losses caused by insect pests may reach 6.5% or more of stored grain (Raju, 1984), making control imperative. Control of these insects by synthetic chemical insecticides is effective, but has several drawbacks such as increasing costs, inconsistent supplies and hazards to man and the environment (Ofuya, 2003). Inert dusts such as ash and diatomaceous earths may be suitable alternatives to contact insecticides from the point of view of resource poor farmers (Stathers et al., 2008). Rice husk ash appears to be especially effective in the control of stored products insect pests (Tee, 1981; Ofuya and Adler, 2014). Diatomaceous earth is an inert dust of almost pure amorphous silicon dioxide and made up of fossilized diatoms; and has been variously applied for the management of stored-product pests with good results (Shah and Khan, 2014; Perisic, 2018). The main ingredient of rice husk ash is silica (SiO_2), accounting for more than 90% of the total content, and therefore similar in composition as diatomaceous earth. However, direct comparison of any diatomaceous earth and rice husk ash in stored products protection against insect infestation has scarcely been reported. This paper reports the results of a study comparing the lethality of rice husk ash and a diatomaceous earth, Silico Sec to adults of four storage beetles namely *Sitophilus zeamais* Mots. *S. granarius* L., *Lasioderma serricorne* F. and *Callosobruchus maculatus* F.

2. Materials and Methods

The study was carried out at the Federal Research Centre for Cultivated Plants, Institute of Ecological Chemistry, Plant Analysis and Stored Product Protection, Berlin, Germany under controlled conditions of 25 ± 2° C and 60 ± 3% relative humidity.

Insects

The storage insects tested in the study are the cowpea seed beetle, *Callosobruchus maculatus* Fabricius, the maize weevil, *Sitophilus zeamais* Mots., the granary weevil, *S. granarius* L. and the cigarette beetle, *Lasioderma serricorne* Fabricius. Their cultures are maintained at Institute of

Ecological Chemistry, Plant Analysis and Stored Product Protection, Berlin, Germany using standard procedures (e.g. Tofel *et al*., 2015). The *C. maculatus* was tested using blackeye cowpea whilst *S. zeamais*, *S. granarius* and *L. serricorne* were tested on yellow maize.

Paddy Husk Ash (RHA)

Paddy husk was obtained from a processing mill in Emure in Ekiti State, Nigeria (7.4500° N, 5.4667° E) and rice variety was Igbemo local grown by communities around the metropolis. Paddy husk was first pulverized in an electric blender into coarse powder which was thereafter converted to ash material in electric oven at 550° C for three hours. The husk ash was pulverized in a laboratory mill into a fine powder with particle size of ≤ 150 µm using a British standard sieve (Ofuya and Dawodu, 2002). The ash powder (approximately 100 g) was then put in a plastic container with tight fitted lid.

Diatomaceous Earth (DE)

The diatomaceous earth (DE) used was SilicoSec, a natural silica powder obtained from processed fossilized diatoms. It is composed of 96% amorphous SiO_2 with particle size between 13 µm to 15 µm (Erb-Brinkmann, 2000).

Effect of high dosages of RHA and DE on mortality of adult beetles

Twenty unsexed adults of *C. maculatus* (< 2 days old), *L. serricorne* (< 1 week old), *S. zeamais* (< 2 weeks old) and *S. granarius* (< 2 weeks old) were separately dusted by shaking with either rice husk ash powder (RHA) or SilicoSec (DE) in clear glass Petri dishes (9.0 cm diameter) containing 20 g of cowpea seeds for *C. maculatus* and maize grain for the other beetle species. Each product was tested 0.05, 0.1, 0.2, 0.3, 0.4 and 0.5 g respectively. There was a control treatment with neither RHA nor DE. Adult mortality was observed daily for up to 10 days. The experiment was replicated three times.

Effect of combining RHA and DE on mortality of adult beetles

Twenty unsexed adults of *C maculatus* (< 2 days old), *L. serricorne* (< 1 week old), *S. zeamais* (< 2 weeks old) and *S. granarius* (< 2 weeks old) were separately dusted by shaking with mixtures of RHA and DE in three ratios (1:1, 3:1 and 1:3) in clear glass Petri dishes (9.0 cm diameter) containing 20 g of cowpea seeds for *C. maculatus* and maize grain for the other beetle species. Each mixture was tested at 0.4 g. There was a control treatment with no protectant. Adult mortality was observed daily for up to 10 days. Each treatment was replicated three times.

Effect of low dosages of RHA and DE on mortality of *C. maculatus* adults

Twenty unsexed adults of *C maculatus* (< 2 days old) was dusted by shaking with either rice husk ash powder (RHA) or SilicoSec (DE) in clear glass Petri dishes (9.0 cm diameter) containing 20 g of cowpea seeds. Each product was tested 0.01, 0.02, 0.03 and 0.04 g respectively. There was a control treatment with neither RHA nor DE. Adult mortality was observed daily for up to four days and each treatment was replicated three times

Data analysis

Data were analyzed using the SigmaStat® 3.5 software (Systat Software GmbH, Germany). Mortality data, where necessary, were corrected as recommended by Abbott (1925). Percentage data were arcsine transformed and subjected to one-way analysis of variance (ANOVA. Where the ANOVA indicated significant difference between treatments, least significant difference (LSD) method was used to separate the means at 5% level of probability.

3. Results

Three-days post treatment *S. zeamais* and *S. granarius* suffered higher mortality in DE treated seeds than in the RHA treated seeds with each dosage except with 0.5 g of ash that produced a higher kill

of *S. zeamais* than the DE counterpart (Table 1). Five-days post treatment mortality of *S. zeamais* was generally similar to RHA and DE treatments, but DE treatments produced significantly higher kill of *S. granarius* with the 0.05 g and 0.1 dosages in comparison with the RHA counterparts. The trend in adult mortality observed 7 days post treatment was similar to that recorded 5 days post treatment. Ten-days post treatment mortality of *S. zeamais* was generally similar with RHA and DE treatments, but DE treatments produced significantly higher kill of *S. granarius* with the 0.05 g, 0.1 and 0.2 dosages in comparison with the RHA counterparts. Both RHA and DE produced higher adult mortality in *S. zeamais* and *S. granarius* with increase in dosage from 0.05 g to 0.5 g.

For 1-day post treatment all the DE dosages (0.05 g to 0.5 g) produced 100% mortality in adults of *L. serricorne* and *C. maculatus* which was significantly higher than mortality produced by similar dosages of RHA except 0.4 g and 0.5 g.

for *L. serricorne* and 0.3 g, 0.4 g and 0.5 g for C. *maculatus* (Table 2). For 2-days post treatment the DE dosages also produced 100% mortality in adults of *L. serricorne* and *C. maculatus* which was significantly higher than mortality produced by similar dosages of RHA except 0.3 g, 0.4 g and 0.5 g for both beetle species. Similarly, for 3-days post treatment all the treatments produced 100% mortality in *L. serricorne* and *C. maculatus* except in the case of *C. maculatus* exposed to 0.05 g RHA where 81.7% mortality was recorded.

Mean % mortality of *S. zeamais* and *S. granarius* was not significantly different irrespective of the ratio of mixing RHA and DE (1:1, 3:1 or 1:3) for use against these insects, 3-days post treatment except with the 3:1 ratio against *S. granarius* where 16.7% mortality was recorded (Table 3). At 5-days post treatment the RHA/DE (3:1) produced significantly the highest of 76.7% of S. *granarius*. A similar trend was observed at 7 and 10-days post treatment.

The 1-day post treatment the RHA/DE mixtures produced similar mortality of *L. serricorne* (ranging from 23.3% to 30.0%) which was significantly lower than mortality produced by the same mixtures in *C. maculatus* (ranging from 60.0% to 75.0%) (Table 4). A similar trend was observed at 2 and 3-days post treatment. At 5-days post treatment, all the RHA/DE mixtures produced 100% mortality in both *L. serricorne* and *C. maculatus*. Mean % mortality of *C. maculatus* adults when DE was applied at low dosages (0.01 g to 0.04 g) was significantly higher than RHA applied at similar dosages during 1, 2 and 3-days post treatment except RHA applied at 0.04 g which produced 100% mortality 3-days post treatment as in DE treatments (Table 5). All the treatments produced 100% mortality of *C. maculatus* adults at 4-days post treatment. For the RHA treatments, mortality increased significantly with increase in dosage except on the 4th day post treatment.

4. Discussion

The results of this study showed that DE was generally more toxic to *S. zeamais* and *S. granarius* than RHA. DE produced 100% mortality in adults of these two beetles 10 days post-treatment at the dosage of 0.3 g or more per 20 g of grain whereas it required 0.4 g or more of RHA to achieve the same level of mortality. Similarly, the DE was generally more toxic to *L. serricorne* and *C. maculatus* than RHA. It was further observed that mortality of *C. maculatus* adults when DE was applied at low dosages (0.01 g to 0.04 g) was generally higher than RHA applied at similar dosages. Demissie et al. (2008) reported that diatomaceous earth was superior to wood ash in the control of *S. zeamais*. Our results may support the assertion by Shah and Khan (2014) that DE is probably one of the most efficacious natural dusts used as an insecticide. Sadeghi et al. (2012), however, did not record overwhelming superiority in lethality of Sayan®, a DE, to adults of six stored products insects including *S. zeamais*, *L. serricorne* and *C. maculatus* when compared with bran and sawdust. The DE used in this study is SilicoSec, composed of 96% amorphous SiO_2 with particle size between 13 µm to 15 µm (Erb-Brinkmann, 2000). Sayan® DE formulation contains 92% SiO_2 and an average particle size of 50 µm (Sadeghi et al., 2012). Differences in chemical and physical properties of insecticidal dusts can influence their efficacies (Dawodu and Ofuya, 2002; Olotuah et al., 2010; Shah and Khan, 2014).

Species variation in susceptibility to DE and RHA treatment was clearly observable in this study. Adults of *S. zeamais* and *S. granarius* were less susceptible to DE and RHA than those of *L. serricorne* and *C. maculatus*. For example, irrespective of dosage DE killed all introduced *L. serricorne* and *C. maculatus* adults within 1 day post treatment whereas a DE dosage of 0.4 g or more per 20 g of grain required 7 days to kill all introduced *S. granarius* and *S. zeamais* adults. Also, whilst 0.4 g dosage of RHA killed all introduced *L. serricorne* and *C. maculatus* adults within 2 days post treatment, the same dosage of RHA required 10 days to kill all introduced *S. granarius* and *S. zeamais* adults. Observations that stored products insects show a wide range of susceptibility to inert dusts have been reported by some other workers (Athanassiou et al., 2005; Sadeghi et al., 2012; Doumbia et al., 2014). Differences in susceptibility to inert dusts by insects could be due to size, quantitative or qualitative differences in cuticular lipids, differences in agility through grain, behavioural responses to the dusts or resistance to desiccation (Shah and Khan, 2014).

Ofuya and Adler (2015) observed that DE could be mixed with insecticidal plant powders without jeopardizing its lethality against four different adult storage beetles. Indeed mixing with DE was thought to have putatively increased the lethality of *Piper guineense* Schum & Thonn dry fruit and rice husk powders to the adult beetles. Ofuya et al. (2015) reached a similar conclusion. However, the results of this study indicate that there may be no advantage in mixing DE and RHA for stored products protection against insect infestation in terms of adult mortality. The DE and RHA may not have been physically homogeneous partly due to inherent differences in particle size. RHA has been reported to contain a large amount of needle-like particles presumably derived from setae covering the outer surface of the rice husk which may putatively trigger a physical reaction on the integument of insects that eventually results in their

death (Ofuya and Adler, 2014). It is hereby hypothesized that DE may have obliterated the activity of these needle-like particles in the RHA/DE mixtures, thus decreasing the ability to cause death of the insects.

Overall, data had been provided that further confirm the efficacy of DE and RHA as insecticidal dusts at the dosage rate of 0.5 g or more per kg of grain. The DE was observed to be generally more lethal to the beetles than RHA. *S. zeamais* and *S. granarius* were generally more tolerant to the DE and RHA treatments than *L. serricorne* and *C. maculatus*. For *C. maculatus* there is the possibility of achieving good control at lower dosage rate of DE and RHA of less than 0.5 g per kg of grain.

Abstract

The use of natural inert dusts against storage insect pests is increasing recently, as an alternative to conventional insecticides. Laboratory study was carried out to evaluate the contact effect of three inert dusts, diatomaceous earth (DE), kaoline (KA) and vermiculite (VE), at rates 5, 7.5, 10, 15 and 20 gm^{-2}, against adults of *Sitophilus oryzae* (L.) and larvae of *Plodia interpunctella* (Hubner). Insect mortality was evaluated 1, 2, 3 and 7 days after the exposure. Insect mortality varied depending on the species, concentrations and exposure periods. The DE and KA caused 86.7-98% mortality of *S. oryzae* after 2 days of exposure at the highest rates, while at 5 and 7.5 gm^{-2}, 100% mortality was achieved only after 7 days. The highest rates of inert dusts caused 42-50% (DE) and 60-75% (KA) mortality of *P. interpunctella* larvae only after 7days. The mortality of moths increased gradually with the concentration and 100% was achieved 3 days after the contact with DE and KA (10, 15 and 20 g m^{-2}). However, inert dusts induced faster pupation of *P. interpunctella*, while adult emergence was reduced and adults had smaller body-sizes, compared to control. The VE caused relatively low mortalities (7-11% of *S. oryzae* adults and 5-8% of *P. interpunctella* larvae) at all tested rates during the entire experiment. Our results have shown good insecticidal effect of DE and KA against *S. oryzae* and *P. interpunctella* at 10, 15 and 20 gm^{-2}. These products could therefore be used by small-scale farmers to protect stored grains against insect pest infestation.

Key words: Inert dusts, *Sitophilus oryzae, Plodia interpunctella*, contact exposure, diatomaceous eartth

Introduction

In recent years, the use of contact insecticides and fumigants for controlling storage pests is under increasing restriction due to the presence of residues in food and development of insect resistance (Collins, 2000; Kljajić and Perić, 2005). These shortcomings have stimulated the need for testing and evaluation of non-toxic methods that can replace conventional insecticides in stored grains (Arthur, 1996). Recently, physical control methods, like the use of inert dusts, have become prominent (Field and Korunić, 2002). These materials are classified into different groups depending on their composition and particle size and include materials such as diatomaceous earth, silicophosphate, rock phosphate, sand, kaolinite, clay etc. (Golob, 1997). There is a growing interest especially in desiccant or absorptive dusts, among which, diatomaceous earth is the most widely used in practice worldwide (Golob, 1997; Korunić, 1998a; Subramanyam and Roesli, 2000) and in commercial storages in the developed world. On the other hand, non-silica dusts and those composed of coarse grain silicates, such as kaoline and sand, have been used traditionally as grain protectants by small-

scale farmers in the developing world (Golob, 1997). Inert dusts, regardless of the group, can control a variety of common storage insect pests. Korunić (2013) reported that there are three areas of DE use: a) admixture with grain, b) as structural treatment on walls and floors and c) addition of DE to the surface of grain bulks. However, inert dusts, primarily DE, was found to reduce the grain bulk density, affects the flow characteristics of bulk grain (flowability), and also leaves visible dust residues (Subramanyam et al., 1998; Golob, 1997; Korunić et al., 1998b) and heath concerns (Korunić, 2016). Thus, DE is highly recommended for surface treatments and in general, it is thought that DE should be used primarily as a preventive measure for grain protection and not as a curative measure. In Australia, preparation based on DE (Dryacide) is frequently applied as a structural treatment in empty storages, and on grain bulk surfaces (Aleen, 2001). This work aimed to assess the contact efficacy of three different inert dusts (diatomaceous earth, kaolin and vermiculite) against *S. oryzae* adults and *Plodia interunctella* larvae, as additional preventive measure during storage.

Material and methods

Laboratory studies were conducted to evaluate the contact effect of three inert dusts: diatomaceous earth-DE (commercial preparation SilicoSec, produced by Biofa, uncalcinated diatomite), kaoline clay - KA and vermiculite dust - VE as contact insecticides against *Sitophilus oryzae* adults and 3rd instar larvae of *Plodia interunctella*. Inert dusts were applied on glass Petri dishes (surface area, 153.5 cm^2) at rates 5, 7.5, 10, 15 and 20 gm^{-2}. The dusts were dispersed over the glass surface and 20 (2-4-weeks old) adult weevils or 3th instar larvae of *P. interunctella* were put into dishes. Mortality was evaluated after 24, 48, 72 h and 7 days of exposure. Clean Petri dishes served as the control. The LC_{50} and LC_{90} were calculated using Probit analysis in SPSS 21.

Results

The effect of DE, KA and VE applied at 5, 7.5, 10, 15 and 20 gm^{-2} on *S. oryzae* adults are presented on Figs. 1-3. In all the inert dust treated jars, insect mortality increased with the increase in concentration and exposure period. After 24 h, DE caused significant mortality at rates 10 (68%), 15 (73.5%) and 20 gm^{-2} (98%), respectively. The mortality increased after 48h of exposure and ranged from 45% at the lowest rate (5 gm^{-2}), 67% at 7.5 gm^{-2} to 100% at the highest rates. After 72 h, 100% mortality was achieved in treatments with 10, 15 and 20 gm^{-2} of DE, while satisfactory mortality was also obtained in treatments with 5 and 7.5 gm^{-2} DE (68 and 93%, respectively). After 7 days of exposure mortality was 88-100%. The difference between mortalities depending on the type of inert dust and rates, within the same exposure period (24, 48, 72 h and 7 days) was statistically highly significant (F=57.66**; 102.12**, 93.02** and 145.29**, respectively, p<0.01). earth.

The KA caused significant mortality after 24h only at rates 10, 15 and 20 gm^{-2} (75, 98 and 100%, respectively). However, after 48 h of exposure, the increase in mortality was recorded at all rates, namely 53, 65, 89, 97 and 100%, respectively, while after 72 h it ranged from 97.8-100%. The total mortality (100%) was caused by KA after 7 days for all the rates applied. Like in the case of DE, the difference between mortalities caused by different inert dusts and rates, was statistically highly significant within the same exposure period i.e. after 24, 48, 72 h and 7 days (F=103.09**; 123.54**, 107.23** and 225.62**, respectively, p<0.01).

VE caused low mortality of *S. oryzae* adults irrespective of the exposure periods. After 7 days, mortality ranged from 10-17.5% depending on the rate of VE applied. The difference between mortalities was not significant at all exposure periods (F=7.11NS; 0.96NS, 0.74NS and 14.01NS, respectively, p>0.05).

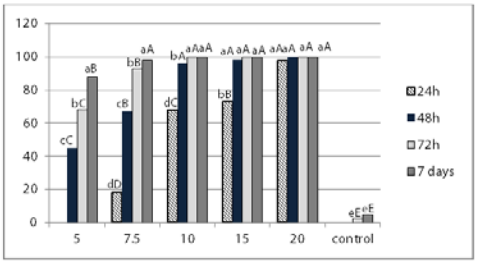

Fig. 1 The effect of DE on *S. oryzae* adults depending on the concentration and exposure period (small-case letters present differences within treatment between different days after exposure, upper-case letters present differences within day of exposure between different concentrations).

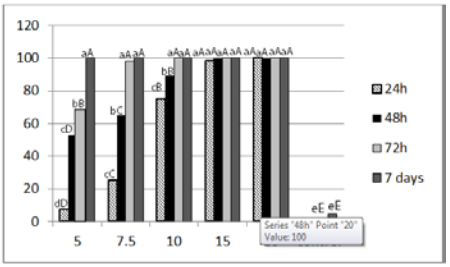

Fig. 2 The effect of KA on *S. oryzae* adults depending on the concentration and exposure period (small-case letters present differences within treatment between different days after exposure, upper-case letters present differences within day of exposure between different concentrations)

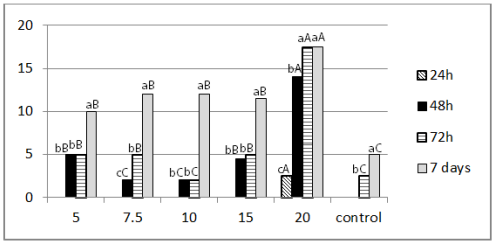

Fig. 3 The effect of VE on *S. oryzae* adults depending on the concentration and exposure period (small-case letters present differences within treatment between different days after exposure, upper-case letters present differences within day of exposure different concentrations)

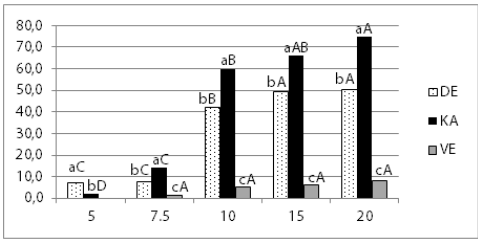

Graph. 3. The effect of DE, KA and VE on *P. interpunctella* larvae depending on the concentration after 7 days (small-case letters present differences within treatment between different inert dusts, upper-case letters present differences within day of exposure between different concentrations).

According to Probit analysis (Tab. 1), the lowest LD_{50} and LD_{90} values were achieved by KA (6.63, 9.66, respectively) indicating at higher toxicity of kaoline to *O. oryzae* adults compared to DE (10.15, 16.52, respectively).

Table 1 Toxicity of tested inert dusts

Inert dust	LC_{50}	LC_{90}	Fiducial limits	Slope	Relative potency
DE	10.15	16.52	9.98-14.13	-9.83	65.32
KA	6.63	9,66	4.95-10.71	- 6.43	100.0
VE*	/	/	/	/	/

*Probyt analysis was not performed for VE due to the lack of relevant data;
Relative potency = (LC50 of the most toxic inert dust / LC50 of candidate inert dust) × 100

The effects of DE, KA and VE applied at 5, 7.5, 10, 15 and 20 gm^{-2} on *P. interpunctella* larvae are presented in Fig. 4. The highest rates of DE (10, 15 and 20 gm^{-2}) caused significant mortality of *P. interpunctella* larvae only after 7days, 42-50%, and the differences between the number of dead larvae was highly significant only after the last exposure period (F=9.12NS; 4.11NS; 0.79NS and 307.54**, respectively, p>0.05/p<0.01).

Discussion

According to El-Sayed, lower concentrations (0.1 and 0.2% w/w) of DE caused low mortality (16.7, 32.0%) of *S. oryzae* adults after 24 h of exposure while after 48 h the mortality increased (86.7 to 100%), regardless on the concentration. These results are in accordance with the results of this work. The high efficacy of DE (SilicoSec used in this work), was also proved by Korunić et al. (2011) reporting that this preparation was the most effective against *S. oryzae* of all other tested types of diatomaceous earth.

The results of this work are partially in agreement with those of Permual and Patourel (1990) who found that *S. oryzae* was relatively tolerant to activated kaolin (8% w/w) when exposed for 72 h on treated paddy. After 96 h mortality was 90%, and after 7 days the complete mortality was reported by mentioned authors, which was also proven in our work. Similar results were presented by Swamiappan et al. (1976) who report that kaoline clay activated by acid and heat treatments caused 100% mortality of several storage pests among which *S. oryzae* L. within 24 h, even at the minimal dose of 10 mg per Petri dish. Present findings are in agreement with observations of Verma et al. (1976). According to Jadhav (2006) kaoline was more effective than other tested materials (sand, sawdust, ash, Neem seed dust etc.), which was also proven in this work. The opposite results than those obtained in this work, were presented by El-Sayed et al. (2010) stating that, in general, DE was more effective than the kaolin against *S. oryzae*.

Results of Vukajlović et al. (2018) indicate that DE, originating from Serbia, exhibited low larvicidal efficacy against *P. interpunctella* 5th larval instar, (23.5-34.5%), while high insecticidal potential was expressed on 3rd and 4th instars larvae. Subramanyam *et al*. (1998) tested the efficacy of DE product Insecto against *P. interpunctella* 5th larval instar. In the same application rates as in our study authors reported that efficacy was significantly lower (10-70%) compared to the efficacy on 1st larval instar (99.5-100.0%), indicating at higher susceptibility of younger larvae to insecticidal effects of DE products than mature larvae. Susceptibility of insects to DEs can be attributed to their anatomy and physiology. Smaller insects are more susceptible because their surface area in relation to their body volume is larger than in bigger insects and therefore they lose great amounts of water from their body (Korunić, 1997). Results of many studies confirm that efficacy of inert dusts increases with the duration of exposure (Athanassiou et al., 2008; 2014; 2016; Kljajić *et al*., 2011; Andrić *et al*., 2012), which was also proven in this work.

The highest rates of KA (10, 15 and 20 gm^{-2}) caused significant mortality (60-75%) of *P. interpunctella* larvae only after 7 days of exposure ($F=115.07^{**}$, $p<0.01$). However, VE caused relatively low mortalities (5 to 8%) to *P. interpunctella* larvae at all tested rates during the entire experiment. The difference between mortalities in different exposure periods (24, 48, 72 h and 7 days) was not significant ($F=11.04^{NS}$; 4.50^{NS}, 0.79^{NS} and 7.11^{NS}, respectively, $p>0.05$).

The mortality of moths increased gradually with the increase of concentration and 100% was achieved 72 h after the contact with DE and KA at 10, 15 and 20 gm^{-2}. Also, a faster pupation was registered for larvae exposed to inert dusts, while adult emergence was reduced and adults had smaller body-sizes, compared to control. Shah and Khan (2014) also report that almost all tested larvae made the silken-web cocoon around their body and fastly entered the diapause or changed into the pupa stage after only two days after the exposure to maize kernels treated with 1.5 gkg^{-1} of DE. The physical properties of DE induced faster than usual pupation or diapause. The authors explain that in this way, larvae protect themselves from different negative effects of DE, such as abrasion of the cuticle, absorption of cuticular waxes from the epicuticle surface, damage to the digestive tract, blockage of the spiracles and tracheae, surface enlargement combined with dehydration and repellence caused by the physical presence of the dust.

As proven in this work, storage insects express different susceptibility to inert dusts due to morphological, physiological and ecological characteristics of each species. All insect characteristics which affect the efficacy of dusts are related to a mode by which insects sustain optimal content of water in the organism, because it has been confirmed that insects with thinner and gentler wax

layer are more susceptible to inert dusts, as insects whose body surface is smaller. Also, it was found that insects from different parts of the world show different susceptibility to dusts (Golob, 1997; Korunić, 1998a; Subramanyam and Roesli, 2000; Vayias *et al*., 2009). Among the representatives of Coleoptera order the most susceptible to diatomaceous earth are species from the genus Cryptolestes, somewhat less from Sitophilus and Oryzaephilus genus, while *R. dominica* and species from the genus Triboliumare the least susceptible (Korunić, 1997; Arthur, 2002; Athanassiou *et al*., 2007).

The results of this work indicate at good potential of DE and KA (10, 15 and 20 gm^{-2}) to be used as a surface treatment in grain stores for prevention of infestation by S. oryzae adults. However, since the contact effect on *P. interpunctella* larvae was not satisfactory within the first days of exposure, the prevention from this pest should not be relied only on the application of inert dusts as surface treatments, but other measures should be involved as well.

Acknowledgement

The work was carried out in the course of project ref. no. III 43001, financed by the Ministry of Education, Science and Technological Development.

Abstract

Pulses have 20-27% proteins which is 2- 3 times higher than traditional cereals. These constitute the main source of proteins for developing countries, like India where per capita consumption of the animal protein is low, thus they are rightly considered the **poor man's meat.** India is largest pulse consumer, importer and producer country of the world occupying an area of 228.47 lakh hectares with the production of 17380 million tones every year. With the United Nations declaration of 2016 as International Year of Pulses to replace the social evil of malnutrition by legume, the research pertaining to the biology and bio intensive management of bruchids pests has become increasingly important. Therefore, laboratory bioassay of essential oils which are regarded as "Green Chemicals" extracted from *Zanthoxylum armatum* DC., *Rabdosia rugosa* Wall. ex Benth, *Artemisia maritima* Linn. and *Colebrookea oppositifolia* Sm. by hydro distillation was carried out against *Callosobruchus analis* (F.) to evaluate biopesticidal potential in terms of oviposition and progeny deterrence and ovicidal activities. There was a significant difference in the number of eggs laid on treated and control sets and among the different treatments of essential oils. *Z. armatum* at 100 µl/ml allowed the bruchid to lay only 19.15±3.6 eggs as compared to 82.35±4.5 in control and proved to be most effective treatment with 76.74% oviposition deterrence. *R. rugosa* and *A. maritima* oil were found most effective in reducing the egg hatchability to 48.00±3.2 and 49.52±2.2% respectively at a lowest dose of 10 µl/ml. Egg hatching inhibition percentage increased with an increase in concentration of all the treatments. *R. rugosa* oil at 100 µl/ml proved to be most effective in reducing the adult emergence with 85.48% progeny deterrence followed by *A. maritima* showing 81.67% deterrence. All the tested essential oils revealed a wide range of bioactivities against the bruchid pest.

Keywords; Ovipositon deterrence, essential oils, bruchid pest, progeny emergence, ovicidal activity.

Introduction

Bruchids attack cereals and pulses both in fields and store and responsible for 10- 15% loss along with a germination inability varying from 50- 92% (Adugna 2006). The cow pea weevil *Callosobruchus analis* (F.) (Coleoptera: Bruchidae) a pest of economic importance for stored-leguminous grain worldwide (Southgate 1979, Rehaman 1989, Khandwe *et. al,* 1997 and Shafique and Ahamad, 2002). Due to the persistence usage of the synthetic insecticides, there is need to unveil the bio-pesticides and insecticides, which tend to be specific on the target species and biodegradable and less toxic to mammalian species. In the search for alternatives to conventional fumigants, essential oils, now designated as "green chemicals" extracted from aromatic plants have been widely investigated. Essential oils have the bioactive fraction of plant extracts (Shaaya *et al,.* 1991; 1997; Roger and Hamraoui 1997). They have potential as fumigants, ovicides, insect growth regulators and lethal against wide range of insect pests (Roger, 1997 and Shaaya *et al.,* 1997). The present study aimed to investigate the oviposition deterrence, ovicidal effects and progeny deterrence of four essential oils extracted from *Zanthoxylum armatum* DC., *Rabdosia rugosa* Wall. ex Benth, *Artemisia maritima* L. and *Colebrookea oppositifolia* Sm. against bruchid pest *Callosobruchus analis* (F.) a pest of stored legumes worldwide.

Material and methods

Leaves of *R. rugosa, C. oppositifolia, A. maritima* and *Z. armatum* were dried in shade and grounded followed by hydro-distilled in Clevenger apparatus. Conditions of extraction were: 50 g of air-dried sample in 1:10 plant material/water volume ratio for 4 hrs distillation. Extracted oil was stored in a refrigerator at 4^0C for further analysis. Cultures of *C. analis* were maintained in the laboratory on cowpeas, in glass containers with their open mouth covered with muslin cloth. Initially, forty pairs of 24 hours old adults were placed in a jar containing host seeds. Experiment was designed by following the method of Kumar *et al.* (2008). Fifty seeds of chickpea filled in glass conical flask were treated separately with different doses of the oils. After 24 hours, 6 males and 6 female bruchids were introduced in each Petridish separately. Mortality of insect was recorded and the number of eggs laid on treated and control seeds were enumerated after ten days of oviposition.

The % deterrency of oviposition was calculated according to the equation:

$$\text{Deterrency \%} = \frac{\text{NC - NT}}{\text{NC}} \times 100$$

Where NC is the number of eggs laid on control seeds, and NT is the number of eggs laid on treated seeds.

The number of eggs laid by gravid females were enumerated and exposed to different doses of essential oils. After an exposure period of 24 hours the eggs were observed for hatching after 8 to 10 days. Percentage egg hatching was calculated as:

$$\text{Egg hatching \%} = \frac{\text{No. of eggs hatched}}{\text{Total no. of eggs}} \times 100$$

Numbers of unhatched eggs in each Petri dish were counted and the percent mortality of egg was calculated by Abbott's formula

Five gm of food media for each insect species was treated separately with different doses of oils. The seeds were then transferred into Petridishes and 6 pairs of *C. analis* (male and female of almost equal age) were introduced into them. The mortality of insects was observed and % progeny deterrence was calculated according to the equation:

$$\text{Deterrency \%} = \frac{\text{NC - NT}}{\text{NC}} \times 100$$

where NC is the number of adults emerged from control, NT is the number of adults emerged from treated food media.

Results

Different doses of essential oils reduced the fecundity of female *C. analis* as compared to control where maximum egg laying was recorded 82.35±4.5. At 100 µl/ml the essential oil of *Z. armatum* proved to be the most effective treatment with 76.74% oviposition deterrence. *R. rugosa* oil at a concentration of 50 µl/ml exhibited a high deterrent activity of 70.57% followed by *A. maritima* showing 67.15% deterrence. *C. oppositifolia* resulted in least oviposition deterrence. (Table 1).

Table 1. Oviposition deterrence of *C. analis* under different doses of four essential oils.

	Doses µl/ml	Oviposition deterrence (%)
Z. armatum	10	56.18(36.08 ±1.6)[a]
	30	65.81(28.15±2.2)[b]
	50	73.09(22.16±4.1)[c]
	100	76.74(19.15±3.6)[c]
R. rugosa	10	54.87(37.16±4.1)[a]
	30	59.65(33.22±2.5)[a]
	50	70.57(24.23±1.2)[c]
	100	75.68(20.02±2.5)[c]
A. maritima	10	53.75(38.08±1.9)[a]
	30	57.00(35.41±3.8)[a]
	50	67.15(27.05±2.4)[b]
	100	73.18(22.08±1.1)[c]
C.oppositifolia	10	51.11(40.26±4.1)[a]
	30	53.70(38.12±1.2[ja
	50	62.10(31.21±3.6)[b]
	100	68.16(26.22±2.1)[b]
Control		(82.35±4.5)[ab]

Values are mean ($n = 3$) ± SE. The means within a column followed by same letter are not significantly different from each other according to ANOVA and Tukey's comparison tests.

The results revealed that *A. maritima* and *R. rugosa* oil were most potent in reducing the egg hatchability to 49.52±2.2 and 48.00±3.2 % respectively at a l dose of 10 µl/ml whereas, egg mortality was calcu 40.94±1.2 and 39.07±2.4% respectively. *Z. armatum* at a dose of 100 µl/ml obtained 55.70±4.8% egg mortality. *C. oppositifolia* was least toxic than any other resulted in a low mortality of 44.63±1.5% against eggs of *C. analis* even at a highest dose of 100 µl/ml. (Table 2).

Table 2. Ovicidal action of essential oils against *C. analis eggs*.

	Doses µl/ml	% Hatching	% Corrected mortality
R. rugosa	10	48.00±3.2[a]	40.94±1.2[b]
	30	40.16±1.2[c]	50.59±2.8[a]
	50	28.00±4.6[b]	65.55±1.4[c]
	100	20.20±1.2[d]	75.14±2.2[d]

	100	72.47(15.32±2.8)[b]
C. oppositifolia	10	36.17(35.52±2.1)[d]
	30	45.39(30.39±1.8)[c]
	50	54.19(25.49±3.2)[c]
	100	63.89(20.09±2.8)[a]
Control		**(55.65±5.8)[ab]**

Values are mean (n = 3) ± SE. The means within a column followed by same letter are not significantly different from each other according to ANOVA and Tukey's comparison tests.

Discussion

There was a significant difference in the number of eggs laid on treated and control and among the different treatments of essential oils. The ability of essential oils and monoterpenoids to reduce fecundity in *Acanthosceildes obtectus* has been already reported (Roger and Hamraoui, 1995). At 100 µl/ml *Z. armatum* allowed the bruchid to lay only 19.15±3.6 eggs as compared to maximum egg laying of 82.35±4.5 in control and proved to be most effective treatment with 76.74% oviposition deterrency. *R. rugosa* and *A. maritima* oil also showed a remarkable acitivity significantly deterring the majority of females from egg laying on seeds than control. *Berberis lycium* in acetone the oviposition in *C. chinensis*was decreased from 38.40±0.81 in control to 11.06±0.65 in 20 per cent concentration and from 38.40±0.65 in methanol control to 9.46 in same concentration of methanol extract. The oviposition was reduced from 37.85±1.10 in control to 6.93±0.49 in 20 per cent roots extract of *B. lycium* in acetone and from 35.50±0.40 in methanol control to 8.60±0.41in same concentration in methanol (Thakur and Devi, 2016). In a similar study Shukla *et al.* (2011) recorded that 0.1µl/ml essential oil of *Callistemon lanceolatus* showed 96% deterrency followed by *Lippia alba*

oil (66.8%) and 1,8-cineole (65.8%). Similarly, *R. rugosa* oil at a concentration of 50 µl/ml exhibited a high deterrent activity of 70.57% followed by *A. maritima* showing 67.15% deterrence. *R. rugosa* and *A. maritima* oil were most potent in reducing the egg hatchability to 48.00±3.2 and 49.52±2.2% at a lowest dose of 10 µl/ml whereas 81.28% egg hatching was recorded in control. *C. oppositifolia* essential oil was least toxic than the others producing a low mortality of 44.63±1.5% against eggs of *C. analis* even at a highest dose of 100 µl/ml. The ionic surfactant at concentrations of 5 and 10 µL showed 68 to 88% mortality in *C. analis* and 63 to 76% in *Sitophilus oryzae* L. respectively after 24 hours of treatment (Brari and Thakur, 2016). The oil vapours diffused into eggs and affected the physiological and biochemical process associated with embryonic development. *R. rugosa* oil at 100 µl/ml resulted in 8.08±3.5 progeny production for *C. analis* while in controls the adult emergence was 55.65±5.8. *Z. armatum* also resulted in a significant progeny reduction even at a dose of 50 µl/ml with a progeny deterrence of 67.33% for *C. analis.* In related studies *Chenopodium* and *Clausena* oils checked more than 84% of adult emergence of both bruchids *C. analis* and *C. maculatus* at different doses (Pandey *et al.,* 2011).

Abstract

Successful storage of harvest is a matter of utmost importance in the Sudano-Guinean agro-ecological zone where intense cultivation takes place only once a year. Poor and rudimentary drying/storage methods, high relative humidity as well as inaccessibility to the chemical pesticides leave stored maize at the mercy of insect and fungal attack. Insect attack favours secondary attack by fungi; both leading to a fall in the nutritional, sanitary and organoleptic qualities of the stored maize. Thus, poor peasant farmers are left with the choice of locally available botanicals as alternatives to chemical pesticides. It is against this backdrop that this study seeks to determine the insecticidal efficacy of essential oils from the leaves of *Chenopodium ambrosioides* and *Cupressus sempervirens* together with their 50/50 binary combination against the maize weevil, *Sitophilus zeamais,* and the fungi: *Rhizopus stolonifer* and *Aspergillus flavus* on stored maize. Insect mortality and progeny inhibition and the inhibition of fungal invasion were evaluated. Pesticidal activities of both essential oils increased with ascending dose of application. 200 µL/kg of the binary combination caused 100% mortality within 14 days and it completely inhibited progeny production in the weevil. The mixture of the two oils showed additive effects against the weevils and fungi. The two essential oils in isolation significantly inhibited fungal spore invasion in 21 days of storage although *A. flavus* was less susceptible than *R. stolonifer*. Therefore both plants could provide active botanical pesticides against *S. zeamais* and fungal pests in stored maize.

Key words: botanical, essential oil, fungal spore, stored maize pests, food security

1. Introduction

Sub-Saharan Africa is the most vulnerable region in the world with the average amount of food available per person per day being 1,300 calories compared to the world wide average of 2,700 calories (FAO, 2013). In 2012, maize had a yield of 70,076,591 tons in Africa (FAOSTAT, 2015). It is grown in diverse agro-ecological zones and farming systems, and consumed by people with varying food preferences and socio-economic background (Langsi *et al.,* 2017a). Cameroon with agriculture as its backbone has about 70% of its active population involved in agriculture, which contributes to about 25% of the GDP (FAO, 2008). Stored maize, especially in regions of high humidity is highly prone to attack by insect and fungal pests. High humidity and water content favour fungal growth (Pitt and Hocking, 2009). The most prolific insect is *Sitophilus zeamais* which bores holes and creates hotspots suitable for fungal growth. The fungi now produce mycotoxins thereby lowering the quality and also rendering it hazardous for consumption (Rashad *et al.*, 2013).

Plants which make excellent leads for new pesticide development (Napoleao *et al.,* 2013) could be used. Essential oils from plants generally contain chemicals which have both curative and protective potentials on stored products (Hamdani *et al.,* 2015). *Chenopodium ambrosioides* L. (Amaranthaceae) and *Cupressus sempervirens* L. (Cupressaceae) locally used as botanicals were chosen for this work. *Ch. ambrosioides* L. (Amaranthaceae) is a plant whose powders have been studied against *Sitophilus*

zeamais Motschulsky for Toxicity, oviposition suppression, ovicidal and larvicidal effects (Abiodoun *et al.,* 2010; Ntonifor *et al.,* 2011; Tapondjou *et al.,* 2002). Tapondjou *et al.* (2002) did *in-vitro* toxicity and progeny control effects using the essential oils while with *Cu. sempervirens* L. (Cupressaceae), mortality, progeny and Repellency effects have also been studied (Achiri *et al.,* 2015, Tapondjou *et al.,* 2005) on *S. zeamais* Motschulsky. Essential oils have also been proven to have antimicrobial and positive food technological potentials such as: *in-vivo* effectiveness and anti-oxidant properties of *Ocimum grattisimum*, *Lippia rugosa* and *Xylopia aethiopica* on *Aspergillus flavus* on maize fungi (Tatsadjieu *et al.,* 2010), antibacterial property of methanol, ethanol and hexane extracts (Sati *et al.,* 2015), significant antifungal activity of *Cu. Sempervirens* (Amri *et al.,* 2013).

The main objective of this work was the use of essential oils of *Ch. ambrosioides* L. and *Cu. sempervirens* L. available locally to control maize weevils (*S. zeamais* Motschulsky) and fungi (*Rhizopus stolonifer* and *Aspergillus flavus).* And specifically to evaluate their effectiveness on insect: Mortality, progeny production and fungal invasion *in-vivo* on treated maize grains.

2. Materials and methods

Insects and maize substrate

2.1. Test maize

The Acid Tolerant Population (ATP) variety of maize was collected from farmers in Big Babanki (North West Region, Cameroon) and identified in the cereals unit of the Institute of Agricultural Research for Development, IRAD, Bambui. The moisture content of maize used in bioassays was determined to be 12.669% (AFNOR, 1982). Weevils were obtained from laboratory stock cultures from the Crop Protection Laboratory of the Institute of Agricultural research for Development, IRAD, Bambui.

2.2. Collection of plant material and extraction of essential oils

Fresh green leaves of *Ch. ambrosioides* and *Cu. sempervirens* were collected from the University of Ngaoundere between December 2015 and February 2016, shade dried on laboratory benches (17.3–28.8°C), and hand crushed to get powder. The unseived powder was then packaged in black polythene bags and used for essential oil extraction.The essential oils were extracted by hydrodistillation with the help of a Clevenger apparatus and dried over anhydrous Sodium Sulphate. It yielded 0.812% (wt.wt) for *Ch. Ambrosioides* and 0.697% (wt/wt) for *Cu. Sempervirens*. Essential oils were analysed for component identification using an Agilent Technologies 6850 gas chromatograph coupled with a mass detector 5973 and a 7683B Series Injector autosampler. The essential oil was diluted with hexane which was injected in splitless mode at 200 °C. Components were separated in the oven following a temperature gradient starting from 50 °C and kept for 7 min; then raised to 300 °C (10 °C/min) and kept at this temperature for 4 min. Helium was used as carrier gas and retention indices were calculated according to Kovats, for alkanes C9-C24 compared with those reported by Adams (2007).

2.3. Bioassays

All bioassays were carried at a temperature of: 17.3–28.8°C and relative humidity: 56.3–97.8% from May to September 2016. Twenty five g of maize grains were placed in 500 mL glass jars. Aliquots of both essential oils and their 50/50 binary combination were applied to the maize grains at the following dosages 0 µL (control), 25 µL/kg, 50 µL/kg; 100 µL/kg, 200 µL/kg (diluted in 1mL acetone). All treatments were replicated 4 times. The maize-essential oil-acetone mixture was then hand shaken to permit complete coating of the maize by the essential oils and later left open for about 45 minutes on laboratory shelves to permit complete evaporation of the solvent. Afterwards, 20 adult (less than 7 days old) *S. zeamais* of mixed sex were separately added into each jar and kept on laboratory shelves. Insect mortality was recorded 1, 3, 7 and 14 days post treatment and percentage

insect mortality was corrected using the Abbott (1925) formula. All tests were carried at temperature: 17.3–28.8°C and relative humidity: 56.3–97.8%

On the 14th day post-infestation, the remaining live insects were removed and the different jars containing grains were kept under the same experimental conditions. The recording of F1 progeny was done once a week for 5 weeks commencing 6weeks post-infestation (Nukenine *et al.,* 2007). Percentage reduction in adult emergence or inhibition rate (% IR) was calculated as:

$$\%\boldsymbol{IR} = \frac{\mathbf{(Cn - Tn)x100}}{\mathbf{Cn}}$$

Where C_n is the number of newly emerged insects in the untreated (Control) jar and T_n is the number of insects in the treated jar.

2.4. Fungal invasion tests

Visibly contaminated stored maize samples surface sterilized using 2% $NaOCl_{(aq)}$ (Hocking *et al.,* 2006). Whole grains were placed directly on solidified PDA (potatoes dextrose agar: 200 g potato infusion, 20 g glucose, 15 g agar, pH of 5.6 with HCl) supplemented with Chloramphenicol (60 µg/mL) medium. The fungi were identified with the help of Domsch *et al.* (1980) manual.This involved treatment of self-contaminated maize grains with essential oils at varying concentrations and stored for a given duration. The method by Aoudou *et al*., (2012) was used. In order to homogenise the water content, the maize grains were soaked in sterile distilled water for 24 hours then dried in an oven at 45°C for 24 hours. Twenty five grams of maize grains were measured and put in 300mL glass jars on whose lids had been attached with the use of plaiting thread, 12 cm^2 Whatman no. 1 filter papers. The sealed containers containing the grains were sterilised by autoclaving at 1 atmosphere, 121°C for 15 minutes. Isolates of *Rhizopus stolonifer* and *Aspergillus flavus* were cultured on a PDA/chloramphenicol medium until the development of mature spores. With the aid of a haemocytometer, a 10^5 spores/mL suspension was prepared. In aseptic conditions, the sterile grains were inoculated with 2 mL of spore suspension (10^5spores/mL) of each fungus species. The containers were sealed and allowed at ambient conditions for three days to allow spore invasion. The filter papers were then soaked with different concentrations of essential oil (0, 20, 40, 60 and 80 µL/Kg) and sealed. Storage was maintained at ambient conditions for 30 days while growth inhibition was accessed every 7 days beginning from day 1 (Chatterjee, 1990). The percentage of contaminated grains was calculated using the formula:

$$\text{Percentage of contaminated grains } (\%\text{CG}) = \frac{\text{NCG}}{\text{TNG}} \times 100$$

Where: NCG = number of contaminated grains; TNG = total number of grains.

2.5. Statistical Analysis

Adult mortality was corrected relative to natural mortality in the controls using Abbott (1925) formula. Data on mortality and progeny production was transformed by using √(x + 0.5), then later ANOVA was done using statistical package for social sciences (SPSS) software. Tukey test (HSD) was used for mean separation for both weevil and fungal data. The dose–mortality response was analyzed by probit analysis (Finney 1971) using the maximum likelihood estimation. The co-toxicity coefficient per *Ch. ambrosioides* and *Cu. sempervirens* mixture was determined using the formula by Sun & Johnson (1960).

3. Results and Discussion

In both oils, monoterpenes hydrocarbons were predominant (Table 1). Monoterpene hydrocarbons constituted 69.2% in *Cu. sempervirens* and 79.87% in *Ch. ambrosioides*. The greatest in *Ch. ambrosioides* being 4-carene (46.32%). Only monoterpenes were found. However, in *Cu. sempervirens* monoterpene hydrocarbons predominated followed by the hydrogenated monoterpenes, the oxygenated sisqueterpenes and last by the oxygenated sisqueterpenes. Of all

the compounds identified α -pinene was the most concentrated (20.10 %) followed by β -phellandrene (6.94%). All sisqueterpenes were below 1% in concentration.

Tapondjou *et al.* (2002) instead found more elevated proportions of Cymol (50%) and terpinene (37.6%) in *Ch. ambrosioides* harvested from Mbouda in the West Region, Cameroon. We also noted the presence of lower proportions of ascaridole (0.86%) same as Rafaela *et al.* (2014) found in Brazil (0.87%) but lower than that found in samples by Ali *et al*. (2016) (Yemen) and Tapondjou *et al.* (2002).

With *Cu. Sempervirens,* Tapondjou *et al.* (2005) instead noticed the absence of cymol, the *Cupressus* essential oil also showed an elevated presence of hydrogenated monoterpenes. A similar chemical composition rich in α-pinene (27.5 to 35.8%), α-cedrol (7.7 to 19.3%), δ-3-carene (5.8 to 13.2%) was found by Amri *et al.* (2013) in Tunisia. While Mazari *et al.* (2010) in Algeria also found that the majority of the compounds found are hudrocarbon monoterpenes. Tapondjou *et al.* (2005) also found α –pinene to be the most abundant component.

The essential oils and their binary combination caused significant the mortality of adult *S. zeamais* relative to the control (Table 2). Mortality rates were generally higher for *Ch. ambrosioides* than for *Cu. Sempervirens* and the binary combination at the dosages of 50 and 100 uL/kg, irrespective of the exposure period. However, at the highest dosage level of 200 uL/kg, *Ch. ambrosioides* essential oil and the binary combination caused greater mortalities than *Cu. Sempervirens* within the first 24 hours of exposure. Only the binary combination achieved 100% mortality with 14 days of exposure at the 200 ul/kg dosage level although this was similar to the 95.83% mortality caused by *Ch. ambrosioides* essential oil. Langsi *et al.* (2017b) found 100% mortality with *Ch. Ambrosioides* and the 50:50 binary combination of *Chenopodium ambrosioides* and *Cupressus sempervirens* within 72hours of exposure.

Table 1: Chemical compositions of *Cupressus sempervirens* and *Chenopodium ambrosioides* essential oils

N°	KI	Name	Percentage (%)	
			Cu. sempervirens	*Ch. ambrosioides*
Monoterpene hydrocarbons			69.2	79.87
	935	α –Pinene	17 .59	/
	1008	3-carene	25 .91	/
	1012	4-carene	/	46.32
	1017	p-cymene	/	32 .62
Oxygenated Monoterpenes			16.95	1.55
	1260	Ascaridole	/	0.86
Sisqueterpene hydrocarbons			4.21	0.00
Oxygenated Siqueterpenes			0.7	0.00
Total			91 .34	81.42

P = 0.05 (Chi-square test). (P<0.01); ***: very highly significant (P<0.001).

The co-toxicity indices indicated that the combination of the two essential oils resulted in additive effect vis-a-vis *S. zeamais* mortality on the treated maize grains for all time-points (Table 3). With additive effects, it has been proven that combinations of insecticidal materials have the advantages to increase the efficacy by complementing the bio-efficacy of the individual products and simultaneously lowering their use on the one hand and broadening the spectrum of activity and overcoming pest resistance to individual pesticide on the other hand (Das, 2014).

Table 3: Lethal contents and co-toxicity coefficients of binary combinations on the mortality of *Sitophilus zeamais* due to treatment of maize grains with essential oils of *Chenopodium ambrosioides, Cupressus sempervirens* from Ngaoundere

Period of exposure	Product	LC_{50} (µL/kg)	Co-toxicity index	Interpretation
	Ch. ambrosioides	114.48		
1 Day	*Ch. sempervirens*	244.58	103.19	Additive
	50:50 combination	151.14		
	Ch. ambrosioides	91.15

	50:50 combination	121.51		
	Ch. ambrosioides	76.31		
7 Days	*Ch. sempervirens*	138.18	106.47	Additive
	50:50 combination	92.35		
	Ch. ambrosioides	67.60		
14 Days	*Ch. sempervirens*	121.05	116.60	Additive
	50:50 combination	74.40		

All the essential oils and their binary combination significantly inhibited progeny production. These inhibitions all increased with dose of administration (Table 4). Apart from *Cu. sempervirens* with 43%, even the lowest concentrations of all the oils inhibited progeny production by more than 50% relative to the control. The 50/50 binary combination at 200 µL/kg, completely supressed progeny production. This was followed by *Ch. ambrosioides* with 99% while *Cupressus* had 95% inhibition to progeny production.

Means ± S.E. in the same column for the same category of insecticide, followed by the same letter do not differ significantly at $P = 0.05$ (Tukey test). Each datum represents the mean of four replicates of 20 insects each. ***: very highly significant ($P<0.001$).

Percentage inhibition generally increased with dose administered. They are shown in Figures 1 (a, b and c). The 80 µL/L dose of *Ch. ambrosioides* gave 88% inhibition of *Rhizopus* growth in the first week. In all the doses administered, inhibition decreased from a maximum in 7 days to less than 10% in 21 days (Figure 1a). From Figure 1.b, it is noticed that *Cu. sempervirens* at 80 µL/L gave 55% inhibition of *Rhizopus'* spore germination and all the different concentrations dropped to zero within 21 days. The 50:50 binary combination however was more efficient than both plants used separately. Its 80 and 60 µL/L doses gave respectively 96 and 90% inhibition to *R. stolonifer* spore germination. Essential oils are very well known for their bactericidal, bacteriastatic, virucidal, fungicidal activity due to their medicinal properties against the wide range of pathogenic microorganisms (Akthar *et al.* 2014, Ambindei *et al.,* 2017). However, the spectrum of antimicrobial activity is dependent on the tested pathogens, measurement conditions and the source of the antimicrobial compounds (Turgis *et al.,* 2009).

Figures 2 (a, b and c) show the efficiency of essential oils from Ngaoundere on *Aspergillus flavus.* From the results, *Aspergillus* was more sensitive to the essential oils of both plants and their binary combination than *Rhizopus.* In figure 2.a, the 80 µL/L content gave 100% inhibition in seven days of exposure while the lower doses all gave inhibitions more than 60%. With *Cu. Sempervirens* percentage inhibition did not go beyond 65% for all the doses administered on *Aspergillus*. And all the percentage inhibitions dropped to zero within 21 days of exposure (Figure 2.b) all these results on *Aspergillus* are in agreement with those of Mahmood *et al.* (2013). With the 50:50 binary combination, percentage inhibition of 100 was gotten after 7 days with the 80 and 60 µL/L essential oil concentrations on *Aspergillus*. The percentage inhibitions dropped to zero within 21 days of exposure. This was followed by the 40 and 20 µL/L with respectively 90% and 80%. However, all inhibitions fell to zero after 21 days of exposure (Figure 2.c). The presence of phenolic compounds in the different essential oils renders them good antifungal agents. Thymol, linalool, carvacrol and eugenol are indications of an outstanding antifungal potential (Hyldgaard et al., 2012, Ambindei *et al.,* 2016, 2017)

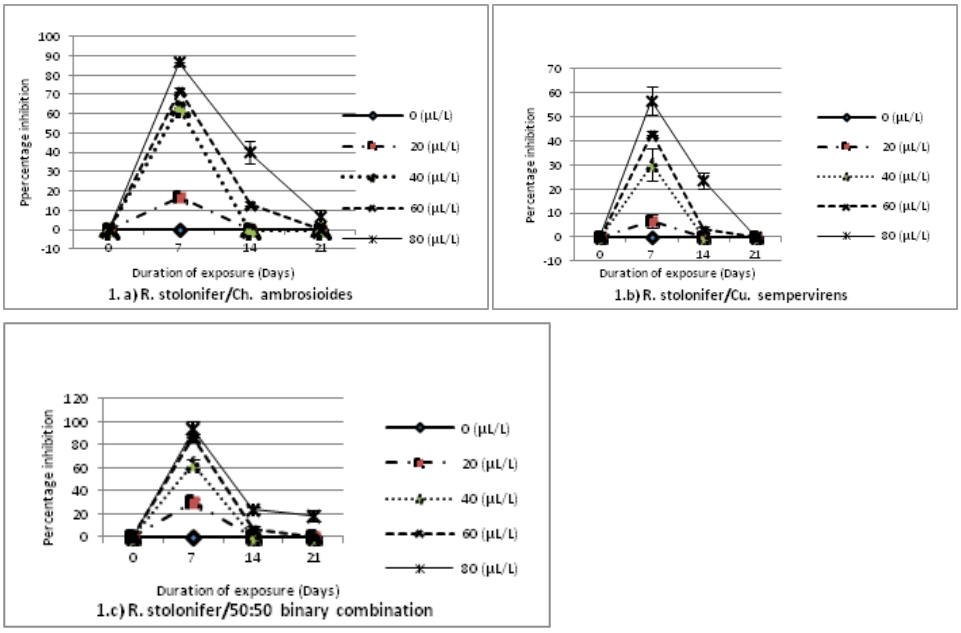

Figure 1: *In vivo* percentage inhibition of *Rhizopus stolonifer* growth on contaminated maize as a result of treatment with essential oils of *Chenopodium ambrosioides, Cupressus sempervirens* and their 50/50 binary combination from Ngaoundere.

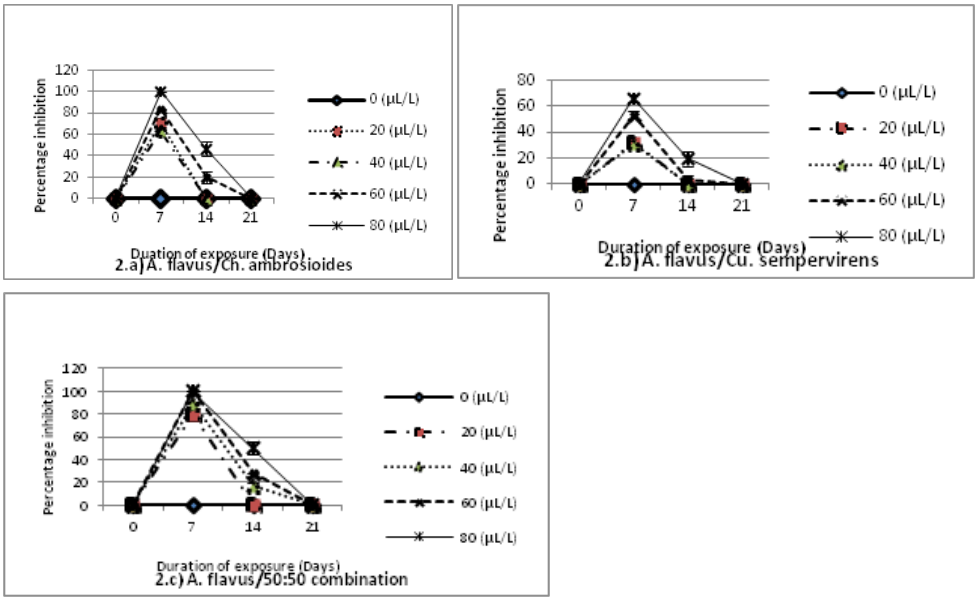

Figure 2: *In vivo* percentage inhibition of *Aspergillus flavus* growth on contaminated maize as a result of treatment with essential oils of *Chenopodium ambrosioides, Cupressus sempervirens* from Ngaoundere and their 50/50 binary combination

Both essential oils were found to be rich in α –pinene and cymol, while *Chenopodium* contains ascaridole; which are all reference fungicides and insecticides (Mazari *et al.,* 2010; Yang *et al,* 2007; Demirci *et al.,* 2007). P-cymene and p-cymeene found in both oils, on their own, are not an excellent

antifungal agent (Bagamboula *et al.,* 2004), but will boost the activities of components with functional side groups (Rattanachaikunsopon and Phumkhachorn, 2010).

Essential oils of *Ch. ambrosioides* and *Cu. sempervirens* available locally presented additive insecticidal and fungicidal efficacy against both weevils and fungi. The ability to control the proliferation of *S. zeamais, A. flavus* and *R. stolonifer* in stored maize by these essential oils is dose dependent and increases with period of exposure to the pesticide. Therefore both pesticides stand highly recommended due to their insecticidal and progeny control effects as well as their ability to inhibit fungal spore germination on stored maize.

Acknowledgement

Deep gratitude goes to the entire staff of IRAD Bambui for the provision of work space for laboratory manipulations as well as to the laboratory of Industrial Chemistry and Bio-resources of ENSAI, Ngaoundere for providing the necessary resources for the extraction of the essential oils. Some of the equipment used to carry out the research were purchased with financial assistance from the Alexander-Von-Humboldt Foundation, Bonn, Germany under grant number 3.4-B151/11016 (Equipment grant) to E.N Nukenine.

Abstract

Results of laboratory bioassays in Petri dishes on evaluation of contact toxicity of *Illicium verum*, *Artemisia absinthium* and *Abies sibirica* essential oils (EOs) against larvae of khapra beetle, *Trogoderma granarium* Ev., adults of grain weevil, *Sitophilus granarius* L., and rice weevil, *Sitophilus oryzae* L., and confused flour beetle, *Tribolium confusum* Duv., and larvae and adults of the lesser mealworm, *Tenebrio molitor* L., are presented. EOs commercial samples from retail pharmacy were tested at doses 0.01, 0.25, 0.50, 0.75 and 1.00 µl/cm^2. A treated Petri dish surface treted with acetone was used as a control. The experiment was carried out in triplicate. Mortality of insects was assessed after 1, 3, 6 and 24 hours post exposure. After exposure insects were placed into untreated Petri dishes for 3 days. The main components of the *A. absinthium* EOs are thujil alcohol (19.65%), phellandrene (16.71%), borneol (12.1%) and thujone (11.55%) was found. The major component of *I. verum* EOs was anethole (98.64%). Isobornyl acetate (57.25%), α-pinene (13.55%) and limonene (10.62%) were found as the main components of *A. sibirica* EOs. *S. oryzae* and *S. granarius* were most sensitive to each EO. *I. verum* EOs was the most effective and caused 100% mortality of each insect at the dose 0.25 µl/cm^2.

Keywords: essential oils, stored product pests, contact toxicity, *Illicium verum*, *Artemisia absinthium*, *Abies sibirica*

Introduction

Aluminium and magnesium phosphides formulations for phosphine fumigation and chemical protectants based on deltamethrin and pirimiphos-methyl for spraying are allowed for grain disinfection in Russian Federation. Regular and non-alternative application these formulations could cause development of resistance in major stored product pests (Nakakita & Winks, 1981; Mordkovich, 2003, Holloway et al., 2016) and also accumulation of pesticide residues in food commodity. Therefore, it is necessary to apply the same effective but more environmental friendly not chemical synthetic formulations for stored product protection. Essential oils (EOs) could be used as alternative formulation for management of stored product pests.

Materials and Methods

Test Insects

The insects used in bioassays were adults of *S. granaries*, *S. oryzae*, *T. confusum*, larvae and adults of *T. molitor* and larvae of *T. granarium*. *S. granaries* and *S. oryzae* were reared on *Triticum aestivum* whole grain in 25±1°C and 70±5% relative humidity (r.h.). *T. confusum* and *T. granarium* were reared on *T. aestivum* crushed grain in 27±1°C and 70±5% r.h. *T. molitor* was reared on *T. aestivum* crushed grain with *Zea mays* whole corn grain in 25±1°C and 70±5% r.h. The rearing conditions were darkness.

Essential oils and GC/MS spectrometry analysis

Commercial samples of *I. verum*, *A. absinthium* and *A. sibirica* EOs from retail pharmacy were tested. The obtained oils were subjected to GC/MS analysis using an Agilent 7890A gas chromatograph (Agilent Technologies, USA) equipped with a Agilent 5975C mass spectrometer, fitted with a DB17MS capillary column (30 m × 0.25 mm; 0.25 µm film thickness). Temperature was kept at 50 °C for 2 min and programmed to reach 200 °C (a rate of 10 °C/min), then to reach 260 °C (a rate of 20 °C/min) and held at this temperature for 4 min. Helium was used as the carrier gas at the rate of 1.18 mL/min. The samples were injected at the injector temperature of 240 °C.

Experimental procedure

A direct contact application assay (Qi and Burkholder, 1981; Broussalis et al., 1999) was used to evaluate the insecticidal activity of the tested essential oils. Five concentrations (640, $16{\cdot}10^3$, $32{\cdot}10^3$, $48{\cdot}10^3$ and $64{\cdot}10^3$ ppm) of each EO were prepared using acetone as a solvent. Aliquots of 1 ml of each concentration correspond to the respective 0.01, 0.25, 0.50, 0.75 and 1.00 µl/cm^2 were placed on the surface of Petri dish (9 cm diameter, ~ 64 cm^2). After evaporation of the solvent, 20 adults of *S. granaries*, *S. oryzae*, *T. confusum* and 20 larvae of *T. granarium* and 10 adults and larvae of *T. molitor* were separately introduced on the treated Petri dish's surface. The experiment was carried out in 25±1°C and 70±5% r.h. and a photoperiod of 10/14 L/D during the entire period. Control sets were made, where the same number of insects were placed in Petri dishes with surface treated with acetone only. The experiment was carried out in triplicate. The mortality was assessed after 1, 3, 6, and 24 hours (h) of exposure under a Zeiss stereomicroscope (Stemi-2000, Carl Zeiss Microscopy GmbH, Germany). Then, after exposure, insects were moved to untreated Petri dishes and were hold there during 3 days. The viability of insects was estimated every day during this period. The data were subject to a two-way ANOVA. A 5% probability level was used for individual pairwise comparisons by the made Tukey-Kramer's HSD test.

Results

Chemical composition of the test oils

Data of the chemical composition analysis (Table 1) revealed that the *A. absinthium* EO contains, mainly thujil alcohol (19.65%), phellandrene (16.71%), borneol (12.1%) and thujone (11.55%).

Isobornyl acetate (57.25%), α-pinene (13.55%) and limonene (10.62%) were found as the main components of *A. sibirica* EO, while anethole (98.64%) was the main compound in the essential oil of *I. verum*.

Total, %	-	98,17	100	98,62

Contact Activity

Results show (Tables 2-4) that the test essential oils showed variant degrees of toxicity, where the *I. verum* EOs was the most toxic, followed by *A. absinthium* and *A. sibirica*. Essential oil of *I. verum* at the dose 0.25 µl/cm^2 caused 100% mortality of *S. oryzae* and *T. confusum* and also significant mortality (96,7%) of *S. granaries* after 24 h exposure. In addition, the total mortality of adults and larvae of *T. molitor* were found on 1 and 3 days during post-exposure period. *Trogoderma granarium* larvae were also sensitive to *I. verum* at the dose 0.25 µl/cm^2, where percentage of killed insects 98% was recorded on third day during post-exposure period. Essential oil of *A. absinthium* was the less toxic, where 100% mortality of tested pests were found after application at the dose 0.5 µl/cm^2. *A. sibirica* displayed the least contact activity. In this case, total mortality of insects was found to the dose 0,75 µl/cm^2. *S. oryzae* and *S. granarius* were the most sensitive to each tested essential oil. Larvae of *T. molitor* were the most resistance to *A. absinthium* and *A. sibirica* EOs. Larvae of *T. granarium* were the most resistance to *I.verum* EO.

Tab. 2 Mean ±SE mortality (%) of insects exposed to *A. absinthium* EO at different doses after 24 h exposure. For all Tables, means within columns followed by different lower-case letters represent significant differences between doses, means followed by capital letters represent significant differences between species ($P < 0.05$).

Discussion

The composition of tested *I. verum* and *A. sibirica* essential oils in the present study showed a similarity to that reported in the literature (Tuan and Ilangantileke, 1997; Singh et al., 2006; Matsubara et al., 2011). For example, according to Singh et al. (2006), major component of *I. verum* EOs was trans-anethole (85-90%). Some differences were observed in the composition and abundant compounds of *A. absinthium* EO (Lawrence, 2006; Gandomi Nasrabadi et al., 2012). For example, myrcene (21.5 %), thujyl alcohol (18.9 %), sabinene (17.3 %), α-thujone (7.4 %) and camphor (5.5 %) were found to be the main components in *A. absinthium* essential oil growing in Russia (Lawrence, 2006). These differences in essential oil compositions might arise from several environmental (climatical, seasonal, geographical) or genetic differences and different chemotypes and the nutritional status and the extracted part of the plant.

Acknowledgement

I would like to thank Department of Pheromone Synthesis and Applications, All-Russian Plant Quarantine Center (Bykovo, Moscow region, Russia) for the help in analyzing the compound composition of tested essential oils.

Abstract

Fumigant toxicity of insecticidal principles extracted from tuber rind, fresh leaf, fresh leaf with petiole, and dried leaf of cassava (var. M4) was studied against four major stored-product insect pests *viz. Sitophilus oryzae (*L.*)*, *Rhyzopertha dominica* (F.*)*, *Tribolium castaneum* (Herbst) and *Callosobruchus chinensis* (L.) under laboratory conditions (28±2ºC, Rh. 75±5%). Mortality of the test insects varied with respect to extracts collected from different parts of the plant, and time of exposure. Extract collected from cassava rind recorded the highest toxicity. *Callosobruchus chinensis* was highly susceptible and showed immediate knockdown effect to the active principles extracted from tuber rind, fresh leaf, fresh leaf with petiole, twig and semi-dried leaf. The extract collected from various parts of plant caused 100% mortality of *R. dominica* at 1 hour after treatment (HAT), but the same collected from tuber and dried leaves did not show any toxic effect. Mortality of *S. oryzae* was 100% at 1 HAT with tuber rind extract, but no response was observed from the extract collected from semi-dried leaf, twig, and leaf with petiole. No fumigant action was observed in all the four coleopteran pests exposed to the extract collected from dried leaves. The study revealed that fresh leaf and tuber rind are good sources for the extraction of biofumigant against major coleopteran pests, however dried leaves are unfit for same purpose.

Key words: Cassava, extracts, Sitophilus oryzae, Rhyzopertha dominica, Tribolium castaneum, Callosobruchus chinensis.

Introduction

Insect pest infestation is a major problem in the storage of cereals and pulses. Realising the fact that indiscriminate application of synthetic pesticides has created major challenges to man and ecosystem, there is a global concern to contain pests using non-chemical methods, particularly to lessen the pesticide residues in food (Flinn and Hagstrum, 2001). Fumigation is an effective method to protect stored-products from insect infestation. The commonly used fumigant like aluminium phosphide, ethylene dibromide and methyl bromide are associated with health and environmental pollution, and also many of the stored- product pests have developed resistance against synthetic fumigants (Zettler, 1982). Phillips et al. (2001) opined that exposure to low or sublethal doses pose an increased risk in phosphine resistance. Opit et al. (2012) reported high levels of resistance in several strains of major storage pests to phosphine in the USA.

The use of natural compounds in place of synthetic insecticides is an alternative strategy to reduce environmental pollution, and to preserve non-target organisms. Phytochemicals have been suggested as the alternatives to synthetic insecticides as they are the storehouse of a wide range of bioactive chemicals (Wink, 1993). Plant products are inexpensive products for the management of stored-grain pests (Mishra et al., 2012b), and are potentially suitable as vital components in integrated pest management strategies (Saxena, 1989; Schmutterer, 1992). The insecticidal activity of many plant derivatives against several stored-product pests has been demonstrated (Malik and Mujtabe Naqvi, 1984; Singh, S. 2017).

Cassava (*Manihot esculenta* Crantz), originally from Amazonia, is a woody shrub extensively cultivated as an annual crop in tropical and subtropical regions that provides the staple food of an estimated 800 million people worldwide. Although the leaves of cassava are rich in proteins, minerals, and vitamins, the presence of antinutrients and cyanogenic glucosides are the major drawbacks to human consumption. However, cyanogen can play a pivotal role in pest management.

Desmarchelier and Ren (1996) has patented cyanogen as a fumigant to replace methyl bromide in a variety of applications. Being a good source of cyanogen, cassava was used for the isolation of insecticidal molecules for the development of a fumigant against the stored-product pests.

Materials and Methods

Insects

Colonies of four beetle species were reared under laboratory conditions (Temp. 28±2ºC; Light and Dark photo period 12:12). *Sitophilus oryzae*, *Tribolium castaneum* and *Rhyzopertha dominica* were reared on whole grain wheat, and *Callosobruchus chinensis* was reared on cowpea seeds in plastic containers (100 g capacity).

Sample preparation

Twigs, leaves, leaves with petiole, semi-dried and dried leaves, tuber flesh and tuber rinds of cassava variety, M4, were collected from the experimental field of ICAR-Central Tuber Crops Research Institute, Thiruvananthapuram, India for the isolation of insecticidal molecules. Each sample (200 g) was macerated and distilled in 500 ml of distilled water. The distillates were collected 25 ml each, and thus four fractions were collected for bioassay on the selected four weevil species.

Bioassays

The bioassay revealed that first fraction of the extract was highly toxic to the four species of weevils exposed; hence this fraction was used for the subsequent toxicity study. Plastic tubes of 3 ml capacity were loosely impregnated with cotton and each tube was separately loaded with 1 ml of the extract. The tubes were perforated around with a needle to ensure the dissipation of biofumigant. The tubes were introduced separately into plastic containers of 250 ml capacity wherein the test insects were released. Cotton impregnated with distilled water was run as control. To retain the biofumigant within the experimental containers, these were closed airtight. All the treatments were replicated three times. Mortality of *S. oryzae*, *R. dominica* and *T. castaneum* was recorded at 1, 2 and 12 hours after treatment (HAT), whereas *C. chinensis* was observed at 2, 3 and 5 minutes after treatment as these are highly susceptible to the fumigant.

Statistical analysis

The percentage of mortality was determined and transformed to arcsine values for analysis of variance (ANOVA) using SAS (version 9.3). Treatment means were compared using least significance difference (LSD) at $p < 0.05$ level of significance. .

Results

The extracts collected from cassava tuber rind, fresh leaf, fresh leaf with petiole, twig and semi-dried leaf were highly toxic to *R. dominica* (Table 1). Mortality of *R. dominica* was 100% at 1 HAT in all the treatments, except with dried leaf. The extract collected from cassava tuber flesh was significantly less toxic to *R. dominica* than all other treatments. No mortality was observed in the control and treatment with dried leaf extract.

Mortality of *S. oryzae* at 1 HAT was 100% due to the treatment of extract collected from tuber rind, but there was no difference in the rate of mortality between the extracts of fresh leaf and semi-dried leaf. In all the treatments, except tuber flesh and dried leaf extracts, over 70% mortality of *S. oryzae* was noticed, however no mortality was observed with the treatments of extracts collected from tuber flesh and dried leaf.

The extracts collected from tuber rind and from semi-dried leaf were shown significantly higher toxicity to *T. castaneum* than the other treatments (Table 2). Mortality of *T. castaneum* was 100% at 1 HAT due to the treatment with tuber rind extract. The extract of semi-dried leaf recorded higher toxicity than fresh leaf with petiole, and twig extracts. In all the treatments, except the extracts of tuber flesh and dried leaf, 100% mortality was observed at 12 HAT

Preliminary study revealed that *C. chinensis* was highly susceptible to the bioactive components extracted from cassava, hence the mortality was observed at 2, 3 and 5 minutes after treatment. Immediate knockdown effect of the test insect was noticed due to the treatment with the extracts of tuber rind, and semi-dried leaf. Except the extract from tuber flesh and dried leaf, higher mortality was also observed in all other treatments.

Table 2. Mortality of *Tribolium castaneum* and *Callosobruchus chinensis* due to the fumigant action of cassava extract

Discussion

The use of chemical fumigants for the management of stored-product pests is highly discouraged due to multiple reasons. Aulicky and Stejskal (2018) reported that although fumigation with phosphine proves satisfactory control of major stored-product pests, its effect sharply declines with the increasing distance from the fumigated spot. In the present investigation, the extracts collected from different parts of cassava was found toxic to *R. dominica*, *S. oryzae*, *T. castaneum* and the toxicity was extremely high as in the case of *C. chinensis.* Cassava tuber rind extract recorded the highest toxicity among the extracts from other parts of the plant. Burns et al. (2012) observed that concentration of cyanide in the tuber rind was much higher than that of the tuber parenchyma and leaves. Aggarwal et al. (2001) reported the fumigant action of essential oil from *Artemisia annwa* against *C. maculatus*, *R. dominica* and *S. oryzae*. Fumigant action of extracts collected from semi-dried leaf was significantly higher than that of fresh leaf; this may be due to the increase in concentration of active principles in leaf due to the loss of water during slow drying. The extract collected from fully dried leaves did not show any toxicity to all the test insects, which is a clear indication that the active principles are fumigant in nature. Plant extracts and essential oils are

known to possess insecticidal, ovicidal and repellent activities against various stored-product insects (Desmarchelier, 1994: Shaaya et al., 1997). El- Nahal et al., (1989) reported that adults of *C. chinensis*, *S. granarius*, *S. oryzae* were susceptible to the essential oil from *Acorus calamus,* but *T. castaneum* and *R. dominica* were tolerant to all doses and exposure time. They also reported that the exposure period is the most important factor affecting the efficiency of the vapours than dosage. Leaf, bark and seed extracts of *Aphanamixis polystachya* have been reported to exert repellent and insecticidal effects against *C. chinensis* (Talukder and Howse, 1994). Several natural products including principles from many spices, herbs and medicinal plants are known to have a range of useful biological properties against insects (Tripathi et al., 1999a, b). Insecticidal activity of *Cinnamomum* cassia bark, *Illicium verum* fruit and *Foeniculum vulgare* fruit was reported by Kim et al., (2003).

Although phytochemicals are reported to have very good insecticidal action against stored-product pests, poor extractability and cumbersome techniques in the isolation of active principles are the bottlenecks in its commercial availability in the markets. In the present study, cassava bio-wastes, which are either underutilized or thrown as waste, are promising source for the extraction of biofumigant.

ABSTRACT

In present investigation, toxic, repellent, antifeedent and growth inhibition effects of five different plant extracts: *Melia azedarach, Pegnum hermala, Salsola baryosma, Azadirachta indica* and *Zingiber officinale*, were evaluated on different life stages of *T. castaneum*. The highest mortality (10.14%) was observed with *A. indica* and the minimum mortality (0.67%) was invoked by *Z. officinale* treatment. Similarly, *A. indica* showed highest repellent effect compared to rest of the plants. Feeding deterrence was highest (90.15%) with *S. baryosma* treatment, followed by *P. hermala* (84.85%), *M. azedarach* (80.19%), *A. indica* (73.48%) and *Z. officinale* (57.58%). The extracts inhibited the growth of *T. castaneum*. Inthe case of *A. indica,* the lowest numbers of larvae (32.67), pupae (16.33) and adults (11.33) emerged at 15% concentration, while the highest emergence of larvae (80.33), pupae (75.00) and adult (71.00) were observed for *Z. officinale*. The other three plant extracts had moderate regrowth inhibition on the beetle. Overall, *A. indica* extract was found to be the most effective while, *Z. officinale* extract was least effective against the beetle. This study can be very helpful in future when the use of plant extracts become common and available to the farmers as an alternative to synthetic pesticides.

Key words: Mortality, repellency, antifeedant effect, growth inhibition, plant extracts, *T. castaneum*

Introduction

Food security is an emerging threat to world's expanding population. Stored grain insect pests are severely damaging our valuable products like wheat. These stored grain pests are responsible for about 10% loss of cereals all over the world (Danahaye *et al*., 2007). According to Matthews, (1993) 10-40% losses per annum have been estimated globally due to the infestation of these insects. These losses can reach 9% in developed and up to 20% in the developing countries throughout the world (Phillips and Throne, 2010).

Among the stored product insect pests, *T. castaneum* is the pest of economic importance throughout the world which cause serious damage to stored products (Arbogast, 1991). It is one of the major pests of wheat flour (Howe, 1965). Both larvae and pupae are responsible for the losses. In case of severe destruction, flour may be converted into greyish and moldy produce with pungent off-smell. Thus, the commodity becomes unfit for human use (Atwal and Dhaliwal, 2002). It can cause economic loss of 40% of wheat flour (Ajayi and Rahman, 2006).

Widespread and indiscriminate use of pesticides is posing a serious threat to the environment and human health (Subramanyam and Hagstrum, 1996). Consequently, the use of biopesticide for the control of stored commodity pests has received considerable attention throughout the world (Faraz

et al., 2015). Bio pesticides have potential to replace the use of conventional insecticides (Regnault-Roger *et al*., 2002). Plant extracts contain several compounds which are responsible for the control of insect pests of stored grain (Rahman and Schmidt, 1999). Several plant derivatives have been investigated to have mortality effect on stored product pests (Mukherjee and Joseph, 2000) and a number of plants of Pakistan have been known for their repellency to stored grain pests (Verma *et al.,* 2000). Some of the plants show repellency and growth inhibition effects (Kanvil *et al*., 2006).The five plants which were tested in this research are abundantly available and possess numerous medicinal properties (Iqbal *et al*., 2010). *Azadirachta indica* and *M. azedarach* are two closely related species of Meliaceae and are known in India and Pakistan for more than 2000 years. It is best known to have various medicinal properties including toxic and repellent effect. *Melia azedarach* (dhrek) has been found to have insecticidal, antifeedant, growth regulatory activities (Nakatani *et al*., 2004; Al-Rubae, 2009). They contain azadirachtin, meliacarpinin, bakayanin and triterpenoids (Vishnukanta, 2008). The pharmacological effects of *Pegnum hermala* are found to be due to the presence of alkaloids which include: β-carboline, harmine, harmaline, harmalol, harman, peganine, dipeganine, isopeganine, deoxypeganine and quinazol (Fathizad *et al*., 2007; Asgarpanah and Ramezanloo, 2012). *Zingiber officinale* (ginger) has beautiful fragrance and bitter taste (Jean, 1995). The compounds which are responsible for bitter taste are gingerol, zingiberene, zingerone and shogaol. Kaempferol and quercetin are the flavonoids that are present in the various parts of *Salsola baryosma*(khar booti) (Kaur and Bains, 2012).

The current study was conducted to assess the toxicity repellency, the antifeedent behavior and the growth inhibitory action of five different plant extracts namely *Azadirachta indica, Melia azedarach, Pegnum hermala, Salsola baryosma* and *Zingiber officinale*) against *T. castaneum* using acetone as solvent.

Materials and Methods

Collection and Rearing of Insects

The heterogeneous population (larvae and adults) of *Tribolium castaneum* was collected from grain market, poultry litter and stores of Rehman Farms and J. K. Agricultural Farms located at Faisalabad District, Punjab, Pakistan. The insects were reared in plastic jars (1.5 kg capacity) containing wheat flour which had been sterilized at 65^{0}C for 30 minutes before putting into rearing jars. In the rearing jars, 50 adults of *T. castaneum* were released on wheat flour. After 5 days the parent adults were removed from the rearing jars and culture medium containing eggs of the beetles were kept in incubator (Sanyo M.I.R 254) at optimum conditions (30±2°C and 65±5% r.h.) for getting homogenous population.

Collection and Preparation of Plant Materials

Fresh leaves of Dhrek, *Melia azedarach,* and Neem, *Azadirachta indica, s*eeds of Hermal, *Pegnum hermala,* stem of Khar booti, *Salsola barysoma* and rhizome of Ginger, *Zingiber officinale* were collected from different farms and fields located at District Faisalabad. The different plant parts were washed and after drying in shade for 5 days the leaves, seeds, stems and rhizomes were ground using electric grinder (Pascall Mortar grinder, Machine no. 20069) into fine powder. The powder was used to prepare extract using acetone as a solvent. In 250 ml flask, 50 gram of plant powder was soaked in 100 ml of acetone. The flasks were placed on rotary shaker at 220rpm for 24hr and then filtered. The filtrate thus obtained was used to make different concentrations for the various experiments. Three concentrations (5, 10 and 15%) of plant extracts were prepared in acetone (solvent). To make 5% solution, 5 ml of stock solution was added to 95 ml acetone and for 10% solution 10ml stock solution was added to 90 ml acetone and for 15% solution 15 ml stock solution was added t0 85 ml acetone.

Toxicity and Progeny Emergence of Plant Extracts

The diet incorporation method was used to estimate the efficacy of the different plant extracts in terms of beetle mortality and growth inhibition. The three concentrations of plant extracts were applied to 100 g of wheat flour along with an untreated check. About 30 adults of *T. castaneum* were put into the vials and the treatments were replicated three times using Completely Randomized Design. The mortality of the beetles was recorded after 24, 48 and 72 hrs. The survivors of *T. castaneum* from the above experiment were released on fresh wheat grains to determine progeny emergence. The number of beetles that emerged was recorded after 30 and 60 days. Corrected mortality was calculated using Abbot's formula given below:

$$\text{Corrected Mortality (\%)} = (Mo-Mc)/(100-Mc) \times 100$$

Where, Mo = observed mortality

Mc = control mortality

Percent inhibition rate of progeny was calculated using following formula:

$$\text{Percent Inhibition Rate (\%)} = (Cn-Tn)/Cn \times 100$$

Where, Cn = no. of progeny in control jars

Tn = no. of progeny in treated jars

Repellent Effect of Plant Extracts

The repellent effect was determined using area preference method. After cutting the filter papers into two equal halves, one half of each paper was treated with plant extracts. After evaporation of excess solvent, the two halves were joined together and placed in petri dishes. 50 adults of *T. castaneum* were released in the center of treated filter papers. Repellency was recorded after 12, 24 and 48 hrs.

Percent repellency was calculated following the formula used by Guruprasad and Pasha (2014).

$$\text{Percent Repellency (\%)} = (Nc-Nt)/(Nc+Nt) \times 100$$

Where, Nc = No. of insects in control half

Nt = No. of insects in treated half

Antifeedant Effect of Plant Extract

The jars containing 20 g of treated grains were kept in open environment for 24 hrs in order to allow the excess acetone to evaporate. After 24 hrs, thirty insects were released in each jar. The jars were weighed to take the initial reading. After 7, 14 and 21 days' interval the weight loss was recorded to check the antifeedant effect of the extracts.

$$\text{Feeding Deterrence Index (\%)} = ((C-T))/((C+T)) \times 100$$

Where, C = food consumed in control jars

T = food consumed in treated jars

Growth Inhibitory effect of Plant Extracts

Thirty adults of mixed sexes of *T. castaneum* were released into the jars containing wheat flour treated with the different concentrations of the five plant extracts. The number of larvae emergence, pupae transformation and adult emergence was recorded after 15 days for larvae, 25 days for pupae and 40 days for adult.

Statistical Analysis

Data were subjected to Analysis of Variance using STATISTICA 6.0 as one factor complete randomized design. Means were compared using Tukey's HSD test at 0.05 probability level, to check the significant difference among treatments.

Results

Toxicity of Plant Extracts against *Tribolium castaneum*

In general, all the extracts showed low toxicity to *T. castaneum* as the highest percent mortality of 10.14% was recorded in the diet treated with extract of *A. indica* (Table 1). In all the diets treated with each of the five plant extracts, percent mortality was time and dose dependent as it increased with the increase in concentration and exposure time (Table 1). In diets treated with the extracts of *A. indica, M. azedarach*, *S. baryosma*, *P. hermala* and *Z. officinale,* percent mortality ranged from 1.33-10.14%, 1.33-9.46%, 0.00-8.79%, 0.00-6.76% and 0-6.08%, respectively (Table 1). For example, in diets treated with the extract of *A. indica*, the highest mortality 10.14% was recorded at maximum concentration of 15% after 72hrs while the lowest mortality of 1.33% was recorded at 5% after 24 hrs of exposure time.

Repellency of Plant Extracts against *Tribolium castaneum*

All the plant extracts were highly repellent to *T. castaneum* and repellency was dose and time dependent as it increased with the increase in concentration and exposure time. (Table 1). Percent repellency ranging from 50.67-89.33%, 56.00-85.33%, 58.67-89.67%, 60.00-89.33% and 56.00-82.67% were recorded in diets treated with the extracts of *A. indica. M. azedarach*, *P. hermala. S. baryosma* and *Z. officinale*, respectively. (Table 2). The highest percent repellency of 89.67% was invoked by the extract of *P. hermala* and the lowest by *M. azedarach* at the highest concentration of 15% and 48 hours exposure time (Table 2).

Progeny Inhibition and Feeding Deterrence Effect of Plant Extracts against *Tribolium castaneum*

Both percent inhibition and feeding deterrence were time and dose dependent as they increased with the increase in concentration and exposure time (Tables 3 & 4). Percent inhibition ranging from 59.08-89.70%, 52.30-81.62%, 48.36-79.10%, 3.76-75.15% and 49.80-80.06% were recorded in diets treated with the extracts of *A. indica. M. azedarach*, *S. baryosma, P. hermala.*and *Z. officinale*, respectively. (Table 3). The highest percent inhibition of 89.70% was recorded at the highest *A. indica* extract concentration of 15% after 60days and the lowest percent inhibition of 75.15% was invoked by the extract of *P. hermala.*

Similarly, percent feeding deterrence effect ranged from 51.45-73.48%, 53.31-85.61%, 66.39%-90.15%, 43.98-84.85% and 25.30-57.58% in diets treated with extracts of *A. indica. M. azedarach*, *S. baryosma, P. hermala.*and *Z. officinale*, respectively. (Table 4). The highest percent feeding deterrence of 90.15%) was recorded at the highest concentration of 15% of *S. baryosma* after maximum exposure period of 21days and the lowest percent deterrence of 57.58% was recorded in diets treated with the same concentration and exposure period (Table 4).

The results depict that the highest inhibition of larvae, pupae and adults was observed at the highest concentration of 15% (Table 5). The highest number of larvae (111.00) emerged in control treatment. Lower numbers of larvae (32.67, 38.00, 52.67, 57.33 and 71.67) emerged in diets treated with *A. indica,M. azedarach, S. baryosma, P. hermala and Z. officinale,* respectively (Table 5). Similarly, lower numbers of pupae (16.33, 14.67, 32.67, 39.00 and 57.33) emerged in diets treated with *A. indica M. azedarach, S. baryosma, P. hermala* and *Z. officinale* respectively compared with control in which 110 pupae emerged (Table 5). In the case of adults the highest number (110 adults) emerged in the control treatment compared with lower number of adults (11.33, 10.67, 26.00, 32.00 and 47.33) that emerged in diets treated with extracts of *A. indica, M. azedarach, S. baryosma, P. hermala* and *Z. officinale* respectively (Table 5).

Discussion

The plant products have growth regulatory effects on different pests particularly red flour beetle, *T. castaneum* (Joseph *et al.,* 1994; Haque *et al.,* 2000).The most effective plant was *A. indica* in our study. It is known that *A. indica* contains bioactive compounds like azedarachtin. This compound affects the growth behavior and reproduction of stored grain insect pests (Pascual *et al*., 1990; Mordue (Luntz) and Blackwell, 1993; Singh, 1993). *A. indica* interrupts the normal development of larvae and adults as well as metamorphosis of insects (Koul *et al*., 1987). *A. indica* also significantly reduces the emergence of adults of *T. castaneum* and weight of the adults (Anonymous, 1992). The emergence of larvae, pupae and adults is affected by the change in dose rate of the plant extracts (Sagheer *et al*., 2011). Reduced growth of the *T. castaneum* was observed with the use of different plants including *P. heramala* (Jbilou and Sayah, 2006). *Melia azedarach* has been found to have insecticidal, antifeedant, growth regulatory activities (Nakatani *et al*., 2004; Al-Rubae, 2009)

In our study, all the plant extracts showed very low toxicity against *T. castaneum*. According to Fang *et al*. (2002) *Tribolium* sp. are the most tolerant among all stored grain insect pests so they are more difficult to control. Plant extracts contain several compounds which are responsible for the control of insects (Rahman and Schmidt, 1999). Several plant derivatives have been investigated to have mortality effect on stored product pests (Su, 1990; Desmarchelier, 1994; Schmutterer, 1995; Mukherjee and Joseph, 2000). Plant extracts reduce the release of phosphate ions for the production of energy during transphosphorylation reactions (Senthil-Nathan *et al*., 2004; Senthil-Nathan *et al.,* 2006). Anita *et al*. (2012) reported the dose-dependent insecticidal activity of *Eucalyptus globulus* against *T. castaneum*.

In the present study, neem extract was proved most effective in term of mortality. Neem possesses toxic effect against *T. castaneum* (Ahmed *et al.,* 2000). Many compounds in neem have been reported for their toxic effects the most potent is azadirachtin (Mordue and Blackwell, 1993; Lin-er *et al*., 1995). As a polyphagous pest, *T. castaneum* has been controlled successfully by the use of different insecticides (Okonkwo and Okoye, 1996; Islam and Talukdar, 2005). However, this pest have developed resistance against these pesticides (Guedes *et al*., 1997). Some plants have toxic effect against *T. castaneum* (Tripathi *et al*., 2000). The efficacy of neem against insect pests varies with the change in the storage atmospheres and storage period. Reduced activity of neem as a bio pesticide has been reported when it was stored in sun. Hence, the bioactivity of neem was higher when it was stored for two weeks than when it was stored for 4-6 weeks (El Shafie and Almahy, 2012). The activity of the neem increased 10 times at low temperature (Kabaru and Mwangi, 2000). To use the plant extracts as bio pesticides, farmers should be well aware of its production as well as application (Hellpap and Dreyer, 1995).

A number of plants of Pakistan have been known for their repellency against grain pests (Jilani *et al*., 1991, 1993; 2000; Verma *et al.,* 2000). Few plants show repellency and growth inhibition effects (Kanvil *et al*., 2006). Neem possesses repellent, antifeedant, oviposition inhibition and deterrent effects (Lale and Abdulrahman, 1999; Weathersbee and Tang, 2002; Liang *et al*., 2003; Hou *et al*., 2004). Jilani *et al*., (1984) reported the repellent effects of 30 plant extracts including *P. harmala* against *T. castaneum*. Diwivedi and Kumari (2000) reported the repellent action of different plant extracts prepared in acetone and petroleum solvents against *C. chinensis*.

Trematerra and Sciarretta (2002) reported that the mortality of the insects by plant extracts is due to its repellent and feeding deterrent effects. They also reported that the alkaloids present in the plants affect the chemoreceptors of insects thus inhibiting food consumption. Azadirachtin excites the deterrent cells of chemoreceptors and inhibits the sugar receptors thereby preventing the insects from feeding (Mordue-Luntz *et al*., 1995).

Neem also significantly reduce the emergence of adults of *T. castaneum* and weight of the adults (Anonymous, 1992). The emergence of larvae, pupae and adults is affected by the change in dose rate of the plant extracts (Sagheer *et al*., 2011). Reduced growth of the *T. castaneum* was observed with the use of different plants including *P. heramala* (Jbilou and Sayah, 2006).

The results of the study has shown that plant extracts can be used as a component of an IPM strategy for the control of insects both in the crops growing in the field and stored commodities. The use of plants as an insect control strategy can be a better substitute to synthetic insecticides.

Abstract

Rind of matured fruits of *Citrus jambhiri* Lush was hydro-distilled to obtain essential oil (EO) which was subjected to Gas chromatography-Mass spectrometry (GC-MS) analysis. The EO was evaluated for fumigant toxicity (at 27-107µL/L air) and repellence against maize weevil (*Sitophilus zeamais* Motschulsky). Area preference methodology was used to evaluate the repellence of the EO at 0.15-0.9 µL/cm^2, while isopropanol served as control for both bioassays. The experiments were set up in a completely randomized design and data were subjected to analysis of variance and probit analysis. Fifty-two compounds were identified in the EO with the

predominant compounds being α-terpineol (8.03%), citral (7.00%), 4-terpineol (6.52%), caryophellene (4.58%), cis-geraniol (4.44%), citronellal (4.38%), β-bisabolene (4.01%) and n-hexadecanoic acid (4.70%). Others were α-bergamotene (3.74%), lemonol (3.23%), precocene I (3.33%) and β-copaene (3.09%). Toxicity progressed with EO dose and exposure period and application of EO at 80 and 107µL/L air caused significantly higher mortality (33.75-100.00%) than isopropanol (0.00-22.50%). Lethal time for 50% assayed weevil (LT_{50}) for the EO application at 107 µL/L air {7.51 (6.95-8.13) h} was significantly lower than the values obtained for 27 and 53 µL/L air {44.78 (27.49-312.61) and 21.87 (11.91-45.96) h, respectively}. EO caused significantly higher repellence (75.00-90.00%) than control (15.00%) at 24 hours after treatment. The results indicate that *C. jambhiri* rind EO has prospects as effective biorational formulation for control of maize weevil.

Keywords: *Citrus jambhiri,* Essential oil, Fumigant toxicity, GC-MS, Lethal time, Maize weevil

1. Introduction

Maize weevil (*Sitophilus zeamais* Motschulsky 1855) (Coleoptera: Curculionidae) is a cosmopolitan tropical postharvest pest attacking cereals, processed tubers and their products (Haines, 1990; Babarinde et al., 2008, 2013). Its infestation can cause quantitative loss like weight reduction, or qualitative losses like reduction oF aesthetic/market value, nutritional values and loss of seed germination ability, especially when weevils feed on the seed's embryo. Its control with synthetic chemicals, although very effective, can cause several economic, ecological and health risks (Arthur, 1996); hence the need for bio-rational control options for the pest. Several formulations of botanicals had been studied (Dales, 1986), but essentials oils (EOs) are receiving renewed attention due to the fact that they are effective at low concentrations, even without direct contact with the target organisms (Babarinde *et al*., 2015). Due to the multiple bioactive compounds present in EOs and their multiple sites and modes of action, the tendency for a pest to develop resistance against EOs is comparatively low (Venkitanarayanan *et al.,* 2013)

Several authors have worked on different *Citrus* species as protectants of stored produce against postharvest pests (Don-Pedro, 1996; Dutra *et al*., 2016; Fouad and Camara, 2017; Lu, 2017; Oboh *et al*., 2017). The need to convert agricultural waste product into useful by-products is a major concern in many developing countries. This is primarily because of poor waste management practices peculiar to the region. *C. jambhiri* rind usually constitute a a nuisance compared to other agricultural wastes that can be converted to positive use like animal feed, for instance. Therefore, any positive use of the waste product will be embraced by rural dwellers to whom its handling is an ecological or economic burden. To a very great extent, evaluation of the insecticidal properties of *C. jambhiri* seems to be scarce in the literatures. Different parts of *C. jambhirir* have differs uses. In India, its ground root is orally administered to control vomiting (Tiwari *et al.,* 2017) In Nigeria, it is formulated into concoction for medicinal purposes like tooth whitening and human weight loss. The fruit is also used for making local juice. Despite its several uses, the rind id usually thrown away after peeling without any productive utilization. In some rural areas of south western Nigeria, *Citrus* species rinds are often dried and put on indoor charcoal fire to produce smoke which acts either as toxicant or repellent to mosquitoes This ethno botanical practice was one of the major thrusts for this research. The study was therefore designed with the following objectives (a) To evaluate the fumigant toxicity and repellence of *Citrus jambhiri* rind EO against *Sitophilus zeamais,* and (b) To identify the chemical components of the EO using Gas chromatography-Mass spectrometry.

2. Materials and methods

2.1 Insect culture

Sitophilus zeamais was reared on Tsolo variety maize under laboratory conditions of 28±2°C temperature and 70±3% relative humidity as described by Babarinde *et al.* (2008).

2.2 Essential oil Extraction and Chromatographic analysis

Rinds of freshly harvested *C. jambhiri* fruits were manually removed and pounded in a mortal with the aid of a pestle. EO was extracted from the rind using hydro distillation method (British

Pharmacopoeia, 1988; Babarinde *et al*., 2017b). The EO was subjected to Gas chromatography-Mass spectrometry (GC-MS) using the following procedures. EO (1.0 µL) was injected into a GC-MS machine (GCMS-QP2010SE®, a product of Shimadzu, Kyoto, Japan), equipped with an AOC-20i auto sampler and a split injector (split ratio 1:50). The description and conditions of the GC-MS machine are as follow. Column used: Optima® 5MS (a product of Macherey – Nagel, USA) (30 m × 0.25 mm internal diameter × 0.25 µm film thickness) coated with 95% dimethylpolysiloxane 5% diphenyl packing materials; helium was the carrier gas at 56.2 kPa inlet pressure and 36.2 cm/s linear velocity, 3 and 0.99 ml/min purge flow rate, respectively. Oven temperature began at 60 °C and ramp of 10 °C/min up to 180 °C held for 2 min, and subsequent increase to 280 °C with a 15 °C/min heating ramp at 280 °C for 4 min. Injection temperature was 250 °C. The MS operating conditions were as follows: ionization with an ion trap detector in full scan mode under electron impact ionization (EI) at 70 eV, ion source temperature 200 °C; interface temperature 250 °C, scan range, 40–700 m/z. The identification of the components was done as earlier described (Adams, 2001; Joulain and Koenig, 1998: Babarinde *et al*., 2017b).

2.3 Entomological bioassays

2.3.1 Fumigant toxicity bioassay

Varying doses of *C. jambhiri* EO (27, 53, 80 and 107µL/L air) were separately dissolved in 0.2 mL isopropanol and applied to 8 cm^2 Whatman filter paper attached to the inner surface of the cork of 750 mL capacity fumigation chamber. Isopropanol (0.2 mL) served as control. Twenty 1-3-day old mixed sex *S. zeamais* adults were introduced into the fumigation chamber and covered. Mortality data were collected at 1, 3, 6, 12, 24 and 48 h after treatment (HAT). The weevils were adjudged to be dead when they were unable to move their body parts after a gentle shaking of the fumigation chamber.

2.3.2 Repellence bioassay

Area preference methodology was adopted for the repellence bioassay. Whatman filter paper (9 cm diameter) was used following the method of McDonald *et al*. (1970), which was modified by Zhang *et al*. (2015) and Babarinde *et al*. (2017b) using the following doses: 0.15. 0.30. 0.45 and 0.90 µL/cm^2. Each dose was separately dissolved in 0.2 mL isopropanol, while isopropanol served as control. Twenty insects similar in all respects with those used for fumigant toxicity bioassay were introduced into the repellence chamber. Numbers of insects on the treated (Nt) and untreated (Nc) discs of the filter paper were counted at 24 hours after treatment and percentage repellence (PR) was calculated using the formula:

$$PR= \{(Nc-Nt)/(Nc+Nt)\} X 100$$

2.4 Experimental design statistical analyses

The experiments were set up in completely randomized design and data were subjected to analysis of variance (ANOVA), while significant means were separated using Studentized Neuman Keuls (SNK) post-hoc test at 5% probability level. Lethal times (LT_{50} and LT_{90}) for each of the EO doses were determined using probit analysis. All statistical analyses were done with the aid of SPSS software package version 16 (SPSS, 2006).

3. Results

3.1 Chromatographic analysis

A total of 52 chemical compounds were identified in *C. jambhiri* rind EO. Among the identified chemical groups were monoterpenoid and sesquiterpenoid compounds (hydrocarbon and oxygenated or alcohols), fatty acids and aldehydes. Major compounds were α-terpineol (8.03%), citral (7.00%), 4-terpineol (6.52%), citronellal (4.38%), β-bisabolene (4.01%) and n-hexadecanoic acid

(4.70%). Others were caryophellene (4.58%), lemonol (3.23%), precocene I (3.33%) and β-copaene (3.09%) (Table 1).

3.2 Entomological bioassays

At 1 Hour after treatment (HAT), there was no mortality due to the applied treatments. Observed mortality in all EO doses (5.00-100.00%) was significantly higher than mortality observed in isopropanol (0.00-22.50%). At 3 HAT, treatment had no significant (df=4,19; F=3.29; p=0.051) effect on weevil's mortality; thereafter, toxicity increased with increase in EO doses. At 6 HAT, mortality observed when 80 µL/L air (33.75%) and 107 µL/L air (40.00%) was significantly (df=4,19; F=10.317; p<0.0001) higher than the observed mortality when lower doses of EO and isopropanol were applied (0.00.16.25%). At 12-48 HAT, all EO doses caused significantly (p<0.0001) higher mortality (28.75-100.00%) than 5.00-22.5% mortality observed in isopropanol (Table 2).

The results of probit analysis followed similar pattern as ANOVA results. LT_{50} for EO applied at 107 µL/L air {7.51(6.95-8.13) h} was significantly lower than the values for 53 µL/L air {21.87(11.91-45.96) h} and 27 µL/L air {44.78(27.49-312.62) h}. LT_{90} values followed the same pattern; application of EO at 107 µL/L air had significantly lower value {11.7(10.82-12.85) h} than 18.33(13.02-42.72) - 87.53(53.25-804.05) h observed in other EO doses (Table 3). All EO doses caused significantly (df=4, 19; F=5.173; p=0.008) higher percentage repellence (75.00-90.00%) than isopropanol (15.00%) (Fig. 1).

4. Discussion

The result of the GC-MS analysis of C. jambhiri rind oil shows that the oil was predominated by terpenoid compounds. Apart from the terpenes, other chemical groups identified were aldehydes, alcohols and fatty acids. Monoterpenes and sesquiterpenes have been associated with the bioactivity of EO against many invertebrate pests (Obeng-Ofori and Reichmuth, 1999; Yildrim *et al.,* 2013; Saad *et al.*, 2018). Previous studies (Usman *et al.*, 2016; Fouad and Camara, 2017) on chemical components of different parts of *Citrus* species show the dominance of terpenoid compounds. The variations in the constituents of EOs are attributable to the difference in the activity of the synthases that mediate the formation of the compounds from their respective precursors (Degenhardt, 2009). Basically, however, the disparity in the chemical composition of any plant could be the differences in the species studied and the environmental factors involved in its cultivation (Jemaa *et al.,* 2012; Fouad and Camar, 2017).

The toxicity of *C. jambhiri* EO against *S. zeamais* conforms to recent studies (Campolo *et al.*, 2014; Dutra et al., 2016; Heidari *et al*., 2017; Oboh *et al*., 2017) on the bioactivity of EO obtained from *Citrus* species against stored product pests. According to Don-Pedro (1996), toxicity of *Citrus limon* against *Callosobruchus maculatus, S. zeamais* and *Dermestes maculatus* depended on strong fumigation action. Kumar and Tiwari (2016) reported the fumigant toxicity of *Citrus reticulata* against *Sitophilus oryzae. Apart from Citrus* species*,* other botanical EOs which have been reported to be toxic or repellent against *Sitophilus species* include Hoslundia opposita *(Babarinde* et al., 2017a), *Lippia javanica (Kamanula et al.,* 2017), *Teucrium capitatum* and *Salvia pomifera* subsp. c*alycina (Koutsaviti* et al., 2018). Although the mechanism of toxicity of the EO against *S. zeamais* was not covered in the scope of this study, fumigant toxicity of another EO (*X. parviflora)* against *C. maculatus* was suggested to be due to the inhalation of the EO which led to neurotoxicity and eventual mortality (Babarinde *et al*., 2015). The fumigant toxicity of *C. jambhiri* implies that the EO can be used to protect infested maize against the damage of *S. zeamais*.

Whereas Dutra *et al.* (2016) classified the repellence of the EO from four *Citrus* species against *C. maculatus* as neutral; our study shows *C. jambhiri* to be repellent against *S. zeamais.* The disparity in the result of Dutra *et al.* (2016) and the present study was due to the differences in the studied Coleoptera species and their physiological responses to the exposures to the chemical compounds in the different EOs. Repellence of *Citrus reticulata* EO *against Cryptolestes ferrugineus has been reported by* Lu (2017). The repellence of the *C. jambhiri* rind EO against *S. zeamais* implies that the EO

is effective to prevent re-infestation after an initial effective control of *S. zeamais* in stored maize. It also indicates the ability of the EO to prevent the infestation of non-resident pest population (Lale and Alaga, 2001; Babarinde *et al*, 2014).

5. Conclusion

C. jambhiri EO was effective as a toxicant and repellent against *S. zeamais*. With the appreciable number (52) of identified chemical compounds in the EO, the tendency of the development of resistance against the EO by maize weevil is low. Therefore, the EO can be incorporated into Integrated Weevil Management scheme. Since citrus rind is often thrown away after peeling, the results of this research have established a potential of the waste product of *C. jambhiri* in the pest control segment. The scope of the study did not extend to the evaluation of the bioactivity of the prominent chemical constituents, we therefore suggest that the observed bioactivity of the EO could be due to the combined effects of the chemical constituents identified in *C, jambhiri.*

Abstract

The aim of this study was to determine the insecticidal efficacy of mixture of NeemAzal a commercial neem product and *Plectranthus glandulosus* leaf powder against *Callosubruchus maculatus* and *Sitophilus zeamais*. Mixed at various proportions (100 + 0, 75 + 25, 50 + 50, 25 + 75 and 0 +100%, these powders were tested on adult mortality, inhibition of offspring production and their persistence on *C. maculatus* and *S. zeamais*. All the mixed NeemAzal and *P. glandulosus* caused significant mortality to adult *C. maculatus* and *S. zeamais*. No

significant difference was observed among the mixed powders that were subjected to the three mixture proportions regarding the mortality they caused to the weevils. The mixed 75% NeemAzal + 25% *P .glandulosus* of powder led to a higher mortality (100%) of both insect species, three (5 g/kg) days post exposure. The three days LC_{50} values decreased with ascending proportion of NeemAzal in the mixture from 3.21 g/kg (25% NeemAzal + 75% *P. glandulosus*) to 0.24 g/kg (75% NeemAzal + 25% *P. glandulosus*) in *S. zeamais*. In *C. maculatus,* the opposing effect was observed. The number of F_1 progeny produced reduced significantly ($P \leq 0.01$) in both insect species with the mixture proportion of botanicals. The mixtures reduced better the adult progeny production than the botanicals applied alone. The 75% *P. glandulosus* + 25% NeemAzal persisted well on grains up to 180 days for all dose levels. Powder from NeemAzal and *P. glandulosus* leaves stand as good candidates to protect maize and cowpea against the infestation of *S. zeamais* and *C. maculatus* respectively during storage. Mixing these products could not be advantageous since the binary mixture gave similar result as when they were applied alone.

Key words: Callosobruchus maculatus, Sitophilus zeamais, mixture, Plectranthus glandulosus, NeemAzal, efficacy

Introduction

Crop production plays major importance in the livelihood of people all over the world and particularly in developing countries where it is considered as the principal activity on which most economies depend on (Gustavsson et al., 2011. Paradoxically many farmers loss heavy quantity of cultivated plants because of the attack by insect pests. *Sitophilus zeamais* and *Callosobruchus maculatus* are the most important pests stored maize and cowpea respectively with great losses mostly in tropical countries(Guèye et al., 2011). To reduce post-harvest losses, different methods of grain protection are used by small holder farmers as well as at the industrial level (Isman, 2006). However, over the past decades, synthetic chemical insecticides have played a significant role in modern agricultural pest management (Guo *et al.,* 2014). Their repeated use over the years has led to the evolving of resistance in pest populations and fostered environmental and human health concerns (Ofuya, 2003). These problems have highlighted the need for the development of new types of selective insect-control alternatives (Lee et al., 2001), which combine broad spectrum action against stored product insect pests with low toxicity to non-targeted organisms, but at the same time also readily available and affordable to the small-scale grower (Nukenine et al*.,* 2007). Nowadays, products from plant origin are recommended as alternative to the hazardous synthetic chemicals. *Plectranthus glandulosus* leaf powder and essential showed greater insecticidal efficacy against adult insects of stored cereals (Nukenine et al*.,* 2011).The commercial NeemAzal powder which is constituted of the mixture of diatomaceous earth with azadiracthin was effective against the maize weevil (Nukenine et al., 2011). To promote the use of safer NeemAzal or *P. glandulosus* leaf powder combined with good efficacy in stored product protection, the mixture of these powders to reduce the quantity applied need to be reconsidered. The aim of the present work is to determine the insecticidal efficacy of mixture of NeemAzal a commercial neem product and *P. glandulosus* leaf powder against *C. maculatus* and *S. zeamais***.**

Material and Methods

The leaves of *P. glandulosus* were collected around Ngaoundere (Quartier Champ de prière) (latitude 7°22′ North and longitude 13°34′ East, altitude of 1,100 m.a.s.l.), located in the Adamawa region of Cameroon. The plants were less than one-year old and only the green leaves were harvested from plants which were yet to attain the flowering stage. The collected leaves were sun-dried (29 ± 4°C). Dried leaves were hand crushed. The crushed leaves were ground into powder using a Bosch Universal grinder (model MUM 6012, Remscheid, Germany) until the particles passed through 0.1 mm mesh sieve. NeemAzal powder, was provided by Trifolio-M GmbH, Lahnau, Germany.

The parent adults of *S. zeamais* and *C. maculatus* were obtained from colonies maintained at JKI, Institute for Ecological Chemistry, Plant Analysis and Stored Products Protection, Berlin since 1968 and 2011, respectively. *S. zeamais* were reared on maize (Ricardino variety) while *C. maculatus* were reared on cowpea (Black eyes Perou).

NeemAzal powder were mixed with *P. glandulosus* leaf powder in the proportions of 100/0, 75/25, 50/50, 25/75 and 0/100% in glass jars. Each glass jar was shaken with a bidimensional mixer (Gerhardt, Dreieich, Germany) for 5 hours to ensure uniform mixture of the powders. The masses 0.125, 0.25, 0.5, 0.75 and 1 g were separately introduced to 50 g of maize or cowpea in 250 ml glass jars to give the doses of 2.5, 5, 10, 15 and 20 g/kg of maize or cowpea. Controls consisted of grains devoid of the plant powders. Each binary mixture was tested on *S. zeamais* and *C. maculatus* for adult toxicity, progeny production. The persistence test was performed with 75% *P. glandulosus* + 25% NeemAzal.

The co-toxicity coefficient of powder mixture was used to determine their responses: A co-toxicity coefficient of less than 80 is considered as antagonistic, between 80 and 120 as additive, and higher than 120 as synergistic (Sun and Johnson 1960; Islam *et al.,* 2010). If a mixture (M) compounds of two parts (A and B), and both components have LC_{50}, then the following formulas are used (A serving as standard):

Toxicity index (TI) of A = 100

$$\text{Toxicity index (TI) of B} = \frac{\text{LC50 of A}}{\text{LC50 of B}} \times 100$$

$$\text{Actual TI of Mixture} = \frac{\text{LC50 of A}}{\text{LC50 of M}} \times 100$$

Theoretical TI of M = TI of A × percentage of A in M + TI of B × percentage of B in M

$$\text{Co-toxicity coefficient} = \frac{\text{Actual TI of M}}{\text{Theoretical TI of M}} \times 100$$

If one component of the mixture alone (for example B) causes low mortality at all doses (< 20%), then the co-toxicity coefficient of the mixture was calculated by the formula: Co-toxicity coefficient = LC_{50} of A alone/LC_{50} of A in the mixture × 100.

Data on % cumulative corrected mortality and % reduction in F_1 progeny were arcsine [(square root(x/100)] transformed and the number of F_1 progeny produced were log (x + 1) transformed to homogenise the variance. The transformed data were subjected to the ANOVA procedure using the Statistical Analysis System (SAS Institute, 2008). Tukey (HSD) test (P = 0.05) was applied for mean separation**.**

Results

All the different combinations of NeemAzal and *P. glandulosus* generally caused significant mortality to adult *C. maculatus* and *S. zeamais* compared to the control (Tables 1and 2). The increase in mortality with ascending dose levels and time exposure was much more pronounced within three days post exposure than thereafter, irrespective of mixture proportions and insect species. Overall, mixture proportions generally had no effect on the mortality of the two insect species caused by the mixed *P. glandulosus* leaf powder and NeemAzal. However, the combination 25% NeemAzal + 75% *P .glandulosus* powder tended to be less potent to both insect species, since the lowest tested powder dose of 2.5 g/kg caused lower than 100% mortality to *C. maculatus* (6-d) and *S. zeamais* (7-d) for this combination while the other two combination proportions caused complete mortality . The highest tested dose (20 ml/kg) achieved complete mortality of both weevils three days post exposure for all mixtures, except the 25% NeemAzal + 75% *P. glandulosus* leaf powder which caused a maximum mortality of 87.50% in *S. zeamais*.

[†] Means ± SE in the same column followed by the same lower case letter or in the same line followed by the same upper case letter, do not differ significantly (Tukey's test; $P < 0.05$).
[‡] ** $P < 0.01$; *** $P < 0.001$. *P. gland = Plectranthus glandulosus.*

The toxicity parameters of the binary mixture of *P. glandulosus* and NeemAzal powders to *C. maculatus* and *S. zeamais* are given in (Table 3). The 3-d LC_{50} values decreased with ascending proportion of NeemAzal in the mixture from 3.21 g/kg (25% NeemAzal + 75% *P. glandulosus*) to 0.24 g/kg (75% NeemAzal + 25% *P. glandulosus*) for *S. zeamais*. With *C. maculatus,* the opposite effect was observed, the LC_{50} values increased as the quantity of NeemAzal in the mixture increased. When the proportion of NeemAzal was ≥ 50% the LC_{50} and LC_{95} LC were not estimated due to complete adult mortality. The slopes seemed similar (1.24 – 1.51) for all the combinations of the powders in *S. zeamais* while they decreased (18.82 – 1.45) with increase in the quantity of *P. glandulosus* in the mixture. All the estimated co-toxicity coefficients were less than 80.

The number of F_1 progeny and the percentage inhibition of the progeny of *C. maculatus* and *S. zeamais* that emerging from grains treated with different combinations of NeemAzal and *P. glandulosus* at different doses are shown in Table 4. The number of emerging F_1 progeny reduced significantly ($P \leq 0.01$) in both insect species with ascending of the botanicals. The binary combinations of the powders reduced progeny emergency more than each botanical applied alone, with NeemAzal being more potent than *P. glandulosus*. All the binary combinations of the powders completely suppressed progeny production in *S. zeamais*. On cowpea 97.77%, 97.15% and 66.78% inhibition of *C. maculatus* emergence were recorded respectively with the combinations 25% *P. glandulosus* + 75% NeemAzal, 50% *P. glandulosus* + 50% NeemAzal and 75% *P. glandulosus* + 25% NeemAzal at the highest tested dose of 20 g/kg.

P. gland = *Plectranthus glandulosus.*

Figure 1 shows the results of the persistence of the mixture of 75% *P. glandulosus* + 25% NeemAzal on *C. maculatus* and *S. zeamais*. The efficacy of the mixture varied significantly (P < 0.001) with the ascending dose but not with the storage interval as the efficiency persisted up to the 180-d storage interval. For this binary combination, the mortality caused to *S. zeamais* and *C. maculatus* at the 180-d storage interval did not differ from the observed mortality at the 0-d storage interval (P > 0.05) for all the dose levels.

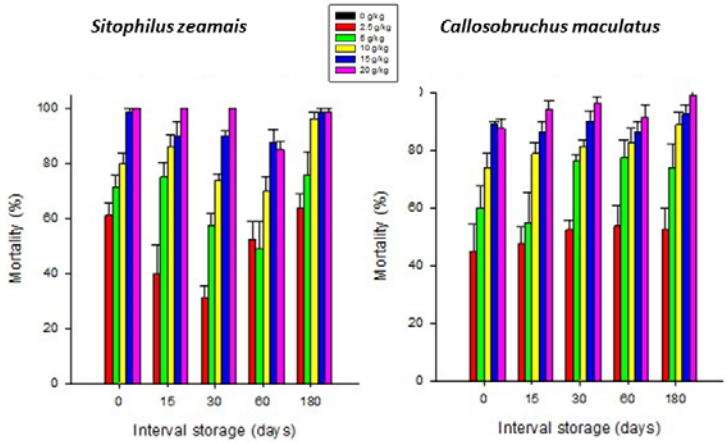

Figure 1: Corrected cumulative mortality of *Callosobruchus maculatus* and *Sitophilus zeamais* exposed in grains treated with the combinations of *Plectranthus glandulosus* with NeemAzal powders at different storage intervals

Discussion

The mixture of NeemAzal and *P. glandulosus* leaf powder was also antagonistic regarding the mortality they caused to *C. maculatus* and *S. zeamais*. In isolation, NeemAzal caused greater mortality to both insects than *P. glandulosus*. The mixture of *Vernonia amygdalina* and neem powder was antagonistic with respect to insecticidal efficacy (Akunne et al., 2013). The NeemAzal used in the present study was produced by incorporating azadirachtin into silica gel. The mortality observed with NeemAzal could largely be due to the presence of silica gel compared to that of azadirachtin (Ogemah, 2003). Silica gel acts by desiccation, as the insects move through grains, they pick up the powder on their cuticle which leads to the absorption of the cuticular waxes from the epicuticule surface of the insect, thus enhancing the rate of desiccation (Prasantha, 2003). Ulrich and Mewis (2000) showed that combinations of diatomaceous earth (Fossil shield (1 gm/kg) and a commercial neem product NeemAzal (1 gm/kg) resulted in higher mortality of the weevils. Since NeemAzal contains silica gel, the mixture of this powder with Fossil shield implies the doubling of the concentration of diatomaceous earths, which resulted in higher mortality in the study of Ulrich and Mewis (2000).

It could also be concluded that the binary mixtures at different proportion levels of the powders from NeemAzal and *P. glandulosus* has various effects on adult emergence. the mixture of NeemAzal and *P. glandulosus* reduced almost completely the emergence of adult insects when the rate of NeemAzal ≥ 25%. Nukenine et al., (2011) reported that under fluctuating conditions, NeemAzal powder registered similar results on *S. zeamais.* It seems that the silica gel absorbed the water contained in grains which affected the development of the weevils. Before treatment the moisture content of the grains was above 12% and after F_1 progeny evaluations, this value decreased to less than 10%. When the moisture content of the grains is less than 10%, the development of immature stages of both insect species is hindered.

NeemAzal contains silica gel and for this reason, the activity of its mixture with *P. glandulosus* was more or less constant up to 180 d compared to the 70% reduction in the efficacy of *P. glandulosus* alone. Silica gel is an inert durst and does not contain volatiles like *P. glandulosus,* which loses its active ingrediants with time. The activity of *Ocimum basilicum,* an aromatic plant of the Lamiaceae family like *P. glandulosus on S. zeamais* mortality declined most 0 (80% mortality) and 28 d (15%

moratlity) (Mwangangi and Mutisya, 2013), which is in conformity with the results of the present work.

Effects of chlorpyrifos-methyl and pirimiphos-methyl applied with 5°C temperature on *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae) in wheat grain

Marijana Pražić Golić*, Goran Andrić, Petar Kljajić

Pesticide and Environment Research Institute, Banatska 31b, 11080 Belgrade, Serbia

Abstract

The effects of the insecticides chlorpyrifos-methyl and pirimiphos-methyl in combination with low temperature treatment at 5°C were tested in the laboratory to improve the existing pest management programs for *S. oryzae* control. Adults were released into wheat grain pretreated with three insecticide doses: 0.08, 0.12 and 0.16 mg/kg of chlorpyrifos-methyl, and 0.125, 0.19 and 0.25 mg/kg of pirimiphos-methyl, and exposed to 5°C temperature over intervals of 5, 6, 7 and 8 days. Mortality after low temperature only, insecticides only, and their

combinations, was assessed after 1, 2, 7 and 14 days of recovery at 25±1°C and 60±5% r.h., as well as their impact on F1 progeny production/reduction (PR) after 8 weeks. The combined application of 0.16 mg/kg chlorpyrifos-methyl and 5°C temperature (5-7 days of exposure) caused a significantly higher mortality of *S. oryzae* after 1, 2, 7 and 14 days of recovery than the activity of low temperature alone, as well as the combined application of 0.12 mg/kg chlorpyrifos-methyl and 5°C after 7 and 14 days of recovery. Adults mortality and progeny reduction of *S. oryzae* was ≥92% after 14 days of recovery from an interaction of 0.16 mg/kg dose of chlorpyrifos-methyl and exposure for 6 days to 5°C, as well as all doses in combination with 7 days exposure to 5°C. Combined application of 0.25 mg/kg pirimiphos-methyl and 5, 6 and 7 days of exposure to 5°C caused a significantly higher mortality of *S. oryzae* after 7, 2 and 1 day of recovery, respectively, compared to temperature-only exposure. High mortality (91-95%) and progeny reduction >92% were caused by the same pirimiphos-methyl rate in combination with 6 and 7 days of exposure to 5°C after 7 days of recovery as the combination of 5, 6 and 7 days of exposure to 5°C after 14 days of recovery.

Keywords: *S. oryzae*, chlorpyrifos-methyl, pirimiphos-methyl, 5°C temperature, combined effects.

1. Introduction

Since the 1960s, residual grain protectants, chiefly organophosphorus and pyretroid insecticides, have been used in management programs for insect pest control in stored raw agricultural commodities. Protectants are usually applied when commodities are loaded into storage, and residues from this single application are expected to protect grain throughout the storage period (Arthur, 1996). Malathion, first registered in the United States in 1958, received extensive use as a storage spray and grain protectant (Arthur and Subramanyam, 2012). The use of malathion decreased significantly after control failures in stored grain (because the extensive use of this compound has resulted in a worldwide resistance of several species). Thus, malathion has been replaced by other organophosphorous insecticides, such as chlorpyrifos-methyl and pirimiphos-methyl (Boyer et al., 2012). Chlorpyrifos-methyl and pirimiphos-methyl are the most common organophosphate insecticides, and both are used as chemical protectants of stored grain throughout the world, either alone or in combination with some pyirethroid compound, e.g. chlorpyrifos-methyl plus deltamethrin in the United States (White and Leesch, 1996; Arthur and Subramanyam, 2012). This class of insecticides is favored for use in stored grains because of relatively low mammalian toxicity and suitable degradation rates that are directly influenced by temparature and product moisture content (White and Leesch, 1996). Compared to contact insecticides, treatments with extreme temperatures as a physical method of controlling stored-product insects have a number of advantages: they leave no residues on products, they are effective against populations resistant to contact insecticides, and the risk for operators is minimal (Fields, 1992, 2001; Burks et al., 2000; Beckett and Morton, 2003; Hagstrum and Subramanyam, 2006; Beckett et al., 2007; Fields et al., 2012). Over the past three decades, low temperatures have been largely used to disinfest either commodities or storage facilities from stored product pests, or for quarantine purposes (Fields, 1992, 2001; Donahaye et al., 1995; Burks et al., 2000; Loganathan et al., 2011; Fields et al., 2012).

Another area of potential benefits from low temperature treatments is their combination with some other pest control methods, such as chemical protectants as part of an integrated approach to manage stored products pests and their resistance to insecticides (Kljajic et al., 2014). Cold pre-treatment at -5°C of adults of granary weevil, *Sitophilus granarius* (L.), has consistently increased the insecticide efficacy of deltamethrin, compared to an unexposed weevil population. Deltamethrin toxicity to field and selected populations after 24 h recovery, following exposure to -5 °C, was 12.1 and 11.0 times higher, respectively, while it was 6.9 and 36.6 times higher, respectively, after 72 h of recovery (Kljajic et al., 2014).

However, insufficient information is available about the influence of the lethal supra-optimal extreme temperature of 5°C on insecticide effectiveness. Research of the interactions between insecticides and temperature in recent years have been mostly based on testing temperatures that ranged from 10 to 30 °C. Organophosphate compounds were found to be more toxic at higher temperatures (≥ 30 °C), in contrast to pyrethroids, which were more toxic at lower temperatures (≤

20 °C) (Tyler and Binns, 1982; Watters et al., 1983; Thaung and Collins, 1986; Subramanyam and Cutkomp, 1987; Longstaff, 1988; Subramanyam and Hagstrum, 1996; Fleurat-Lessard et al., 1998). Wilkin et al. (1999) exposed *Sitophilus oryzae* (L.) adults to treated wheat for five days and reported pirimiphos-methyl (4.0 mg/kg) effectiveness of 64 % at 5 °C, and 100% efficacy at 10° C, revealing the insecticide's higher effectiveness at higher temperature. However, almost none of these studies examined how the combination of treatments affected the survival of insects at low temperatures. However, the effects of acclimation on their survival at low temperatures are well documented (Andreadis and Athanassiou, 2017).

Working on potential improvements of current pest management programmes for *S. oryzae* control, we focused our present laboratory study on examining the effects of a combination of 5° C temperature with the contact insecticides/grain protectants chlorpyrifos-methyl and pirimiphos-methyl on a lab population of rice weevil, *Sitophilus oryzae* (L.) in wheat grain. The effects on its progeny production/ reduction in F1 generation were also examined, and all data compared with the effects of extreme temperature and independent insecticide treatments.

2. Materials and methods

Test insects and insecticides applied

Adults of a laboratory population of *S. oryzae*, reared at the institute were used as test insects in experiments as described by Harein and Soderstrom (1966) and Davis and Bry (1985). The weevils were reared on whole soft wheat grain of 12% moisture, in 2.5 L glass jars at 25 ± 1°C temperature and 60 ± 5% relative humidity. Unsexed 2-5 week old adults were used in all trial variants. The following insecticide products were used in tests: chlorpyrifos-methyl (Reldan EC 40 with 400 g/L a.i., Dow AgroSciences, Austria) and pirimiphos-methyl (Actellic EC 50 with 500 g/L a.i., Galenika-Fitofarmacija, Serbia).

Bioassays

Moisture content in the soft wheat grain variety NS 40 S was 11.0 ± 0.5% and was measured by a DickeyeJohn Mini GAC (DickeyeJohn Co., USA) device before the experiment. Based on a preliminary experiment, three application rates were determined for each insecticide, i.e. chlorpyrifos-methyl (0.08, 0.12 and 0.16 mg/kg) and pirimiphos-methyl (0.125, 0.19 and 0.25 mg/kg), as well as four intervals of exposure to 5° C temperature: 5, 6, 7 and 8 days, in order to test the combined activity of the insecticides and low temperature. Four standard solutions were prepared for each insecticide and diluted into dose series, so that each insecticide dose was used for four treatments (replications) of 500 g lots (one treatment included a single replication of each interval of grain exposure to 5° C temperature: 0, 5, 6, 7 and 8 days. Each 1000 mL glass jar was filled with 500 g of wheat grain and treated with 5 mL of water solution of one of the insecticides, or 5 mL of water for control grain. After hand shaking the treated wheat grain for 30 s, it was mixed on a rotary shaker for 10 min. Plastic 200 mL bottles were then filled with 50 g of treated wheat grain and untreated control grain, and 25 *S. oryzae* adults, previously acclimed in a refrigirator at 15 °C over 24 h, were added into each bottle and the bottle was topped with cotton cloth and fixed with a rubber band. The lots representing each time interval were then independently placed in an incubator (LE-519, MRC, Israel) set to 5 ± 0.5 °C temperature. Temperature in all trial variants was recorded by a data logger (Kestrel 4000, USA). The bottles had a completely randomized arrangement in the incubator. They were transferred after each interval to laboratory conditions (25 ± 1° C and 60 ± 5% r. h), and lethal effects were determined after 1, 2, 7 and 14 days. The same procedure was used to determine the independent effects of both insecticides. After the last assessment, insects were seaved out (seive density 2.0 mm) to enable F1 progeny counts eight weeks after the adults made contact with treated wheat grain and the bottles were kept in the laboratory at 25 ± 1° C and 60 ± 5% r. h.

Data analysis

Mortality data were analyzed using one-way ANOVA. Means were separated by Fisher's LSD test at P=0.05 (Sokal & Rohlf, 1995). *S. oryzae* progeny production/reduction in wheat grain was determined using the formula PR (%) = (K-T) 100/K (Tapondjou et al., 2002), where K - number of progeny in the untreated control, and T - number of progeny in treatments.

3. Results

In the variant without exposure to 5°C, none of the adults in grain treated with all rates of chlorpyrifos-methyl and pirimiphos-methyl (Tab. 1) died after 1 day of contact, while 1% and 5% mortality, respectively, occurred only under the highest doses of chlorpyrifos-methyl and pirimiphos-methyl (0.16 and 0.25 mg/kg, respectively) after 2 days of exposure. Adult mortality increased significantly after 7 and 14 days of contact with both insecticides, the highest being after 14 days of contact with 0.16 mg/kg chlorpyrifos-methyl (87%), and 0.25 mg/kg of pirimiphos-methyl (91%). Average counts of *S. oryzae* progeny in wheat decreased nominally with increasing rates of the tested insecticides. The highest number of progeny (around 530 and 400) and lowest progeny reduction (10.5 and 32.1%) were detected after treatment with the lowest rates of chlorpyrifos-methyl and pirimiphos-methyl (0.08 and 0.125 mg/kg, respectively), while the highest rates of chlorpyrifos-methyl and pirimiphos-methyl (0.16 and 0.25 mg/kg) allowed the lowest average number of progeny (207 and 232, respectively), i.e. the greatest progeny reduction (65.0 and 60.8%, respectively).

The mortality of S. oryzae adults after 1 and 2 days of recovery from exposure to 5° C temperature in grain untreated with insecticides (Tab. 2) ranged from 15- 83% and 26-86%, respectively, depending on exposure duration, and increased after 7 and 14 days of recovery to 41-96%. Regardless of the period of recovery, a significant increase in adult mortality occurred after 7 and 8 days of exposure to 5° C (43-96%), compared to the shortest exposure periods of 5 and 6 days (15-49%), and 7 and 8 days of exposure (43-74% and 83-96%), while no statistical difference was detected between the shortest exposure periods of 5 and 6 days (15-42% and 20-49%).

In all investigated combinations of insecticide treatment with 5° C temperature (Tab. 2), adult mortality significantly increased with the duration of exposure to extreme temperature, with increasing insecticide doses, and duration of insect exposure to treated wheat grain. Excepting the 8 day exposure, which caused high adult mortality (83-100%) and progeny reduction (92-100%) regardless of recovery period and insecticide, both independently and in all combinations, high adult mortality (>89%) and high progeny reduction (>92%) was also revealed for the combination of 0.16 mg/kg chlorpyrifos-methyl and 6 days of exposure to 5° C temperature, after 14 days of recovery, and for all combinations of chlorpyrifos-methyl treatment and 6 and 7 days of exposure to 5° C after 7 and 14 days of recovery. Adult mortality (>91%) and progeny reduction (>92%) were also high in the combination of the highest dose of pirimiphos-methyl (0.25 mg/kg) with 6 and 7

days of exposure to 5° C after 7 days of recovery, and with 5, 6 and 7 days of exposure to 5° C after 14 days of recovery.

Tab.2. Combined effects of chlorpyrifos-methyl and pirimiphos-methyl, and 5°C temperature on *S. oryzae* in wheat grain after 1, 2, 7 and 14 days of recovery/exposure.

[a] For each insecticide separately, means within columns followed by the same letter are not significantly different, Fisher's LSD test at P > 0.05.

[b] Progeny reduction compared to control 1 (weevil progeny in untreated wheat grain exposed to 5°C).

[c] Progeny reduction compared to control 2 (weevil progeny in untreated wheat grain not exposed to 5°C).

The lowest doses of both insecticides (0.08 and 0.12 mg/kg of chlorpyrifos-methyl and 0.125 mg/kg of pirimiphos-methyl) stimulated progeny production of treated parents by 26-38.7%, compared untreated wheat exposed to 5° C temperature over 5 days, and 5 and 7 days, respectively.

4. Discussion

Our results showed that the mortality of *S. oryzae* lab adults exposed to 5 °C temperature in untreated cold grain increased with exposure duration (5-8 days) and recovery duration (1-14 days), while weevil mortality after 7 and 8 days of exposure and 7 days of recovery were roughly the same as they were after 14 days of recovery (74% and 96%, respectively). Experimental data have shown variable effects of low temperatures on this species. A survey by Fields (1992) of the then available

data on lethal effects of low temperatures on *S. oryzae*, cited a 50% survival of adults exposed for 10-16 days to 4.5 °C temperature, while other data showed no (0%) surviving adults after exposure to the same temperature, or survival of 4-6% adults after 14 days of exposure to 4.4 °C, the data depending on conditions in each particular experiment and on acclimation. On the other hand, when Pražić Golić et al. (2013) tested lethal effects of 5° C temperature in wheat grain on *Sitophilus* species, they found that *S. oryzae* adults mortality after 1-7 days of recovery from exposure to 5 °C for 5, 6, 7 and 8 days was 27-58, 33-61, 58-90 and 64-93%, which is similar to the present research data.

Our data on *S. oryzae* mortality caused by the insecticides chlorpyrifos-methyl and pirimiphos-methyl without cold treatment at 5°C showed that mortality increased with insecticide concentration and exposure interval, which generally agrees with many other studies on *S. oryzae* and some other stored-product insect pests (Wilkin et al., 1999; Arthur et al., 2004; Kavallieratos et al., 2009; Kljajić and Perić, 2009; Andrić et al., 2011; Athanassiou et al., 2008). In our present study, the highest mortality of *S. oryzae* adults of 87 and 91% was detected after 14 days of exposure to wheat treated with 0.16 mg/kg chlorpyrifos-methyl and 0.25 mg/kg pirimiphos-methyl, respectively. Some earlier studies had shown high efficacies (100%) of chlorpyrifos-methyl at 1.0 mg/kg and 5.0 mg/kg rate against *S. oryzae* after 7 and 14 days of exposure, respectively (Fleurat-Lessard et al., 1998; Daglish, 2008) and high efficacies (100%) of pirimiphos-methyl at 1.0 mg/kg and 4.0 mg/kg rates against *S. oryzae* after 7 days exposure (Huang and Subramanyam, 2005; Rumbos et al., 2013). In our research, 0.25 mg/kg pirimiphos-methyl caused 0.0, 5.0, 87.0 and 91.0% adult mortality after 1, 2, 7 and 14 days, respectively. In a study with the same exposure intervals conducted by Rumbos et al. (2013), a double dose of pirimiphos-methyl (0.5 mg/kg) caused a significantly lower mortality, 0.4, 1.2, 66.6 and 69.2%, respectively. The inconsistent data may be attributed to a higher susceptibility to insecticides of our lab population.

Generally, very little is known about the effects of insecticide treatments of storage insects in combination with extreme low temperatures in wheat grain. The results in our present study on wheat grain showed that the exposure of *S. oryzae* adults to combinations of insecticide treatment and 5° C cold treatment over a period of 7 days caused, in almost all cases, a mortality that significantly exceeded the independent activities of either component, i.e. insecticide or low temperature. For example, regardless of the recovery period (1-14 days), Weevil mortality was 55-92%, 79-100% and 64-93% in grain treated with 0.08, 0.12 and 0.16 mg/kg chlorpyrifos-methyl, respectively, while adult mortality in wheat treated only with the insecticides was 0-2%, 0-46% and 0-87%, respectively, and 43-74% in untreated wheat after exposure at 5°C. Similarly, each individual component (insecticide and temperature) an interaction with 0.125, 0.19 and 0.25 mg/kg of pirimiphos-methyl and 7 days exposure to 5° C caused a statistically significant difference in adult mortality, i.g. mortality in wheat treated with pirimiphos-methyl was regardless of the recovery period 47-83%, 60-86% and 63-92%, respectively, while mortality in wheat treated with the insecticides only was 0-9%, 0-61% and 0-91%, respectively. After exposing *S. oryzae* (L.) adults to treated wheat for five days, Wilkin et al. (1999) found that pirimiphos-methyl applied at 4.0 mg/kg rate and 5 °C temperature achieved 64 % efficacy, while our 16 times lower dose (0.25 mg/kg) caused 4 times lower mortality (16 %), which demonstrates how the insecticide application rate greatly determines the effects of combined application of insecticide and low temperature.

As data on the effectiveness of insecticides as grain protectants vary, Subramanyam and Roesli (2000) insisted on the importance of checking their effects on progeny production of various storage insects. High progeny reduction of *S. oryzae*, >92%, was reported after the application of 0.16 mg/kg chlorpyrifos-methyl in combination with 6 days of exposure to 5° C, and all application rates of that insecticide (0.08, 0.12 and 0.16 mg/kg) in combination with 7 days of low temperature exposure. The same rate of progeny reduction was detected for the combination of the highest dose of chlorpyrifos-methyl (0.25 mg/kg) and 6 and 7 days of exposure to 5° C. Individual exposure of *S. oryzae* adults to 5° C over 8 days caused 92% progeny reduction. However, the highest doses of both chlorpyrifos-methyl and pirimiphos-methyl (0.16 and 0.25 mg/kg) caused a significantly lower

progeny reduction in the laboratory, 65.0 % and 60.8 %, respectively. Kljajić and Perić (2010) found that contact of laboratory *S . granarius* weevils with sublethal doses of pirimiphos-methyl caused increases in progeny counts of 40%, while contact of weevils selected with a sublethal dose of chlorpyrifos-methyl caused 127% increase. In our present experiment, the lowest doses of chlorpyrifos-methyl, 0.08 and 0.12 mg/kg, combined with exposure to 5°C over 5 days, compared to the control not treated with insecticides but exposed to 5°C, increased the number of progeny 26.4 and 38.7%, respectively, while the lowest dose of pirimiphos-methyl (0.125 mg/kg) applied with 5°C temperature over 5 and 7 days, resulted in 30% and 27.4% increase, respectively. The data in our own and some earlier studies show evidently that there is a risk of lower or recommended insecticide doses, applied either alone or in combination with other control methods, becoming sublethal to stored product insects in certain situations, which may then further reflect on their survival and progeny production.

In conclusion, our findings show that the existing pest management programmes for *S. oryzae* control in wheat grain can be significantly improved through highly effective combinations of lower doses of the insecticides chlorpyrifos-methyl (0.08-0.16 mg/kg) and pirimiphos-methyl (0.25 mg/kg) with cold treatment at 5°C for 7 days.

Abstract

Residual efficacy of the insecticide deltamethrin, EC formulation with 25 g/L AI + 225 g/L PBO (synergist piperonyl butoxide), against lab populations of *S. granarius* and *P. interpunctella* by applying product water solutions (12.5 mg AI/m^2) to porous surface, and against *B. germanica* by applying them to non-porous surface,

was investigated in laboratory (at 25±1°C and 55-60% r.h.). The mortality of cockroach adults on deposits aged 0, 14, 30 and 45 days was estimated after 30 minutes of their contact with the treated surfaces, and additional 24 h and 48 h of recovery, while the mortality of stored-product insects (adults or larvae) on 0, 7, 14 and 30 days old deposits was estimated after 2, 7 and 14 days of exposure to treated surfaces and additional 7 days of recovery. Mortality of cockroaches in all variants was 100%, except on 45 days old deposit and after 24 h of recovery, when it was 97%. Deltamethrin caused 0% weevil mortality after 2 days of exposure to deposits of all ages (0-30 days), while *P. interpunctella* larval mortality was 87-93%. However, mortality was 100% after 7 and 14 days of weevil/moth exposure in all variants of deposit ages and/or additional 7 days of recovery. The results show that deltamethrin applied to porous and non-porous surfaces is a highly effective insecticide for weevil/moth and cockroach control, and it showed a good residual activity for up to 30 and 45 days, respectively.

Keywords: *S. granarius*; *P. interpunctella*; *B. germanica*; Deltamethrin; Residual efficacy.

1. Introduction

The granary weevil *Sitophilus granarius* (L.) (Coleoptera: Curculionidae) and Indian meal moth *Plodia interpunctella* (Hübner) (Lepidoptera: Phycitidae) are very important insect pests of stored plant products, which are able to cause major losses unless controlled. Also, the German cockroach *Blattella germanica* (L.) (Dictyoptera: Blattellidae) is a widespread urban pest which is frequently present in storages, stored-products and food processing facilities (Hill, 1990; Ebeling, 1991; Rees, 2004; Almaši, 2008; Stejskal et al., 2015).

The use of contact (residual) insecticides, besides sanitation of storage ambient and surfaces, is the most important step in prevention and control of pests (Kljajić, 2008; Arthur, 2012; Jankov et al., 2013; Rumbos et al., 2014). Several products, mostly in the class of organophosphate insecticides and synthetic pyrethroids, have been registered worldwide (Arthur and Subramanyam, 2012; MacBean, 2012) and in Serbia (Team of editors, 2016) as plant protection products (PPPs) and/or biocide products (BP) (WHO, 1999 and 2006).

The residual efficacy of contact insecticides on treated surfaces is known to depend on the type of insecticide, its formulation, type of surface (e.g. metal, wood or concrete), species of stored product insect or duration of exposure (Arthur, 1996; Athanassiou et al., 2013; Jankov et al., 2013; Rumbos et al., 2014). The present study therefore focused on examining the residual efficacy of deltamethrin (with piperonyl butoxide synergist), EC formulations, applied at the recommended rate against stored-product insect pests, represented by *S. granarius* and *P. interpunctella* on porous surface, and an urban pest, *B. germanica* on non-porous surface after different periods of contact with treated surface.

2. Materials and Methods

Test insects and insecticides

Laboratory populations of test insects were reared in an insectary at 25±1°C temperature and 60±5% relative humidity (r.h.). Adults of the *S. granarius* were reared in 2.5L glass jars containing whole grain soft wheat of 12% moisture content as described by Harein and Soderstrom (1966) and Davis and Bry (1985). Indian meal moths *P. interpunctella* were reared on a diet containing corn meal (flour), ground wheat flour, honey and glycerol as described by Boles and Marzke (1966). German cockroaches *B. germanica* were reared in 5.0 L glass jars with cardboards inside, mainly containing coarse wheat meal and/or pelleted food, as described by Morgan (1985).

Two-to-four weeks old *S. granarius* unsexed adults, third instars (L_3 stage) of *P. interpunctella* larvae and one week old *B. germanica* adults, were used in the bioassays.

An insecticide (EC formulation) based on deltamethrin 25 g/L AI, with the synergist piperonyl butoxide 225 g/L, (Kontakt, Galenika-Fitofarmacija a.d., Serbia) was tested.

Bioassay

For stored-product insects, the residual efficacy tests were performed using a methodology described in PP 1/202 (1) and PP 1/204 (1) (OEPP/EPPO, 2004). Porous surface, made by plates of burned bricks (33 x 33 cm) of around 1 m^2, was cleaned, washed and dried before treatment. Water solutions of the insecticide deltamethrin were made immediately before treatment (49.5 mL water and 0.5 mL product). After stirring, the 1 m^2 plate surfaces were treated with 50 mL of water solutions of deltamethrin (12.5 mg AI/m^2) using a low-pressure sprayer. The procedure was repeated (two treatments) with fresh water solutions of the same insecticide. Untreated control surface was sprayed with water only (50 mL/m^2) following the same procedure. Temperature in the facility was 25±1°C and 60±5% r.h. throghout the experiment.

After deposits were dried (0 days deposit age), three glass rings (h=25 mm, R=55 mm) were placed to represent each treatment, each species and each duration of exposure. About 0.25 g of coarse wheat meal was placed into each ring and spread over ring area before 20 adults of *S. granarius* and 10 larvae of *P. interpunctella* were inserted (3 x 2 repetitions per each test species and each exposure). Ring edges were coated with paraffin after insect insertion and the rings lidded with plastic sieves to prevent insects escape. Insect mortality on deposits of different age (0, 7, 14 and 30 days) was estimated after 2, 7 and 14 days of insect exposure to treated porous surface and 7 days of recovery on untreated coarse wheat meal in the laboratory.

For cockroaches, according to principles described by Busvine (1971) and WHO (1999),

tests were performed on non-porous surface made of tile plates (33 x 33 cm) of around 1 m^2, previously cleaned, washed and dried. The plates were treated with 50 mL of water solutions of deltamethrin (12.5 mg AI/m^2) using a low-pressure sprayer. The procedure was repeated (two treatments) with fresh water solutions of the same insecticide. Untreated control surface was sprayed with water only (50 mL/m^2). After deposits were dried (0 days deposit age), 10 adults of *B. germanica* were put on treated surface and covered with three glass Petri dishes (h=2 cm, R=15 cm) (3 x 2 repetitions). Insect mortality on deposits of different age (0, 14, 30 and 45 days) was estimated after 30 minutes (non-choice exposure), and 24 and 48 hours of lab recovery with addition of coarse wheat meal.

Data analysis

Mortality data were initially corrected as suggested by Abbott (1925) and then analyzed using one-way ANOVA. Means were separated by Fisher's LSD test at P=0.05 (Sokal & Rohlf, 1995). Before analysis, mortality percentages were transformed using *arcsine*. However, untransformed means and standard deviations are shown in tables.

3. Results

Sitophilus granarius

The residual efficacy of deltamethrin after 2 days of adult exposure to porous surface was 0%, on deposits of all ages (0-30 days) (Table 1). After 7 and 14 days of exposure, deltamethrin efficacy was 100%, also on deposits of all ages (0-30 days). After seven days of recovery on untreated wheat in the laboratory, the mortality of adults in all treatment variants was 100%, including the variant of 2 days of exposure.

Plodia interpunctella

After 2 days of larval exposure to treated porous surface, deltamethrin achieved the highest efficacy (100%) on the 0-day deposit, while on 30 days old deposit it was 90%, with statistically significant differences (Table 2). After 7 and 14 days of larval exposure to deltamethrin deposits, residual efficacy were 100% in all treatament variants.

Blattella germanica

After 30 minutes of cockroach exposure to treated non-porous surfaces, deltamethrin achieved the highest paralysis (100%) on 0-45 days old deposits (Table 3). After 24 and 48 h of cockroaches recovery, deltamethhrin caused 100% adult mortality in all treatament variants, except in the variant of 24 h of recovery from exposure to 45 days old deposit when it was significantly lower, 97%.

Tab. 3 Paralysis/mortality (%) of *B. germanica* after 30 minutes of adult exposure to non-porous surface treated with deltamethrin (12.5 mg AI/m^2) and 24 h and 48 h recovery. For each exposure period separately, means within columns followed by the same letter are not significantly different, Fisher's LSD test at $P>0.05$. Where no letters exist, no significant differences were recorded.

4. Discussion

In reviewing analysis by Arthur (2012) we concluded that aerosols and contact insecticides are becoming good alternatives to the fumigant methyl bromide in flour mills, food production facilities and food warehouses. A number of later studies showed good potential of various contact insecticides after application on different surfaces in control of stored-product insect pests: e.g. malathion, pirimiphos-methyl and lambda-cyhalothrin against rice wevil *Sitophilus oryzae* (L.) (Jankov et al., 2013), spinetoram against stored-product beetle species (Vassilakos et al., 2014), cypermethrin and pirimiphos-methyl against *S. granarius* and *P. interpunctella* (Andrić et al., 2014) and two formulations of pirimiphos-methyl (EC and CS) against *S. granarius,* lesser grain borer *Rhyzopertha dominica* (F.) and confused flour beetle *Tribolium confusum* (Jacquelin duVal) (Rumbos et al., 2014).

The pyrethroid deltamethrin has been classified as a highly applicable insecticide, and is used for control of many arthropods, including cockroaches that are important in public health (Baur, 1991; WHO, 1984 i 2006; Mac Bean, 2012; Team of editors, 2016). Also, international research (Arthur 1997a,b; Kavallieratos et al., 2016) and studies in Serbia (Kljajić and Perić, 2006; Andrić et al., 2010; Pražić Golić et al., 2015) on the effects of different formulations of deltamethrin have shown that it is a highly effective insecticide in control of different stored-products species and cockroaches having notable residual efficacy (Arthur, 1997a,b and 2018; Kljajić and Perić 2009; Sims et al., 2010; Paudyal et al., 2016).

In our tests with laboratory populations of the stored-product insect pests *S. granarius* and *P. interpunctella*, deltamethrin applied to porous surface at a rate of 12.5 mg AI/m^2 reached its highest efficacy (100%) on up to 30 days old deposits after 7 and 14 days of adult and larval exposure before and after 7 days of recovery, including the 2 days exposure, only after 7 days of recovery. Also, in tests with *B. germanica*, in all treatament variants after 30 minutes of adults exposure to treated non-porous surface, deltamethrin achieved the highest paralysis of 100% on up to 45 days old deposits, and 100% adult mortality after 24 h and 48 h of recovery, except in the variant of 24 h of recovery after exposure to 45 days old deposit (97%). The results of our study showed that the pyrethroid deltamethrin with synergist piperonyl butoxide has high residual efficacy against the stored-product insects *S. granarius* and *P. interpunctella* after application on porous surface, and against the urban pest *B. germanica* on non-porous surface. These findings contribute significantly to the existing IPM programmes, showing that deltamethrin can be used simultaneously as a PPP and BP insecticide.

DOI 10.5073/jka.2018.463.189

In this communication, the insecticidal efficacy of Abamectin against *Tribolium castaneum* adults were evaluated in two sets of bioassays: In the 1st series of experiment, the effect of temperature was assessed on wheat treated at 0.01, 0.10, 0.25, 0.50, 0.75, 1.00 and 1.50 mg kg-1 at 20°C and 30°C, and 65%rh. The moisture content of the wheat ranged between 11.8 and 12.1%. Spraying was performed using a Badger 100 artists' airbrush (Franklin Park, IL, USA) on a stainless-steel tray in which 1 kg of wheat containing 5% (weight:weight) broken kernel was treated with 5 mL of an aqueous solution containing the appropriate volume of the EC formulation corresponding to each dose. Treated and untreated grains were kept into incubators at 30°C for 6 h to remove the excess moisture. After that, the grains were kept at 20 and 30°C and 65% rh in temperature-controlled incubators (Binder Model: KB 720) for 24 h for acclimatization to experimental conditions. For the experiment, eight samples of 60 g were obtained from each treated or untreated lots for each temperature and put into a cylindrical plastic vial (7 cm long × 5 cm diameter). Sixty (1-2 wk old) adults were placed in each vial containing treated wheat. There were 8 replicates for each exposure period and control. Adult mortality were recorded on 7th, 14th, and 21st d after treatment by reintroducing alive adults in the same vial while discarding the dead ones. At the end of the 21th d of exposure, all dead and alive adults were discarded, and the vials containing wheat only was returned to corresponding temperature-control.

The effectiveness of Spinetoram against red flour beetle, *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae)

Muhsin Yunus Derici, A. Guray Ferizli*, Mevlut Emekci

Ankara University, Faculty of Agriculture, Department of Plant Protection
*Corresponding author: ferizli@agri.ankara.edu.tr
DOI 10.5073/jka.2018.463.190

The data were analyzed, after arcsine transformation, with GLM-repeated measures (ANOVA) at a significance level of P less than 0.05 using Statistica version 7, and the means were compared with Tukey's HSD test. Arcsine transformed means were back transformed for presentation. Mortality was proportional to dose rate and exposure period. At 1 ppm dose rate, mortality at the end of 7th day was recorded as 34,44% and increased to 52.59% after 15 day of exposure. Mortality response was more pronounced at/above 1 ppm. Thus at 15th day of exposure, mortality rates were calculated as

3.33%, 52.59%, and 99,26 for 0,01, 1, and 10 ppm dose rate, respectively. F1 development was also proportional to dose rate and the population growth was suppressed by 99% and 100% at 5, and 10 ppm, respectively. Results show that the spinetoram can be effectively used for the control of stored grain insects.

The effectiveness of Spinetoram against maize weevil, *Sitophilus zeamais* Motschulsky (Coleoptera: Curculionidae): influence of dose, exposure interval, and temperature

Tugba Bayer, Mevlut Emekci, A. Guray Ferizli*

Ankara University, Faculty of Agriculture, Department of Plant Protection
*Corresponding author: ferizli@agri.ankara.edu.tr
DOI 10.5073/jka.2018.463.191

In this research, the effectiveness of Spinetoram was investigated against *Sitophilus zeamais* at three temperatures of 20, 25, and 30°C and 65%RH. Radiant 120 SC was selected to test the efficacy of Spinetoram. The formulation was applied to maize at the rates of 0.00, 0.01, 0.10, 0.25, 0.50, 0.75, 1.00, 2.00, 5.00, and 10.00 mg/kg using 9 replicates each. 50 g samples of treated maize were separately put into small PVC vials along with 30 adults. Mortality of insects were observed at 1st, 2nd, 3rd, 7th, 14th, 21st and 28th days after setting up the experiment. At the end of final count at 28th day, all individuals were removed and the test vials containing maize only were additionally kept for 50 days to determine the F1 development. Mortality rates increased along with temperature and exposure time. At the dose of 1 mg/kg, 66.68% and 97,08% adult mortality were obtained at 20 and 30°C, respectively. Similarly, at 25°C at the dose of 5 mg/kg, adult mortality were 71,89%, 98,89%, and 100% for 7, 14, and 21 days of exposure, respectively.

Postharvest Pest Management and Extension in Developing Countries

Postharvest knowledge, perceptions and practices of African small-scale maize and sorghum farmers

Abstract

Due to a single annual food production season in southern Africa, small-scale maize and sorghum farmers store grain until the next harvest. The farmers' postharvest knowledge, perceptions and practices (KPP) is important in reducing postharvest losses (PHLs); a key component of household food and nutritional security. Using random sampling, 310 farmers from two districts of Zimbabwe with contrasting agroecologies and agricultural systems (maize and sorghum) were interviewed to assess their KPP on post-production aspects. Maize and sorghum grain were stored in new and recycled polypropylene bags (93.5% and 42.6%) placed in ordinary rooms (44.5% and 27.1%), brick store houses (28.4% and 54.2%) and traditional huts (23.2% and 16.1), respectively. Farmers recognised field infestation as important source of insect infestation in sorghum (60%) but not in maize (21.3%). Synthetic commercial grain protectants were used more on maize (90.2%) than on sorghum grain (63.2%). Majority of farmers (> 75%) perceived these insecticides as both effective and safe to use. Farmers' household reserved grain ran out before the next harvest and was supplemented through buying grain or mealie-meal with cash, or exchanging grain with labour or livestock. Postharvest information and training were scarce in both systems. The study provides important information to extensionists, policy makers, development agents and researchers for reviewing and benchmarking extension services and farmer training requirements to effectively accelerate progress towards PHL reduction and contribute to household and national food and nutritional security.

Keywords: stored maize and sorghum grain; post-production practices, knowledge and perceptions; small-scale farmers; household survey.

Introduction

Maize is the staple crop in Southern Africa with dietary, economic, social and political importance (Mvumi et al., 1995; Tefera, 2012). Similarly, sorghum is one of second most important cereal staples in semi-arid areas of the region (Taylor, 2003). Stored product protection of these staple cereals is a key component of food and nutritional security largely missing in Africa (World Bank, 2011; Tefera, 2012). This is especially critical to more than 70% of southern African population that depend on unimodal rainy season for rain-fed crop production (Abbass et al., 2014). This means that the major cereal staple grain is harvested only once per year and farmers have to rely on their storage techniques and knowledge to preserve reserves during the long off-season lean-supply-high-demand period before the next harvest. Small-scale farmers are custodians of their household food harvesting, processing, storage and budgeting throughout this non-productive season.

Research has shown that grain is most vulnerable to rodent, moulding and insect pest attack during the storage period. In Southern Africa alone, independent reports from APHLIS and Worldbank show postharvest losses between 10 – 20% (World Bank, 2011; APHLIS, 2014) which is worth about

US$4 billion dollars (World Bank, 2011). After maturity, maize or sorghum grain undergoes various processing steps along the harvesting and postharvest chain of activities. Therefore, farmers' knowledge, perceptions and practices along this post-production chain are strong determinants of the level of losses incurred on-farm (Abbass et al., 2014). Since losses occur at various stages of the post-production chain (Tefera, 2012; APHLIS, 2014), it is imperative to study farmers' practices throughout the various post-production stages to identify major loss points that need redressing.

It has been more than two decades since the last published study that focussed on small-scale farmers' postharvest practices in Zimbabwe which revealed a lot of knowledge gaps (Mvumi et al., 1995). The objective of the current study was not only to compare and contrast the postharvest knowledge, perceptions and practices of maize and sorghum-based farming systems, but also to establish knowledge gaps considering the advances made in developing postharvest technologies in the last two decades. This is important to establish whether the status quo research and extension systems are effective in disseminating postharvest information for future curriculum and policy adjustments.

Materials and Methods

Study sites

The study was conducted in two districts in the semi-arid Insiza District (S20º.54'14.00"; E29º. 27'89.00") Matebeleland South province and the semi-humid Murehwa district (S17°. 64'99.97"; E31°.78'33.30") in Zimbabwe from March to June 2013. Insiza district is a sorghum-producing area, which typically receives an average rainfall of 450-650 mm annual rainfall while Murehwa district is a maize-producing area with a comparably higher average annual rainfall of 650-1,000 mm. Murehwa and Insiza districts lie in Zimbabwe agro-ecological zones II and V, described as intensive and extensive farming regions respectively due to huge differences in rainfall patterns and aridity (Mugandani et al., 2012; Muhoyi et al., 2014). This separates them into maize and sorghum farming areas respectively.

The study approach and data collection

A standard structured coded questionnaire was used for data collection using face to face interviews during the harvesting season (April-May 2014). In each district, four wards (Wards 1, 2, 17 & 19 for Insiza district and 8, 13, 16 and 28 for Murehwa district) were selected using a purposive sampling technique in consultation with agricultural extension staff. Prior to this study (2012 and 2013 storage seasons), under the same grant (UZ-RUFORUM postharvest project grant) farmers from wards 17 & 19 (Insiza District) and 13 & 28 (Murehwa District) were trained on good postharvest practices including pesticide use practices, proper mixing of grain and grain protectants, proper grain storage and insect pest identification and basic ecology. One hundred and fifty-five households were interviewed across all four wards (75 from trained wards and 75 from untrained wards and 3 reserve households for discard questionnaires) in each district, giving a total of 310 respondent households for the study. For the trained wards, households were purposely sampled following the list of participants (attendance lists), while a random sampling (every 5th household) was used for the untrained wards. Both researchers and trained extension staff conducted the interviews in local languages; Shona and Ndebele for Murehwa and Insiza districts respectively. In addition, field observations were used to collect anecdotal evidence where possible; farmers were asked to show researchers grain protectant containers, traditional harvesting equipment and/or techniques. Data were entered in CSPro 6.1 software for Windows 7 and IBM SPSS Statistics 23 was used for statistical analysis. Cross tabulation was used to determine associations between categorical factors and variables of interest through Wald's χ^2 tests at 95% Confidence Interval (CI).

Results

Demographics

More females (62.6%) were observed participating in maize grain postharvest than males (37.4%) whereas more males (68.4%) participated in sorghum postharvest activities (Tab. 1).

Tab. 1. Socio-economic characteristics of farmers from Murehwa and Insiza districts

Characteristic	District

*Zimbabwe Junior Certificate of Education (equivalent to Form 2 or two years of secondary education).

There were more middle aged farmers in Insiza compared to Murehwa. Trends in education were generally similar except that more farmers attained the generally recognised Ordinary level in Murehwa than in Insiza district. Land sizes are much bigger in Insiza (Tab. 1), but Murehwa (60.0%) farmers have more years (> 15 year) of farming experience compared to the Insiza farmers (35.5%).

Knowledge

In both districts, postharvest information was scarce and for the remote sorghum district, the government extension services were the major source of information (94.4%) compared to maize (68.7%) which supplemented by NGO trainings (22.7%) as well as private companies and research institutions (5.3%). Nevertheless, postharvest information was generally not recognised and not perceived as important by farmers from both systems. All farmers knew about grain varietal susceptibility to insect pest attack (85.5%) and (60.0%) for maize and sorghum respectively. However, farmers reported continuously using the more susceptible varieties for reasons of high yields and seed availability. More maize farmers (50.3%) knew about the newly arrived pest, the larger grain borer *Prostephanus truncatus* (Horn) compared to sorghum farmers (29.7%). However, the awareness was spatial depending on the wards that were trained ($\chi^2_{(8.1)} = 42.12$, $p < 0.001$) (maize) and ($\chi^2_{(8.1)} = 97.89$, $p < 0.001$) (sorghum) and gender in maize ($\chi^2_{(2.1)} = 13.69$, $p = 0.001$) but not sorghum) ($\chi^2_{(2.1)} = 1.73$, $p = 0.422$). This awareness was however, independent ($P > 0.001$) of education level, age and time of farming experience in both systems. Most farmers just knew the name 'LGB' but could not physically identify the pest. Almost all maize farmers believed that LGB was absent from their stores (78.1%) compared to about half (51.6%) in sorghum (the rest did not

answer the question or were not sure) although anecdotal evidence showed that some of the maize farmers had the LGB in their stored grain but unaware of it.

We assessed if farmers in trained wards had changed some of their traditional 'methods' as a result of the training. Tab. 2 shows the farmers' responses from both maize and sorghum

Tab. 2. Postharvest aspects changed by farmers after in the UZ-RUFORUM trained wards compared to farmers from non-trained wards

*Trained wards, 13 & 28 (maize); 17 & 19 (sorghum)
ǂNon-trained wards, 8 & 16 (maize); 1 & 2 (sorghum)

In both systems, most farmers reported having changed their timing and methods of some postharvest practices (see Tab. 2). Most of these farmers were from the wards previously trained in on good postharvest practices as confirmed by the positive significant association between the trained wards and changing a postharvest practice both in maize ($\chi^2_{(8.1)} = 47.89$, $p < 0.001$) and in sorghum ($\chi^2_{(8.1)} = 44.12$, $p < 0.001$) farming systems. Considerable proportion of 'no responses' to this question came from the –non-trained wards, since they mostly were not aware of any training.

Practices

Farmers harvested both maize (97.1% and sorghum (94.2%) between March and May every year. Due to relatively high rainfall, 83.6% of maize farmers harvested ≥ 0.5 tonnes, compared to 62.5% of farmers harvesting the same quantity of sorghum. From the field, maize was mainly transported using scotch carts (40.6%), wheelbarrows (31.3%), head-carrying (9.4%) or hired trucks (7.8%) and transport was reported as one of the major challenges. However, most sorghum farmers (78.7%) did not respond to how they carried their produce. Corresponding to their yields, more maize farmers (38.4%) retained more grain (300 – 1000kg) after harvest compared to sorghum respondents (29.7%) who retained the same amount of grain (Fig. 1). However, more sorghum farmers preferred to store more than a tonne of grain (Fig. 1) compared to maize farmers.

Although farmers in both districts did not generally sell their retained grain, the family reserved grain ran out more for sorghum (56.8%) than maize (37.4%) although sorghum farmers stored more. Reserved maize grain started running out starting in November (19.4%), peaking up in December (32.3%) and subsiding gradually in March, whereas for sorghum, grain started running out in March (19.7%) and peaking up in April (27.4%) and subsiding in May (9.4%) every season. Almost equal proportion of farmers supplemented their grain mainly by buying grain with cash from other farmers (35.5% and 37.1%) or buying mealie-meal (27.4% and 31.9% sorghum) for maize and sorghum respectively (Fig. 2). In the maize based system, exchanging grain with labour was more prominent (21.0%) whereas Non-Governmental Organisation (NGO) rations were perculiar in sorghum (6.0%) systems. Exchanging grain or mealie-meal for livestock was less common in both districts (see Fig. 2).

Before threshing and storage, sorghum farmers tested grain for storable moisture content mainly through biting (56.8%), crushing between fingers (29.0%) and by easiness of threshing (8.4%).

Although maize farmers also largely depended on biting (41.3%), a significant proportion also used experienced eyes (24.5%), the kernel sound method (14.8%), crushing (9.7%) and the salt method (6.5%). Maize grain was mostly stored in polypropylene bags (94.8%) which were new (23.2%), recycled (16.1%) or a mixture of both (54.2%). Most of these bags (78.7%) were placed on stones/bricks/timber dunnage in ordinary rooms (44.5%), brick and motor store houses (28.5%) or in traditional huts (23.0%) also used as cooking houses or 'kitchens'. However, only 45.8% of sorghum grain was stored in polypropylene bags in ordinary rooms, most of the farmers (54.2%) stored bulky grain in brick and motor storehouses (54.2%). Therefore, most farmers still largely stored their maize grain in in polypropylene bags (94.8%) in in ordinary rooms as previously reported by Nyagwaya et al. (2010). Unlike in maize, most sorghum farmers (54.2%) preferred storing their grain in bulk inside raised brick and motor storehouse compartments (54.2%) referred to as 'granaries'. Fewer farmers (45.8%) used polypropylene bags for grain storage.

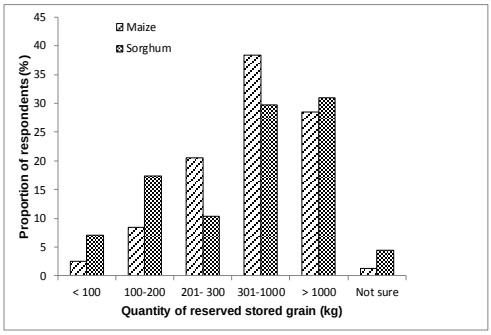

Fig. 1. The quantities of household consumption grain reserves stored by farmers in Murehwa (maize) and Insiza (sorghum) districts after a normal harvesting season.

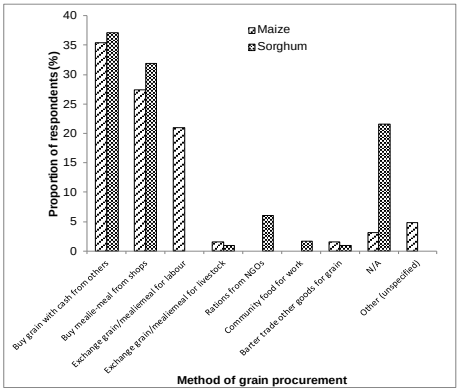

Fig. 2. Farmers methods of household grain procurement in Murehwa (maize) and Insiza (sorghum) districts.

The storage facility was significantly influenced by location (wards) ($\chi^2_{(12, 1)} = 65.146$, $p < 0.001$) and sex ($\chi^2_{(4, 1)} = 23.103$, $p < 0.001$). Commercial chemical grain protectants were mostly used (90.2%) to protect maize than sorghum (63.2%) grain (Fig. 3).

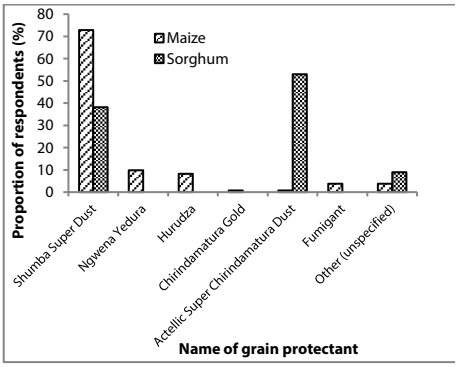

Fig. 3. Types of insecticides used by farmers within the previous five years in Murehwa (maize) and Insiza (sorghum) districts.

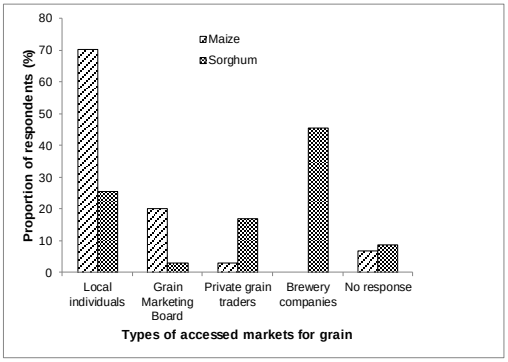

Fig. 4. The types of markets that farmers accessed by the farmers for selling their sorghum and maize grain in Insiza and Murehwa districts respectively

Farmers purchased commercial grain protectants from the local agro-dealer shops (78.0% and 67.9%) respectively for the maize and the sorghum farming systems. Only two insecticides were dominant in the sorghum area; Shumba Super Dust® (fenitrothion 1% + deltamethrin 0.13%) and

Actellic Super Chirindamatura Dust® (pirimiphos-methyl 1.6% w/w + permetrin 0.3% w/w. On the contrary, six registered grain protectants were recorded in the maize farming district, including Hurudza Grain Dust® (fenitrothion 1.7% w/w + deltamethrin 0.05% w/w) and Ngwena Yedura® (pirimiphos-methyl 2.5% w/w + deltamethrin 0.2% w/w) including the two already recorded for sorghum (Fig. 3). More maize farmers knew and had access to more pesticides than sorghum farmers because of their proximity to major cities. Farmers from both farming systems perceived chemicals as safe (94.7% and 76.9%) and effective (77.2% and 75.4%) for maize and sorghum respectively. In the contrary, a significant number of maize farmers (40.6%) reported that insect pests remained a problem post-chemical grain treatment compared to sorghum (23.9%), citing chemical ineffectiveness (15.5%) and improper insecticide use, which was more pronounced in maize (53.4%) than in sorghum (11.6%). Traditional grain protection methods were very minimal, 3.8% and 4.5% in both maize and sorghum respectively. The major postharvest pests for sorghum were quelea birds, *Quelea quelea* L. (81.9%), *Sitophilus species* (90.7%) and rodents (3.2%); while in maize, the major insect pests were *Sitophilus species* (91.0%). The larger grain borer was mentioned as a major pest by only 1.5% farmers in maize while *Tribolium casteneum* (1.3%) was mentioned by few farmers in sorghum.

Perceptions

Farmers perceived insect infestation as originating from the field (81.3%) from March and April when maize is between the hard dough stage and physiological maturity (63.2%). On the contrary, although sorghum farmers equally acknowledged field infestation initiating from the field (95.3%), they believed that infestation started much earlier (milky dough stage) (79.4%) from February to March than observed in maize. Correspondingly in storage, insect pests were first seen earlier (August) (8.4%) on sorghum grain and later (September) (10.3%) on maize. Likewise, peak insect pest populations were reported to occur earlier (September – December) (73.9%) for sorghum and slightly later (October- December) (63.3%) for maize. Farmers recognised and perceived pre-harvest field infestation as an important source of insect inoculum in stored sorghum (60%) but not in maize (21.3%). Apart from insect pests (91.0% and 67.1% for maize and sorghum; respectively), farmers from sorghum farming systems perceived labour shortage during harvesting time (56.8%), domestic and wild animals (11.0%) and poor prices (7.7%) as major postharvest challenges. In maize, most farmers perceived labour shortages at shelling (23.9%) and transport challenges from the field (12.9%) as major challenges while the bulk of farmers (45.8%) perceived having no notable challenges during the harvesting process. Types of markets accessed by the farmers differed with the type of grain that they produced (Fig. 4).

Most maize sold their maize grain to local individuals (70.3%) within their communities compared to sorghum (25.7%), whereas most sorghum was sold to the brewery companies (45.7%). Few farmers, 20.3 (maize) and 2.9 (sorghum) sold their grain to the government parastatal Grain Marketing Board (GMB) (see Fig. 4).

4. Discussion

More females participated in maize grain postharvest than males whereas more males participated in sorghum postharvest activities than females. This is attributed to ethnical differences in gender roles between the two tribes where grain processing is more of a female role (Mvumi et al., 1995; Manda and Mvumi, 2010) in some areas (tribes) than others in Zimbabwe. In addition, the maize district, Murehwa, is nearer to urban areas (Harare and Marondera) where males migrate to seek formal employment in the cities, leaving females in charge of farming activities whilst Insiza district is far from such urban areas. On the other hand, there were more middle aged farmers in Insiza compared to Murehwa, this may be explained by more early adolescent cross border migration to South Africa in Insiza district which borders Southern part of Zimbabwe with South Africa. Trends in education were generally similar except that more farmers attained the generally recognised Ordinary level in Murehwa than in Insiza district; again this is attributable to early adulthood

migration to South Africa before completing school dominant in Insiza District. Land sizes were much bigger in Insiza (Tab. 1) because farmers were resettled in this area by the Government of Zimbabwe whereas Murehwa was a traditional tribal trust land (generational landholdings) where land has been inherited from forefathers and partitioned continuously to current generations over the years, thus gradually dwindling in percapita landholdings as populations increased. This also explains why farmers have more years of farming experience in Murehwa than in Insiza, because they have traditionally been on the same land.

Although almost equal number of farmers from both maize and sorghum systems preferred to store 300-1000kg of grain as reserves for family consumption, more sorghum farmers preferred to store more than a tonne of grain compared to maize farmers. This is because the sorghum producing area is generally arid with low and unpredictable rainfall patterns and farmers store more grain to cushion against frequent droughts, whereas, in Murehwa district, farmers are cautious not to store more than a tonne to avoid storage losses due to insect pests, rodents and thieves. This compels farmers to sell part of their grain early, mainly to local individuals in exchange for cash, livestock or labour. The parastatal responsible for buying the grain, normally offers too low prices to attract both maize and sorghum farmers. Most sorghum farmers rely on the brewery companies (especially Ingwebu Breweries®) for market, which in some cases provides them with inputs under contract farming. Although most farmers from both farming systems stored considerable amount of grain, most farmers ran out of grain before the next harvest without extra income sources for cash requirements to buy grain. New postharvest technologies that could increase the stored grain per household have been introduced in some parts of Zimbabwe (Chigoverah and Mvumi, 2016; Mlambo et al, 2017), most farmers have limited access to this information including new storage technologies and the high cost associated with new technologies (Mvumi, 1997; Nukenine, 2010).

The significant positive correlation between trained wards and changes in postharvest practices and knowledge about the P. truncates suggests that our farmer trainings in the previous 2 seasons were to a larger extent, effective. Majority of farmers from untrained wards in both districts were not aware of any postharvest training. This showed that there is need for huge investment in farmer training to cover as many farmers in as many areas as possible since farmers do not seem to freely share postharvest information even when trained (Mvumi, 1997). The scarcity of postharvest information also shows that dynamics and modern changes in postharvest activities, grain protectants, innovations, stored product insect ecology and research have not been closely followed up by the relevant postharvest technical back-stopping support to improve and update farmers and extension staff knowledge and skills on stored product pest control (Larsen and LilleØr, 2014, Chigoverah and Mvumi, 2016). In addition, postproduction activities have comparably received little institutional and extension efforts (Mvumi, 1997; Abass et al., 2014), limited research investment and limited publication of research results, especially in Southern Africa (Mvumi, 1997; Larsen and LilleØr, 2014; Mvumi and Stathers, 2015; Affognon et al., 2015).

In the maize-based farming system, we recommend the introduction of chemical-free hermetic storage systems such as hermetic bags, cocoons and metal silos to address storage pests and pesticide mis/overuse challenges. Hand-operated shellers and cheap produce transporting systems are also necessary to reduce labour bottlenecks during shelling and transportation for both systems. In the sorghum farming system, we recommend early harvesting to avoid extensive bird damage (Mutisya et al., 2016). There is also need to explore the possible use of new bird-scaring techniques such as the Unmanned Aerial Vehicles (UAV) popularly known as 'drones' to reduce losses by quelea birds. However, benefit-cost analysis will be essential to determine viability of such investments and the potential for wide-spread use of the technology under small scale conditions.

Acknowledgements

The authors are grateful to the Regional Universities Forum for Capacity Building in Agriculture (RUFORUM) (Grant No: RU2011GRG01) for funding the study. We also acknowledge the technical

and logistical support received from the agricultural extension staff from the Ministry of Agriculture, Mechanisation and Irrigation Development in Murehwa and Insiza districts during the surveys.

Abstract

Maize needs to be stored using good and safe postharvest management measures that will maintain the quality as at harvest. Insects and moisture must be controlled in storage to ensure quality and methods to achieve this, such as the use of reduced-risk measures were evaluated in this study, conducted February–December 2016. The efficacy of Bularafa diatomaceous earth (DE), *Piper guineense* (Botanical), PICS bags, ZeroFly® bags and permethrin (Rambo™) in preserving maize quality in Nigerian markets was assessed. A sixth treatment comprised maize in untreated polypropylene bags. Study locations were in four markets in Ibadan, Ilorin and Oyo towns. Each market had a storehouse, which contained experimental 100-kg bags. In each storehouse, each technology

had six bags, which were all sampled monthly except in PICS treatment where six bags were destructively sampled every four months. Data taken in February) and December) showed that quality of maize in PICS bags was best having the lowest percentage of insect damaged kernels, numerical based (%IDKNB), — 0.01 ± 0.01and 0.02 ± 0.01; %IDKWB— weight based were 0.00 ± 0.00 and 0.00 ± 0.00); % weight loss (0.01 ± 0.01; 0.01 ± 0.01), % number of discolored maize (0.02 ± 0.01; 0.01 ± 0.01) and % seed germination (96.77 ± 0.53; 98.37 ± 0.35) respectively. Treated and untreated maize had mean aflatoxin levels below limit of detection of 5 ppb in February and December (0.47 and 1.66), respectively and their proximate composition were within ranges reported in literature. By December, untreated maize had the highest %IDKNB (1.42 ± 0.22), %IDKWB (1.07 ± 0.18), % weight loss (0.36 ± 0.07) and lowest % seed germination (88.09 ± 0.98) when compared to the evaluated storage technologies Therefore, these five technologies can be incorporated in integrated management of storage insect pests in storehouses.

Keywords*:* Insect damage, Weight loss, Aflatoxin, Seed germination, Proximate composition.

Introduction

Maize (*Zea mays* L.) is an important cereal which ranks third in global production/consumption after wheat and rice (Asghar et al., 2010). It is a major cereal for livestock feed and human nutrition. It is also an important raw material for several agro-based industries (Akande and Lamidi, 2006). In addition, in a market that is not controlled, the value of any surplus maize in good condition tends to rise during the off-season period (Nagaraj et al., 2016); meaning maize can be an important cash crop. Maize has the disadvantage of being harvested in the wet season; hence, prone to damage by microorganisms in addition to the problems of insect infestation.

Sitophilus zeamais is a serious cosmopolitan field-to-store pest of maize in tropical and subtropical regions (Hagstrum et al., 2012). Damage caused by the insect becomes noticeable after the adult insect makes holes and deposits its eggs within the hole. Developmental stages of the insect take place within the grain after which the adult weevil bores its way out, leaving a characteristic emergence hole on the grain (Rees, 2004). In developing countries, maize production and consumption often falls below demand as a result of post-harvest losses due to storage pests and other agents (Aulakh et al., 2013). Post-harvest losses due to *S. zeamais* have been reported as an important constraint to grain storage in Africa (Edelduok et al., 2015), these losses threaten household food security and reduced market returns making stakeholders seek any type of option for protecting their grain during storage (Stathers et al., 2008). Despite success in controlling insect pests using synthetic insecticides, their persistence in the environment, the toxic residues they leave in food and development of resistance by insect pests require that more reduced-risk alternatives be sought (Ileke and Oni, 2011).

During storage, grain quality can remain at the initial level or decline to a level that may make it unacceptable for both food and planting purposes. This decline is due to many determinants: adverse environmental conditions during seed production and storage, pests (insects, rodents and micro-organisms), high moisture content, mechanical damage during threshing, long duration of storage, bad packaging, pesticides and biochemical injury of grain tissue (Jyoti and Malik, 2013).

Moreover, the change in color of seed grains, protein and carbohydrate degradation, and the production of mycotoxin reduce the quality of stored grains, and endanger human health (Pimentel et al., 2011). The preservation of quality and nutritional value of grain during the period of storage depends not only on the conditions of production and harvesting, but also on the maintenance of appropriate storage conditions of the grain.

Presently in Nigeria, control of insect pests in stored food products, maize inclusive, is by the use of synthetic insecticides which have some hazards such as pollution of the environment, toxic residues in stored grains, development of resistance in target species, pest resurgence, lethal effects on non-target organisms, direct toxicity to users and other health hazards in addition to the high cost of the insecticide cum inadequate skills in application, (Adedire et al., 2011). However, there are reduced-risk technologies such as botanicals (e.g. *Piper guineense* (Schum & Thonn), diatomaceous earths (DE), Purdue Improved Crop Storage (PICS) bags and ZeroFly® Storage Bags (hereafter referred to as ZeroFly bag) that are available in sub-Saharan Africa and can be used for proper preservation of

grains without the negative effects associated with pesticides. Botanical such as *P. guineense,* which are inexpensive, relatively safe, and poses little or no hazard to human health and the environment have been used for postharvest insect pest control in grains (Asawalam et al., 2007; Otitodun et al, 2015).

Despite the fact that there are reduced-risk technologies available for grain preservation in sub-Saharan Africa, there is little information available on how effective these technologies are for preservation of grains such as maize in storage. This means it is important to evaluate the effectiveness of these reduced-risk technologies in the field. Therefore, the objective of this study was to evaluate five storage technologies — a botanical (*P. guineense*), Bularafa DE, PICS, ZeroFly® bag and permethrin (Rambo™) — to preserve the quality of maize in Nigerian markets.

Materials and Methods

Study Sites

The experiment was conducted during the period February–December 2016 in storehouses located in three grain markets — Eleekara market in Oyo and Arisekola market in Ibadan, Nigeria and Old Ago market in Ilorin, North Central Nigeria.

Maize Samples

Maize used for the experiment was obtained from Ijaye Farm Settlement in Akinyele Local Government Area, Ibadan Oyo State. The variety known as SWAN 2 is widely grown in Southwest Nigeria; Farmers in the settlement had applied aflasafe™ in fields used to produce maize for this study. Aflasafe contains a mixture of four atoxigenic strains of *Aspergillus flavus* of Nigeria origin (Agresults Online). Initial maize moisture content was determined by the ASABE. Maize was fumigated before use to ensure that there was no field to store transfer of insect pests. Fumigation was conducted at the Nigerian Stored Products Research Institute (NSPRI), Ilorin, Nigeria.

Storage Technologies (treatments)

Maize was stored for 11 months using five storage technologies — ZeroFly bags, PICS bags, diatomaceous earth (Bularafa DE), a botanical (*P. guineense*) and permethrin (Rambo™) — to assess their effectiveness in controlling stored product insect pests and were compared with untreated control.

Methodology

In each storehouse six 100-kg maize-filled bags were assigned to ZeroFly, DE, Botanical, Rambo and untreated control; each stack of six bags was on a separate pallet. Sixteen bags were assigned to PICS arranged on four pallets. Bags on pallets were arranged in such a way that they formed two layers. The pallets for each treatment were placed 1 m apart from each other. There were forty-six 100-kg bags per storehouse

The experimental design used was randomized complete block design (RCBD) with four replications and six sub-replications. Each market represented a replication.

Samples of maize were obtained using a 1.2-m open-ended Trier (grain probe) (Seedburo Equipment, Chicago, IL) with six openings, total of 700 g was taken from each bag during each sampling event.

In the PICS treatment, six bags were destructively sampled every 4 months — 1 bag with a sensor and 5 bags without sensors. The six bags to be sampled were randomly selected at the beginning of the study using randomization software

Seed germination, insect damaged kernels, weight loss and maize discoloration were determined monthly, Nutritional composition of maize (Proximate analysis) was determined at 4 months' intervals while aflatoxin levels were determined at the begining and end of the study.

Statistical Analyses

Statistical analyses were performed with SAS Version 9.3 (SAS Institute, Cary, NC). Treatment effects were assessed using analysis of variance methods (PROC MIXED). A repeated measures model in a randomized complete block design was utilized, with market as the blocking factor and month as the repeated factor. An autoregressive covariance structure was used to model the correlations within treatment and across months. An analysis of the aflatoxin level was conducted with the use of a square root transformation. A square root transformation was used to correct for heterogeneous variances and the lack of normality of the count response variable. The simple effects of treatment given month were assessed with protected planned contrasts (SLICE option in an LSMEANS statement). In the case of percent insect damaged kernel, weight loss, seed germination, discoloured grain and proximate composition, data analyses were conducted with the use of an arcsine transformation to stabilize variances but untransformed percentages are reported.

Results

Results presented on the study are in two categories; study involving four treatments (Botanical, DE, Rambo and ZeroFly) and study involving five treatments (Botanical, DE, PICS, Rambo and ZeroFly).

Percent number of insect damaged kernels (%IDKNB), weight of insect damaged kernels (%IDKWB), weight loss (%WL), seed germination (%SG), discolored grains (%DG), aflatoxin levels (AF) and proximate composition of maize preserved in Nigeria market with four treatments

In the study involving 4 treatments, mean values for %IDKNB, %IDKWB and %WL was significantly low in Rambo treatment by December, followed by DE, ZeroFly and Botanical compared to untreated control with the highest mean values (1.42 ± 0.22; 1.07 ± 0.18 and 0.36 ± 0.07), respectively (Fig 1A–C). Furthermore, in December, mean %SG was significantly high in all treatments (>96%) compared to untreated control with significantly low value — 88.09% (Fig. 2). With respect to %DG from March to December, ANOVA result shows no significant interaction between month and treatment and treatment alone (P>0.05) while significant difference occured in %DG within the months (Tab. 1).

Percent number of insect damaged kernels (%IDKNB), weight of insect damaged kernels (%IDKWB), weight loss (%WL, seed germination (%SG), discolored grains (%DG), aflatoxin levels (AF) and proximate composition of maize preserved in Nigeria market with five treatments

In the study involving 5 treatments, mean values of %IDKNB, %IDKWB and %WL were significantly low by December in PICS treatment, followed by Rambo, DE, ZeroFly and Botanical compared to untreated control with the highest mean values (1.42 ± 0.22; 1.07 ± 0.18 and 0.36 ± 0.07), respectively (Fig 3A–C). Also in December, mean %SG was significantly high in all treatments (>96%) compared to untreated control with significantly low value — 88.09% (Fig. 4A); significantly low mean values of %DC was recorded in PICS (Fig. 4B); aflatoxin estimates in maize samples from all treatments and untreated control was below 2ppb (Fig. 4C): Proximate composition values was within recommended range for maize (Tab. 2; Fig 5A–C).

Discussion

Quality of stored maize is dependent on activities of associated insect pests. It is their feeding activity that brings about losses such as insect damaged kernels, loss in grain weight, reduced seed viability and mold growth amongst others. Grading is therefore based on these physical parameters (World Bank and FAO, 2011).

Our investigation showed that insect damaged kernels and weight loss tend to increase as month of storage increases. This could be attributed to increase in insect activities with length of storage time. This observation corroborates the report by Reed et al., (2007) that insect infestation can result, not only in grain damage as understood by shorter storage times, but can also affect the actual weight of the grain, leading to lower market prices and reduction in nutritional value of the grain.

In the five treatment study, PICS had the lowest % IDKNB, % IDKWB, weight loss and moisture content by December, after 11 months of storage (0.02, 0.00, 0.01 and 8.6%). This result confirmed earlier observations reported by Baoua et al., (2014) and Mutungi et al., (2014) that grain damage due to insect and grain weight loss is relatively lower in PICS compared to other tested grain bags because oxygen level has been depleted. High seed germination was also maintained.

In the four treatment study, Rambo treatment had the lowest % IDKNB, % IDKWB, weight loss and moisture content by December, after 11 months of storage (0.19, 0.14 and 0.05% respectively) compared with botanical, DE and ZeroFly. This could be attributed to the active ingredient Permethrin, which has been reported to affect insect nervous system by creating multiple potentials across the membrane and disrupt signal transmission in the insect (Bonny et al., 2014).

In both studies, ZeroFly bags had significantly lower values for percent IDK and weight loss with increasing storage period compared with untreated control. For example, by December in the study involving four treatments, IDKNB, IDKWB and weight loss for ZeroFly was 0.58, 0.43 and 0.15% compared to untreated control with 1.42, 1.07 and 0.36% respectively. This could be attributed to reduction in insect activities as reported by Paudyal et al., (2017) that ZeroFly bag can cause direct effects on knockdown and mortality and sub lethal effects such as reduced progeny production.

Other treatments like DE and botanical also affected insect activities in one way or the other, which invariably led to reduction in IDK, weight loss and maintained seed germination compared to untreated control. Rajapakse, 2006 reported that major action of plant powder against adult insect is through either fumigation or direct contact. Although storage of botanical treated maize in polythene lined bags could possibly improve its efficacy. Diatomaceous earth on the other hand, works by physical abrasion and adsorption of the epicuticular wax of insects by silica (Athanassiou and Steenberg, 2007; Otitodun et al., 2015).

Aflatoxin is one of the most common and important mycotoxins found in maize (Suleiman et al., 2013). Despite the fact that a significant increase was observed in aflatoxin levels from February through December, the values were all below detection limit of 5 ppb for maize meant for further processing (USDA-GIPSA, 2015).

The proximate composition results are in agreement with reports by some scientists. For example, in our study, the moisture content was observed to increase with month of storage; this consequently led to increase in both percent number and weight of IDK in control treatment. This observation corroborated the report by Child, (2007) that when a combination of favorable factors leads to increased insect development there is a co-related increase in the damage to materials through eating, despoiling, burrowing and other activities. Additionally, high moisture content leads to storage problems, respiration and reduction in germination (Suma et al., 2013). The percentage ash content observed in our study ranged between 1.10–1.59%. This is in agreement with the range of 0.70–2.50% reported from different maize hybrids in Nigeria (Keshun, 2009). The percentage protein recorded was found closely related to those reported on different maize varieties in Nigeria. In 2005, Ijabadeniyi and Adebolu reported protein content of three maize varieties grown in Nigeria within the range of 7.71–14.60%. Although some values were found a little higher and can be attributed to environmental factors. Yadav and Yadav, (2002) from their

investigation reported fat content from stored maize to range between 3.98–5.45%. This confirmed the fat content range of 4.54–5.73% recorded from all the treatments and control in our study to be adequate; samples from ZeroFly bags had the highest fat content (5.73%) by December. The crude fibre value of 1.29–2.20% obtained from all samples is in agreement with the report on stored maize by Aminogo and Oguntunde (2000) where they observed crude fibre to be in the range of 0.8–2.35%. Maize is known and reported to be high in carbohydrate and as such, it is a good source of calories (Nuss and Tanumihardjo, 2011). Carbohydrate content of the maize studied was found to be within the range of 72–73% and corroborate report on stored maize varieties by Mlay et al., (2005) and 69.67–74.55% as reported by Ullah et al., (2010).

In developing countries, especially in Nigeria, where maize production is mostly by low-resource and unskilled farmers, affordable and easy to use storage measures needs to be advocated to reduce postharvest losses. Based on results from our study, using better agricultural practices and adequate storage technologies can significantly reduce quality losses attributed to insect activities and help strengthen food security, poverty alleviation and increase returns to small holder farmers and aggregators. Therefore, use of easy to apply and reduced-risk storage technologies such as botanicals (*P. guineense*), diatomaceous earths (Bularafa DE), PICS bag, and ZeroFly bag are recommended to small and medium holder farmers and grain aggregators for storage of maize in Nigeria. However, further work would be required to access the duration of insecticidal action of botanical treated maize stored in polythene lined polypropylene bags.

Abstract

The severity of postharvest losses varies considerably depending on storage method and prevalence of storage insect pests known to bore into storage bags. Polypropylene (PP) bags used by smallholder farmers in Nigeria do not provide effective protection for stored produce due to insect boring activities. Deltamethrin incorporated polypropylene, ZeroFly® (ZF) and ZeroFly® Hermetic Storage Bags are technologies with potential to improve protection of stored food commodities against insect attack. Therefore, a 12-month study was conducted in Ibadan, Nigeria to determine the suitability and potential of combined postharvest bag technologies involving ZeroFly® (hermetic and non-hermetic) bags for smallholder farmers when exposed to *Sitophilus zeamais* and *Prostephanus truncatus* infestation pressure. Cleaned but un-fumigated 50-kg lots of maize were used to fill bags in each of the following 8 treatments — PP and ZF bags alone, diatomaceous earth-treated maize in PP and ZF bags, single and double hermetic liners in ZF bags, single hermetic liner in PP bags and lastly PICS bags. Results obtained over a 12-month period showed infestation by *S. zeamais*, *Tribolium castaneum*, *Cryptolestes ferrugineus* and *Liposcelis* spp and abundance of insect increased with storage period in PP and ZF bags without liner. The percentages of insect damaged kernels by number (IDK) were higher in PP and ZF bags without liner and were 5.4 and 16.9%, respectively; in ZeroFly bags with hermetic liners, these values were ~ 0.5%. The PP and ZF bags without liner also had higher weight loss values of 1.4 and 6.7%, respectively compared with ZeroFly bags with hermetic liners and PICS bags which had a relatively lower weight loss of ≤0.2%. These results indicate that the ZeroFly Hermetic bag mitigates insect infestations, thereby offering a suitable alternative towards achieving significant reduction in postharvest losses during storage.

Keywords: maize storage, ZeroFly® Hermetic bag, smallholder farmer, postharvest loss, integrated pest management

1. Introduction

Maize (*Zea mays* L.) is the most widely cultivated staple food that plays a key role in the food security and economic well-being of sub-Saharan Africa (SSA) population (Abate *et al.,* 2017). With more than 5 million ha of land planted with maize annually, Nigeria is the second largest producer after South Africa, in the continent of Africa and produces nearly 8 million tons annually (Abate *et al.,* 2015). The bulk of this production in Nigeria is by smallholder farmers who face numerous challenges after their grains are harvested from the field (Abdoulaye *et al.,* 2016). Postharvest storage has been indicated as a major constraint in the maize sector in West Africa (Baoua *et al.,* 2014) and every year across sub-Saharan Africa, unacceptable levels of food loss continue to occur (Costa, 2014). These losses are dependent not only on the management practices of the farmers but also on environmental conditions and prevalence of post-harvest insect pests. The larger grain borer (LGB) (*Prostephanus truncatus* (Horn); Coleoptera: Bostrichidae) along with maize weevil (*Sitophilus zeamais* Motschulsky; Coleoptera: Curculionidae) are the major insect threats to stored maize in Africa (Holst, 2000). Losses due to post-harvest pests of maize are estimated to average between 20 and 30% after 3 months of storage (Boxall, 2002). For *S. zeamais* and *P. truncatus* infestations, losses

of 21.5% have been estimated after 6.5 months of storage in woven polypropylene bag (Baoua *et al.,* 2014). Currently, the control of stored grain insect pests is predominantly by the use of chemical insecticides including fumigants (Ceruti *et al.,* 2008); this is the case in Nigeria and worldwide. Storage pests are fast developing resistance to phosphine (Lee *et al.,* 2001). Alternative control methods to reduce insecticide persistence or toxic residues in food and pest resistance are being sought (Ileke and Oni, 2011) and have encouraged the return and development of inert dust formulations (Korunic, 1998). Treatment with diatomaceous earth (DE) dust is an efficient insect control technique in integrated pest management programs of stored grain (Ceruti *et al.,* 2008). As DEs are inert, they offer long term effectiveness, are safe for consumption, and do not adversely affect grain quality (Korunic *et al*., 1996). Polypropylene woven storage bags remain the conventional method of maize storage for smallholder farmers in Nigeria, which shows that bag technologies are culturally acceptable (Abdoulaye *et al.,* 2016). Due to the boring activities of insects into materials such as plastic films, adults of *P. truncatus* (Hodges, 1986; Ramirez Martinez and Silver, 1983) and *Rhyzopertha dominica* (F.) (Coleoptera: Bostrichidae) (Riudavets *et al.,* 2007) may find it easy to penetrate untreated bags used to protect stored grains and cause damaging infestations. Consequently, the use of insecticide-treated bags has been recognized as a possible alternative to direct treatment of grains (Kavallieratos *et al.,* 2017). The deltamethrin incorporated polypropylene (PP) bag, ZeroFly® Storage Bag, is a new technology used to reduce postharvest losses caused by stored-product insect pests. Additionally, the ZeroFly® Hermetic Storage Bag is a novel technology that protects grains and seeds stored in it against both external and internal insect attacks. The ZeroFly® Hermetic Storage Bag is made of an outer woven deltamethrin incorporated polypropylene bag and an 80-µm thick multilayered recyclable mixed polymer hermetic inner-liner with a gas barrier. The use of hermetic grain bags to preserve durable commodities such as grains is practiced in several countries (De Bruin *et al.,* 2012). Hermetic storage bags such as the Purdue Improved Crop Storage (PICS) and SuperGrain bags have been evaluated in previous studies and found to be effective technologies for protection of stored grains (Baoua *et al.,* 2013; William *et al.,* 2017).

Based on the information provided above, a 12-month study was conducted to investigate the suitability and optimal use of combined postharvest bag storage technologies (hermetic and non-hermetic) in the presence of external *S. zeamais* and *P. truncatus* infestation pressure. This study was conducted in a storehouse, located within Arisekola-Bodija market (7°25′59 N, 3°54′43 Ë) Ibadan, Oyo State, Nigeria during the period February 2017 to January 2018.

2. Materials and Methods

2.1. Maize

A yellow variety maize called 'Swan 2' sourced from a single local farm at the Ijaye Farm Settlement (07°42′13 N, 3°44′10 E) Ibadan, Oyo State was used in order to ensure uniformity of maize used for the study. The moisture content of the maize ranged between 11–13% based on measurements by the John Deere moisture meter (SW08120, Illinois, US).

2.2. Treatments

The maize used was cleaned and un-fumigated. Batches of 50 kg of maize were placed individually in bags according to the various treatments as follows: i) three polypropylene (PP) bags filled with untreated maize; ii) three PP bags filled with Insecto® (Insecto Natural Products, Costa Mesa, California, USA) diatomaceous earth–treated maize (hereafter this treatment is referred to as PPDE bags). The diatomaceous earth (DE) was admixed at a rate of 50 g per 50–kg bag of maize (i.e. at a rate of 0.1% w/w or 1,000 ppm) (Nwaubani *et al*., 2014); iii) nine triple layer PICS bags filled with untreated maize; iv) nine PP bags, each with a single hermetic liner (80 µm thick) filled with untreated maize (hereafter referred to as PP + 1 liner bag); v) three deltamethrin incorporated PP bags (ZeroFly® Storage bags) filled with untreated maize, hereafter referred to as ZF bags; vi) three

ZeroFly storage bags filled with Insecto® diatomaceous earth-treated maize filled (hereafter this treatment is referred to as ZFDE bags); vii) nine ZeroFly storage bags, with each having two PICS bag hermetic inner liners, filled with untreated maize (hereafter referred to as ZF + 2 liners bags) and viii) nine ZeroFly storage bags, with each having a single hermetic liner, filled with untreated maize (hereafter referred to as ZF + 1 liner bag).

2.3. Set up of treatments

For the different treatments there were three sub-replicates for each sampling event. Each stack of three or nine bags was placed on a wooden pallet (1.5 m x 1.5 m); pallets for the different treatments were a minimum distance of 2 meters apart from each another. Treatments involving ZeroFly storage bags were arranged on one side of the storehouse whereas PP bags of maize were set up on the opposite side to prevent ZF bags from influencing conditions immediately around PP bags. Altogether, there were forty-eight 50–kg bags of maize placed in the storehouse. Treatments in this study were not replicated but there are plans to conduct another two replicates in short order.

2.4. Storehouse infestation with Prostephanus truncatus and Sitophilus zeamais

Eight vials containing 100 g of maize each were infested with 20 unsexed, newly emerged adults of *P. truncatus* and *S. zeamais* separately in the laboratory and cultured for 1.5 months. The vials containing the adults and presumably the immature stages were placed in the storehouse, near pallets containing the eight treatments to create the required pest pressure on the storage bags. This procedure was repeated every 4 months.

2.5. Sampling and data collection

Bags of maize were sampled at the beginning of the study in February 2017. Monthly sampling was thereafter conducted on all 3 bags of each non-hermetic treatment (PP, PP + DE, ZF, and ZF + DE) from March 2017 to January 2018. For the hermetic treatments, three bags from each of the nine bags were randomly selected and destructively sampled after 4, 8 and 12 months — these treatments were PICS, PP + 1 liner, ZF + 1 liner, and ZF + 2 liners.

2.5.1. Moisture content

Moisture content in each bag sampled was estimated using four moisture measurement methods namely; i) a low cost moisture meter by the USDA-ARS Center for Grain and Animal Health Research, Manhattan KS, referred to in this study as the PHL meter, ii) a GIPSA-approved method (GAC 2100 Agri, DICKEY-john Corp., Auburn, IL.), iii) a commercial meter, the John Deere Moisture Chek PLUS, model SW08120 (AgraTronix Streestboro, Ohio), and iv) a standard oven-dry test method (ASABE standards). The average of three different readings with each meter, from each bag was calculated.

2.5.2. Grain sampling

A brass grain probe (1.2-m open-ended trier) (Seedburo Equipment, Chicago, IL) was used to sample maize and a composite sample of ~ 350 g was taken from each bag and placed in a labeled Ziploc plastic bag for analyses. For each of the samples collected, data on number of insects of each species, percentage number and weight of insect damaged kernels (IDK), weight loss, seed germinability were taken. All maize samples collected were analyzed at Entomology Research Laboratory, Department of Zoology, University of Ibadan, Nigeria. The samples were sifted using a U.S. Standard #10 sieve (2 mm openings) (Seedburo Equipment, Chicago IL) on to a tray to recover both live and or dead insects. The species of insects were identified using a tripod magnifying lens and their numbers were recorded. A 250–g sub-sample was poured on a tray and kernels were examined visually. Kernels with insect exit holes or perforations were separated from undamaged kernels and the numbers in each category were recorded. Percentage of insect damaged kernels

(IDK) by numerical basis (IDKnb) and by weight basis (IDKwb) were calculated per 250-g sample (FAO): the method of Quitco and Quindoza (1986) was used:

Percentage IDK (nb) = $\frac{Nd}{Total\ grain\ count} \times 100$; Percentage IDK (wb) = $\frac{Wd}{250} \times 100$

Where, Nd = Number damaged grain, Wd = Weight of damaged grain

2.5.3. Weight loss (%)

Weight loss due to insect damage was determined using the "count and weigh" method (Gwimmer *et al.,* 1996) and calculated as: % Weight loss = $\frac{[(Wu \times Nd) - (Wd \times Nu)]}{Wu \times (Nd + Nu)} \times 100$

Where, Wu is the weight of undamaged kernels, Nu is the number of undamaged kernels, Wd is the weight of damaged kernel and Nd is the number damaged.

2.5.4**.** Seed germinability (%)

Germination tests were conducted using the method of Baoua *et al.* (2014) with little modification — from each 250–g maize sub-sample previously referred to above, one hundred seeds were picked and 25 seeds were then placed in each of four petri-dishes that had moistened cotton sheets at their bases. The seeds were re-wetted and percent germination was determined after 5–7 days based on the number of seeds that sprouted.

Data were summarized using the SPSS version 20 software to evaluate means of the various response variables.

3. Results

The lack of replication in this study means analysis of variance (ANOVA) could not be conducted. Therefore, information presented in the results section describes only numerical differences between means based on three sub-replicates of each treatment, for each sampling event and not statistical differences. Information in this section also highlights notable patterns in the various response variables that were investigated.

3.1. Moisture content

There was a ≤4% offset in the MC measure by the PHL, JD and GAC2100 meter compared to the oven-dry reference test. MC measurement for the PHL meter ranged from 11–15%; JD meter ranged from 12.5–15.3%; Oven-dry test ranged from 10.6–13% and GAC 2100 meter ranged from 11–14.4% based on data collected during the 12 months of the study, in all the treatments.

3.2. Insect infestation level

3.2.1. Sitophilus zeamais

The pattern for numbers of *S. zeamais* found in the different treatments during the study are shown in Figs. 1 and 2. Live weevil population grew progressively in the PP bags but grew more in the ZF bags after 5 months of storage (during and after June). The number of live *S. zeamais* was higher in ZF bags where 124 insects were found in October but this number decreased to 52 in January (Fig. 1A). There were no live adult *S. zeamais* in the PPDE and ZFDE samples during the first eight months of the study. In the ZFDE treatment, numbers of live *S. zeamais* did not increase substantially during the entire storage period. In the case of PPDE treatment, numbers of live weevil in bags did not exceed 2 during the period February to October, but the number increased numerically to 31 at the end of the experiment in January. On the other hand, the numbers of dead *S. zeamais* were numerically higher in the ZF bags than in the other three treatments except in October where more dead insects were found in PP bags (Fig. 1B). An average of 33 dead weevils per sample were found in ZF bags at the end of 12 months of storage, in January 2018 (Fig. 1B).

For the hermetic treatments, very low numbers of *S. zeamais* were found and did not exceed a mean of 4 in any of the four treatments (Fig. 2A). In the PICS bags, 3.7 live *S. zeamais* per sample were found after 12 months of storage (Fig. 2A). The mean number of dead *S. zeamais* in all the hermetic treatments during the 12 months of storage was ≤1 (Fig. 2B).

3.2.2. Tribolium castaneum

The pattern for numbers of *T. castaneum* found are shown in Figs. 3 and 4. In the PP treatment, the numbers of live *T. castaneum* were much higher during the period October to January (Fig. 3A). The numbers of live *T. castaneum* were lower in the PPDE, ZF and ZFDE bags in all the storage periods and did not exceed the highest number found of 4.3 insects per sample. The mean number of live insects per sample throughout the storage period was 4 in PPDE treatment whereas live insect was below 1 in ZF and ZFDE treatments, respectively (Fig. 3A). Expectedly, higher numbers of dead insects were found in PP bags during all the storage periods (Fig. 3B).

For the hermetic treatments, very low numbers of *T. castaneum* were found and did not exceed a mean of 6 in any of the four treatments (Fig. 4A). In the PICS bags, the number of live *T. castaneum* increased from 3.7 in September to 6 per sample in January (Fig. 4A). The mean number of dead *T. castaneum* in all the hermetic treatments during the 12 months of storage was 4 (Fig. 4B).

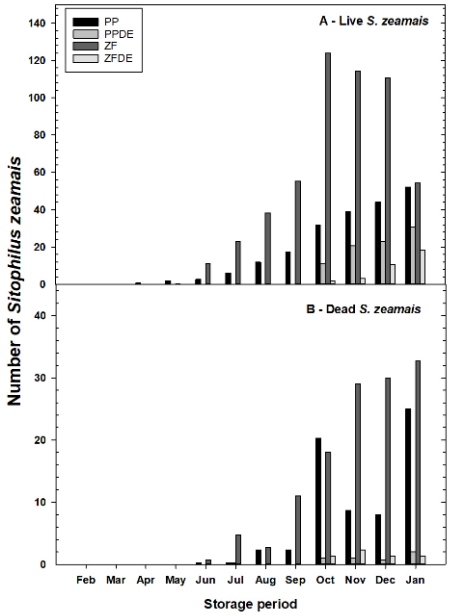

Fig. 1: Number (mean) of live (A) and dead (B) *Sitophilus zeamais* per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

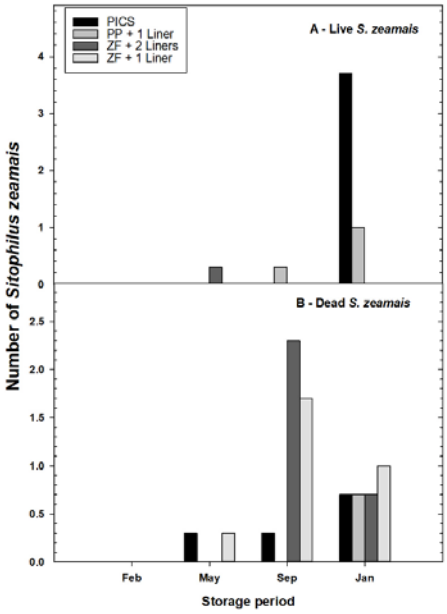

Fig. 2: Number (mean) of live (A) and dead (B) *Sitophilus zeamais* per 250 g of maize kernels in the hermetic treatments (PICS, PP + 1 Liner, ZF + 2 Liners and ZF + 1 Liner) sampled every four months.

3.2.3. Cryptolestes ferrugineus

The pattern for number of *C. ferrugineus* in non-hermetic treatments is shown in Fig. 5. There were no live *C. ferrugineus* from samples in all the four treatments during the first 5 months of storage in May. During the period August to January, more insects were found in the ZF treatment than in the other three treatments, and the number increased markedly from 47 in November to 69 in January (Fig. 5A). In contrast, there was no live or dead *C. ferrugineus* in all the different hermetic treatments during the entire storage period.

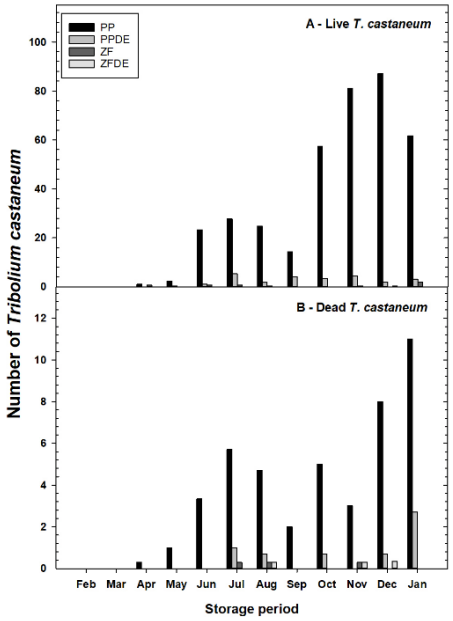

Fig. 3: Number (mean) of live (A) and dead (B) *Tribolium castaneum* per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

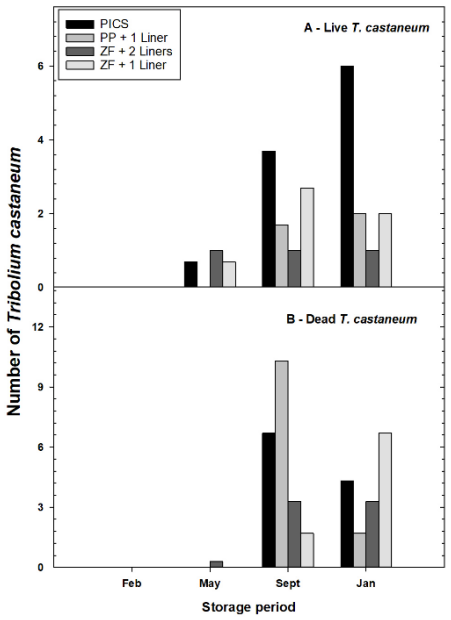

Fig. 4: Number (mean) of live (A) and dead (B) *Tribolium castaneum* per 250 g of maize kernels in the hermetic treatments (PICS, PP + 1 Liner, ZF + 2 Liners and ZF + 1 Liner) sampled every four months.

3.2.4. *Liposcelis* spp.

The pattern for numbers of *Liposcelis* spp. found in the different non-hermetic treatments is shown in Fig. 6. Lower numbers of live *Liposcelis* spp. were found in the PP treatment during the entire storage periods. Among the other three treatments, the ZFDE treatment had the highest number of live insects in July (29) but this decreased to 8 in December (Fig. 6A). *Liposcelis* spp. were not found in all the hermetic treatments.

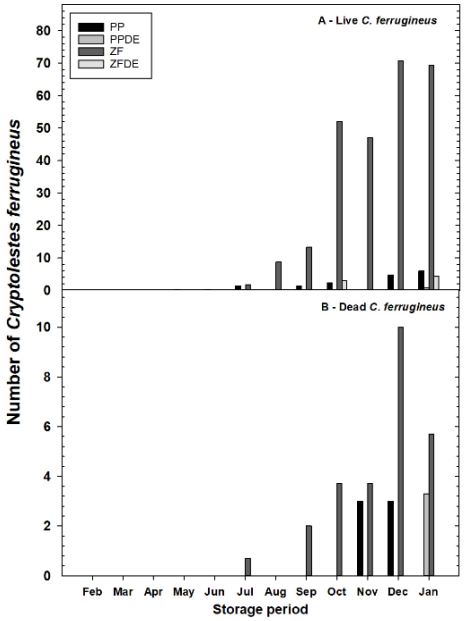

Fig. 5: Number (mean) of live (A) and dead (B) *Cryptolestes ferrugineus* per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

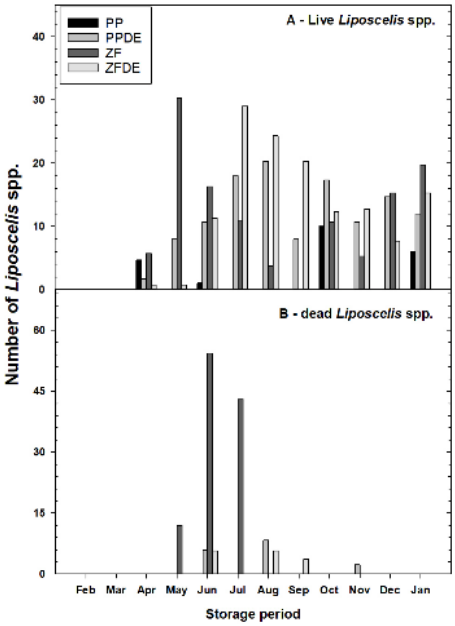

Fig. 6: Number (mean) of live (A) and dead (B) *Liposcelis* spp. per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

3.3. Percent Insect Damaged Kernels (% IDK)

The patterns for % IDK, by both numerical basis (IDKnb) and weight basis (IDKwb), are shown in Figs. 7 and 8. In the ZF treatment, IDKnb markedly increased from 0.2% in March to 16.9% in January (Fig. 7A). In the case of PP treatment, there was consistent increase in IDKnb from 0.4% per 250 g maize sample in May to 5.4% in January. In the PPDE and ZFDE treatments, IDKnb did not exceed 1.9 and 0.8%, respectively, over 12 months of storage (Fig. 7A). The IDKwb values were highest in the ZF treatment followed by PP treatment, and were 10.9% and 5.3%, respectively, at the end of storage in January 2018 (Fig. 7B).

For the hermetic treatments, IDKnb and IDKwb values were below 1% in all the four treatments (Fig. 8). With the exception of May, generally, ZF + 2 liners and ZF + 1 liner treatments had the lowest IDKnb and IDKwb values (Fig. 8A).

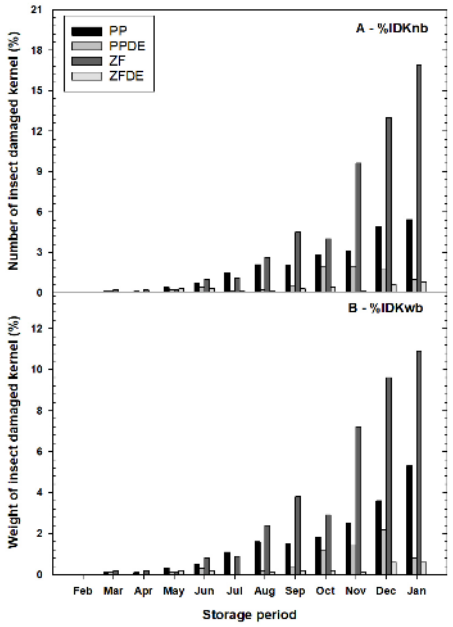

Fig. 7: Percentage number (A) and weight of insect damaged kernels (IDK) (B) (mean) per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

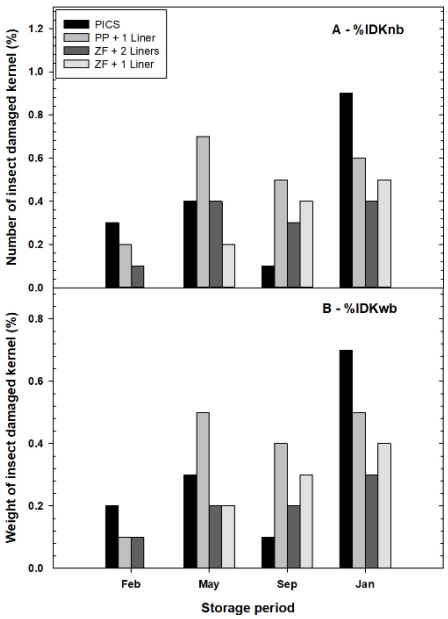

Fig. 8: Percentage number (A) and weight of insect damaged kernels (IDK) (B) (mean) per 250 g of maize kernels in the hermetic treatments (PICS, PP + 1 Liner, ZF + 2 Liners and ZF + 1 Liner) sampled every four month

3.4 Grain weight loss

The general trend from July 2017 to January 2018 was for percentage weight loss to be highest in the ZF treatment followed by PP treatment (Fig. 9). In the ZF treatment, percentage weight loss increased substantially from 0.2% in August to 6.7% in January (Fig. 9). In the PP treatment, weight loss did not exceed 0.5% after 8 months of storage in September but increased to 1.4% at the end of the study in January (Fig. 9). Low weight loss values were found in the hermetic treatments with PP + 1 liner, ZF + 2 liners and ZF + 1 liner bags mostly having a low value of 0.1% and loss did not exceed 0.2% on average in the PICS treatment (Fig. 10).

3.5 Seed germination (%)

The initial mean germination rate for all the treatments (hermetic and non-hermetic) was 97.5% (Figs. 11and 12). At the end of storage period, germination rates in ZF (87%) and PP (91.3%) were relatively the lowest compared to other treatments (Fig. 11). After 12 months, mean germination rates of samples collected from the hermetic treatments was similar to that obtained at the start of experiment (97%) (Fig. 12).

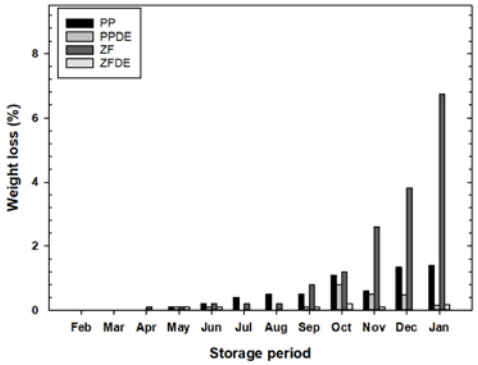

Fig. 9: Percentage weight loss (mean ± SE) per 250 g of maize kernels in the non-hermetic treatments (PP, PPDE, ZF and ZFDE) sampled at monthly intervals over 12 months.

4. Discussion

Among the non-hermetic treatments, our data revealed that PPDE and ZFDE treatments were effective in reducing insect infestation and damage levels compared to the control treatment (untreated maize in PP bags). Maize treated with Insecto DE provided better protection for stored maize from *S. zeamais* infestation for up to 8 months during storage. In the PPDE and ZFDE treatments, mean weight losses of ≤1% and ≤0.2% respectively were observed after the 12-month storage period. Other studies have shown that stored grain insect pests can be controlled by commercially available DE formulations (Ashraf *et al.,* 2016). In the non-hermetic and no DE treatment, *S. zeamais* was the major damaging pest resulting in high IDK levels of 5.4% and16.9% after 12 months of storage in PP and ZF bags, respectively. The ZF treatment (untreated maize in ZeroFly bags) was effective for up to 4 months of storage (June), but thereafter, levels of insects such as *S. zeamais* and *C. ferrugineus* increased markedly. Data obtained from this study correspond to those of (Paudyal *et al*., 2017) who found high insect infestation levels in ZeroFly bags after 4 months of storage. The high level of infestation in ZeroFly bags after 4 months of storage may be due to pre-infestation of maize during bagging by insects at the egg or larval stage — maize used in this study was un-fumigated. Given that the newly-harvested grains can be infested after storage (Vela Coiffier *et al.,* 1997; Hagstrum, 2001), it is recommended by the manufacturer of ZeroFly storage bag that

the grains be pre-fumigated because the bags are designed to give protection to commodities by preventing the entry of insect pests, thereby facilitating preservation of cereal grains and grain legumes. Additionally, as a result of the *S. zeamais* infestation pressure in the storehouse, it is possible that the repeated sealing and unsealing of the ZeroFly bags during grain sampling might have compromised the deltamethrin barrier and consequently allowed easy access of insects into the bags (Paudyal *et al*., 2017). In this study, *S. zeamais* was the major damaging pest eventually causing weight loss of 1.4% and 6.7% after 12 months of storage in PP and ZF bags, respectively (January 2018 weight losses). Comparatively, in all the hermetic treatments, insect infestation was effectively suppressed resulting in fewer insect damaged kernels and lower weight losses due to the low oxygen environment created by the hermetic technologies. Also few live insects were found in maize treated with DE dust throughout the storage period, this may be a result of the killing action or repellency of the diatomaceous earth.

One of the main purposes of storing grain is to ensure seed availability and viability, both of which are important to farmers. In all the eight treatments, germination rates of maize stored in all the hermetic treatments for 12 months were similar to that observed at the beginning of the study. This is consistent with the data obtained by Yakubu (2012) who stored maize hermetically for a period of one year and concluded that the hermetic conditions contribute to preservation of seed quality. The lowered oxygen concentration within the bags thus does not appear to affect the viability of maize seed (Baoua *et al.,* 2014). On the other hand, germination rates of seeds in the PP and ZF bags were greatly reduced at the end of the 12-month storage period. This is most likely a result of higher insect infestation.

Conclusion

The suitability and performance of hermetic storage bag technologies used in this study in mitigating insect infestation and preserving maize was much better than the non-hermetic methods over the 12-month storage period. Based on data from this study, hermetic storage technologies are effective and need to be more widely adopted for improved food quality and security.

Abstract

Improper or poor post-harvest handling and storage of stored grains contributes significantly to product loss, and bagged stored grain presents an option for safe storage and handling. Bagged grain is intended to maintain quality and safety, while protecting it from infestations. The objective of this research was to determine the effect of deltamethrin-treated packaging material on adults and larvae of common stored product pests. Adults or larvae of several species of stored product insects were exposed to deltamethrin-treated packaging for time intervals ranging from 1 h to 4 weeks. The percentage of affected*Prostephanus truncatus, Callosobruchus maculatus* and *Rhyzopertha dominica* adults was < 98% after 60 minutes of exposure to treated packaging. Mortality of adult *Trogoderma granarium* was about 33% after 1 day of exposure, and increased to 93% after 7 day of exposure. Direct mortality of *T. granarium* larvae exposed to the deltamethrin-treated packaging for 8 h was about 15%, but increased to 50% when larvae were exposed for 72 h.*Tribolium castaneum, Oryzaephilus surinamensis,* and *Trogoderma inclusum* larvae continually exposed to the deltamethrin-treated packaging resulted in > 96% larval death within 1-2 weeks.The major primary stored product insects were highly susceptible to the deltamethrin-treated storage bags, but there was variation in susceptibility between species

and life stages tested. The deltamethrin-treated storage bags can offer protection of bagged grains and be used as a preventative measure to reduce infestations during storage.

Keywords: treated packaging, deltamethrin, stored product insects, affected adults

1. Introduction

Stored product insects are a common and persistent problem in grain storage, milling, and, warehouse facilities. *Rhyzopertha dominica* F., lesser grain borer, *Callosobruchus maculatus* F., cowpea weevil, *Tribolium castaneum* (Herbst), red flour beetle, *Prostephanus truncatus* (Horn), larger grain borer, and *Trogoderma spp.* are major stored product species found or associated with stored grains (Rees, 2004; Hagstrum et al., 2012). The improper handling and storage of grains impacts the quantitative and qualitative attributes of stored grain. Traditional integrated pest management (IPM) techniques depend on a series of management evaluations, decisions, and controls in order to provide the best control method (US-EPA, 2017). For IPM of food materials, prevention is one of the most important IPM strategies.

In recent years, use of insecticide-treated packaging has gained interest and proven effective against stored product insects. Use of insecticide-treated packaging can be easily incorporated into existing IPM programs and functions as aprevention techniquefor finished product. Previous research in the area of insecticide treated packaging has focused on the insect growth regulator methoprene and the contact insecticide deltamethrin. Both insecticide treated packaging materials are highly effective against a variety of stored product insects such as *T. castaneum, P. truncatus, Sitophilus* spp., and *R. dominica*. (Kavallieratos et al., 2017; Paudyal et al., 2017a, 2017b; Scheff et al., 2016, 2017). However, there is still a need for research examining the effects of treated packaging materials on more pest species, including evaluations against different life stages, and more information on the impact of exposure duration to better understand the effectiveness of this pest management tool. The objective of this research was to determine the effect of deltamethrin-treated packaging material on adultsand larvae of common stored product pests.

2. Materials and Methods

Experiments with larvae and adult*Trogoderma granarium*Everts, Khapra beetle, were conducted at the USDA-Animal and Plant Health Inspection Service (APHIS)-Center for Plant Health Science and Technology (CPHST), Otis Laboratory, in Buzzards Bay, MA, USA, in the insect quarantine facility. All other insect species were evaluated in experiments conducted at the USDA-Agricultural Research Service (ARS)-Center for Grain and Animal Health Research in Manhattan, Kansas, USA.

Deltamethrin-treated woven polypropylene storage bag material (ZeroFly® Storage bags) was used in the experiments (Vetergaard Frandsen, Lausanne, Switzerland). The deltamethrin concentration of the treated storage bags was 3g/kg or 3000 ppm (Vestergaard, 2015). Untreated control material consisted of a laminated woven packaging material containing no insecticide, as described by Scheff and Arthur (2017). Bioassay arenas used in all experiments were created as described by Kavallieratos et al. (2017) and Scheff and Arthur (2017). In brief, packaging material was cut into ~9 cm circles and affixed to thebottom of 100 x 20 mm plastic Petri dishesusing adhesive caulking. The interior sides of the Petri dishes were coated with Fluon® (polytetrafluoroethylene, Sigma-Aldrich Co., St. Louis, MO, USA) to confine insects to the bottom of the dish.

2.1 Adults

Cohorts of 10 adults of *P. truncatus, C. maculatus*, and *R. dominica* were exposed to treated packaging and monitored every 15 minutes for up to 4 h, and the time until 100% of adults were observed as being affected was determined. Affected insects were those where the adults could not remain upright and exhibited uncoordinated movement for five or more seconds, were turned on their backs and displayed loss of appendage control and tremors, or only exhibited movement in legs, antennae or mouthparts when probed by a fine-hair brush. Additional testing on mortality of adults exposed to deltamethrin-treated material is currently being conducted. Adults of *T.*

granarium were continually exposed to treated or untreated packaging materialas described for *P. truncatus, C. maculatus,* and *R. dominica*, and observed after 1, 2, 5 and 7 daysof exposure on the packaging material to determine the percentage of affected and dead adults at each time. The time to 100% of adults that were affected in 15 minute increments is currently being conducted.

2.2. Larvae

The effects of deltamethrin-treated packaging material on larvae was conducted as either continually exposing larvae on treated or untreated surface (continual exposure assay) or a short term exposure period of ≤4 days on treated or untreated material (short-term assay).

The continual exposure assays were conducted for *T. granarium, Trogoderma inclusum* LeConte, larger cabinet beetle, *T. castaneum* and *Oryzaephilus surinamensis* (L.), sawtoothed grain beetle. Ten individual larvae were added to deltamethrin-treated or untreated arenas along with ~1 g of diet and continually held on each area and monitored for adult emergence, up to 8 weeks. Six replicates were used. Short-term exposures were conducted for *T. castaneum, T. granarium,* and*T. inclusum* as described by Scheff et al. (2017). Briefly, 50 larvae of each species, six replicates, were exposed to deltamethrin-treated or untreated packaging material, and ten larvae were removed from the arenas after 0.3, 1, 2, 3, and 4 days and placed onto an untreated plastic Petri dish along with ~1 g of diet and held for adult emergence for 8 weeks. Two larval sizes for *T. granarium* and *T. inclusum* were used. Small larvae were <3 mm and largelarvae were >4 mm (Anthanassiou et al., 2015).

3. Results

3.1 Adults

The time requiredfor 100% adults tobe affected varied among species tested. The order of susceptibility was *P. truncatus* >*R. dominica* >*C. maculatus.* All adult*P. truncatus* were affected after 30 m of exposure to the deltamethrin-treated packaging material, while only 83% of*R. dominica* and 30 % of *C. maculatus* were affected.*R. dominica* needed 45 minutes of exposure for 100% of adults to be affected and 75 minutes of exposure was needed for*C. maculatus.*
There was 100% affected or dead adult *T. granarium* after 1 day of exposure to deltamethrin-treated packaging and the percentage of mortality increased with longer exposure periods as the affected adult *T. granarium* succumbed to the effects of the deltamethrin. After 7 dayd of continual exposure, 93% of adults were dead.

3.2 Larvae

Continual exposure of *T. granarium* larvae to treated packaging material resulted in approximately95 and 97% mortality for small (<3 mm) and large (> 4mm) larvae, respectively, while on untreated material mortality was <4% for both larvae sizes. Likewise, *T. castaneum* had <7% adult emergence and *O. surinamensis*had 0% adult emergence when continually exposed at two different temperatures, 27 or 32°C, and all the larvae died. Continual exposure of *T. inclusum* larvae to treated packaging material resulted in 10% adult emergence for large larvae held at 32°C, and <3% for small larvae at 27 or 32°C and large larvae at 27°C. Larval death ranged from 65-100% among small and large larvae held at 27 or 32°C. However, roughly 25% of large *T. inclusum*larvae held at 32°C were alive after 8 weeks of continual exposure and 22% of small larvae at 27°C were still alive.
Short-term exposure of large*T. granarium* larvae, > 4mm, resulted in adult emergence ranging from 61-34% among the exposure periods. Larval death ranged from 15-50% depending on exposure time. As exposure time to deltamethrin-treated packaging material increased, the percentage of emerged adults decreased and the most effective exposure period was 3 days. We observed a significant reduction in adult emergence for *T. castaneum* larvae exposed to the deltamethrin-treated material for >3 days at 32°C. Adult emergence was 62% after 3 days of exposure and 50% after 4 days of exposure to treated material. Similar to *T. granarium,* the precentage of small *T. inclusum* larvae, < 3 mm, exposed to deltamethin-treated material at 32°C that emerged as adults

was reduced as exposure time increased. After 0.33 days of exposure, 72% of larvae emerged as adults but only 42% of larvae emerged as adults after 4 days of expsoure to treated material.

4. Discussion

Results of this study show there is variationin the susceptibility among life stages andstored product insectspecies, and a strong effect of exposure duration on susceptibility and lethality. We first observed that exposure to the deltamethrin-treated packaging material yielded affected adult stored product insects within 60 minutes. The exposure time required to yield affected adults reported here was similar to previous research by Kavallieratos et al. (2017), in which the order of susceptibility based on knockdown and mortality during 5 dayexposures to deltamethrin-treated material was*T. variabile* >*P. truncatus* > *R. dominica* >*T. castaneum*. Kavallieratos et al. (2017) found out that all *P. truncatus* and *R. dominica*were knocked down after 60 minutes of exposure. In our experiements, we were able to deterime time to knockdown or affected, was less than 60 minutes for both species.

Larvae of several different stored product insects showed susceptibility to treated packaging. Among all species tested, adult emergence was <10% and larval death was 100% for *O. surinamensis* and large *T. inclusum* larvae at 32°C. Scheff et al. (2016, 2017) observed differences in susceptibility to methoprene-treated packagaing between *T. castaneum* and *T. variabile* aftercontinual exposure for egg-to-adult development. The differences observed in the previous studies and the current study could be due to physiological differences between species and pubescenceof larvae. *T. inclusum* and *T. granarium* larvae are covered in fine hairs, which could reduce the precentage of body surface exposed to the treated packaging. Scheff et al. (2017) also observed longer exposure periods to methoprene-treated packaging material, decreased the percentage of normal adult emergence from exposed larvae of*T. castaneum* and *T. variabile.* We observed similar results for *T. granarium, T. castaneum,* and *T. inclusum* when exposed to deltamethrin.

Our study demonstrated that some major primary stored product insects were highly susceptible to the deltamethrin-treated storage bags among various life stages. The use of these deltamethrin-treated storage bags can offer protection of bagged grains and be used as a tool in the integrated pest management approach to stored grains.

Abstract

Food Security is an issue that will impact everyone by 2050 it is projected there will be a global crisis unless action is taken. The ZeroFly® Storage Bag is a new combination of key technologies developed to reduce post-harvest losses. It contains an insecticide, Deltamethrin that is incorporated within the polypropylene yarns woven into a storage bag. The level of insecticide residue found on grains stored for up to two years in ZeroFly® Storage Bag are below CODEX & EPA maximum residue levels. This technology can be combined with natural rodent repellent compounds and the multilayer hermetic liners, meaning these bags can adhere to and improve on currently accepted practices and requires limited behavior change for the user. Studies show that the ZeroFly® Storage Bag can effectively control key stored product insects. The presentation will explore the current scale-up efforts and strategies of distribution planned throughout Africa and Asia, this would also include an assessment of the broader impact of ensuring the most appropriate combinations of technologies reach the most vulnerable groups.

On-Farm Comparison of Different Postharvest Storage Technologies for effectiveness in pest management in a Maize Farming System of Tanzania Central Corridor

Abstract

Seven methods for storing maize were compared with traditional practice of storing maize in polypropylene bags. Twenty farmers managed the experiment under their prevailing conditions for 30 weeks. Stored grain was assessed for damage every six weeks. The dominant storage insect pests identified were the Maize weevil (*Sitophilus zeamais*) and the Red flour beetle (*Tribolium castaneum*). There was no significant difference ($F = 87.09$; $P < 0.0001$) in insect control and grain damage between hermetic storage and fumigation with insecticides. However, the insecticide treated polypropylene yarn (ZeroFly®) did not control insect infestation of grain for the experimental period under farmers' management. Grain damage was significantly lower in hermetic storage and fumigated grain than ZeroFly® and polypropylene bags without fumigation. No significant difference in grain damage was found between airtight treatment alone and when combined with the use of

insecticides. During storage, *S. zeamais* was predominant and could be of more economic importance than *T. castaneum* as far as maize damage is concerned. Even though ZeroFly®, and polypropylene bags without grain treatment did not control storage pests, farmers still prefered this cheap technology. Hermetic storage techniques can be recommended to farmers without the use of insecticides provided they are inexpensive, and the proper application of technologies is ensured.

Key words: Maize Farmers; Hermetic storage; Grain damage; Food loss; Insect damage

1. Introduction

Maize is one of the crops most severely affected by Post harvest Losses (FAO, 1998; Abass et al., 2014). Major losses of stored maize are caused by insect pests especially the larger grain borer (LGB), *Prostephanus truncatus* (Horn) (Coleoptera: Bostrichidae), the Red flour beetle (*Tribolium castaneum*), and the Maize weevil (*Sitophilus zeamais* Motschulsky) (Coleoptera: Curculionidae) (Golob and Hanks, 1990). If the grain is dried to an appropriate moisture level of 12–13% storage insects can be controlled effectively with fumigants such as Phostoxin (Hodges, 1986). In Tanzania, farmers are allowed to use Phostoxin if supervised by authorized extension agents, but the effectiveness of such arrangements at the community level is yet to be ascertained. Farmers widely use a mixture of Pirimiphos-methyl (Actellic) and Permethrin, commercially sold as Actellic Super (local name: *Shumba*) but farmers are often unable to verify the genuineness of some local brands.

More recently hermetically sealed containers are being promoted in Africa to control storage insect pests, based on the oxygen depletion mechanism that rapidly occurs in the containers, causing an increase in CO_2 concentration and death of the pests (Yakubu et al., 2011; Murdock et al., 2012; Baoua et al., 2013; de Groote et al., 2013; Moussa et al., 2014, Chigoverah and Mvumi, 2016; Likhayo et al., 2016; Midega et al., 2016). Metal silos, plastic barrels and flexible hermetic storage systems, such as Purdue Improved Crop Storage (PICS) bags, super grain bags (SGB), Zerofly bags, cocoons, and others, are being tested to control storage insect pests in different African countries (Quezada et al., 2006; Phiri and Otieno, 2008; Baoua et al., 2013, 2014; Jones et al., 2014). However, the potential adaptability of the technologies and their acceptance by farmers as alternatives to the use of insecticides is required. This study was conducted in Tanzania to determine the relative effectiveness of different hermetic storage materials under actual on-farm conditions and farmers' management practices and elucidate sociocultural evidence on their acceptability.

2. Materials and Methods

2.1 Description of the experimental sites

Twenty farmers in four villages located in three agro-ecologies (Southern Guinea Savannah, Northern Guinea Savannah, and Semi-arid Sudan Savannah) within two regions of Tanzania (Dodoma and Manyara) were involved in the experiment. The relative humidity (H_{in}), and temperature (T_{in}) inside the storage facilities were monitored using electronic data loggers *(Dickson TK550 model)*.

2.2 Experimental set up

Shelled maize with natural insect infestation was stored in eight different storage treatments as follows.

Metal silo hermetic: Hermetic storage of untreated maize using a metal silo filled to 90% of the 500 kg capacity.

Metal silo phostoxin: Hermetic storage using a metal silo filled to 90% of the 500 kg capacity with a Phostoxin-treated grain (active ingredient is aluminum phosphide, 57% w/w).

Plastic barrel hermetic: Hermetic storage of untreated grain using a plastic barrel (a flat-topped 50-liter high-density polyethylene container) filled to 90% of its capacity.

Plastic barrel Photoxin: Hermetic storage of Phostoxin-treated grain using a plastic barrel filled to 90% of its capacity.

PICS: Hermetic storage of 100 kg of untreated grain using two 100-kg Purdue Improved Crop Storage (PICS bags, described by de Groote et al., 2013) purchased from Pee-Pee Tanzania Ltd, Tanga, Tanzania.

ZeroFly®: Storage of 50 kg of untreated grain using a ZeroFly® storage bag (non-hermetic; polypropylene bag with deltamethrin insecticide incorporated at the rate of 3 g/kg ± 25%) purchased from Vestergaard, Lagos, Nigeria, and shipped by airfreight to Tanzania. Four 50-kg bags were used.

PP Shumba: Storage of 100 kg of grain treated with Actellic Super® (Pirimiphos-methyl 16 g/kg plus Permethrin 3 g/kg) in polypropylene (PP) bags (non-hermetic). This is the common farmers' practice known as *Shumba* in Tanzania. Two 100-kg bags were used.

PP without treatment: Storage of untreated grain in polypropylene (PP) bags (non-hermetic) commonly used to transport and store grain. Two 100-kg bags were used (control).

2.3 Grain sampling and field assessments

Sampling: A representative sample (1 kg) from each treatment was collected at 6-week interval, transferred into a labeled paper bag, sealed, and then transported to the laboratory for further analysis. All samples were stored at ambient conditions until processed.

Grain moisture (GM) and Bulk Density (BD): Samples were tested for percentage grain moisture (GM), and bulk density (BD; g/cm^3) using a hand-held grain moisture tester (Dickey-John GAC ® Plus, Illinois, USA).

2.5 Laboratory assessment

Insect counts: The type and population of insects were visually evaluated in the laboratory following the method described by Ng'ang'a et al. (2016).

Grain assessment: In the laboratory, samples were visually examined for broken and damaged grain (DG) using the 1000 grains count. The percentage DG was calculated following the formula described by Boxall (1986). Weight loss (WL) was calculated as shown by Njoroge et al. (2014).

2.6 Farmers' perceptions of the storage technologies

At the end of the experiment, the participating farmers (20 respondents: 6 female, 14 male; 70% aged between 40 and 60 years) were asked to rate the storage technologies according to their perceptions about effectiveness to prevent grain loss and how the farmers liked the storage technologies.

2.7 Data analysis

Data were entered into an Excel spreadsheet and analyzed using SAS® version 9.4 (SAS Institute, Cary, NC). To determine means and frequencies to explain the data pattern. A stepwise multiple comparisons GLM procedure was used to determine the pattern of differences in the samples. Significant differences in storage parameters were concluded when the coefficient of the interaction term was significant at $P < 0.05$, $P < 0.01$, or $P < 0.001$ as the statistical significance levels. Additionally, standard errors were calculated and used as means separation tests.

3. Results and Discussion

3.1 Relative humidity and temperature conditions during the experiment

Average relative humidity (H_{in}) inside four selected treatments representing insecticide treated and untreated maize inside all polypropylene bags (including ZeroFly), PICS bags, all metal silos, and all

plastic barrels during the entire period of storage was 60.35±0.97, 66.24±1.14, 68.50±0.27, and 66.7±1.24 respectively. Similarly, average temperature (T_{in}) condition inside the containers was 29.65±0.51, 25.02±0.23, 25.57±0.03, and 25.07±0.20 for all PP bags without treatment (including ZeroFly), PICS, all metal silos, and all plastic barrels, respectively.

Maize stored in hermetic storage containers had a higher GM content than in non-hermetic bags (ZeroFly®, PP *Shumba,* and PP bags without treatment; Fig. 1).

The moisture content of grain stored in non-hermetic conditions (ZeroFly®, PP bags) reduced until week 18 of storage and increased slightly afterward. The moisture content of grain in hermetic conditions increased slightly during storage. These values were significantly higher than the moisture content of the maize stored in the non-hermetic facilities (especially the PP bags).

3.3. Bulk Density (BD) of stored grain

The BD of stored grain decreased from the start of storage until storage Week 6 in all the storage conditions (Fig. 2). The BD of the grain in ZeroFly® and PP bags decreased during storage.

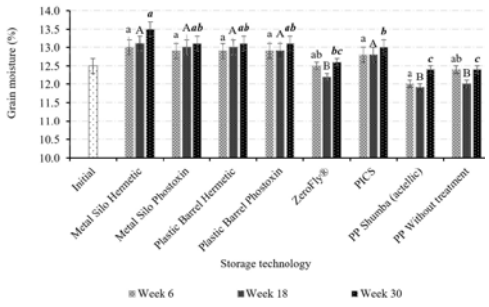

Fig 1: Percent (Mean±SE) grain moisture in the storage technologies over 30 weeks of storage. Foot note: Significant difference between means at Week 6 denoted by different lower-case letters (F=5.04, P<0.0001), significant difference at Week 18 denoted by different upper case letters (F=11.46, P<0.0001), significant difference at Week 30 denoted by different bold lower case letters in ***italics*** (F=7.69, P<0.0001).

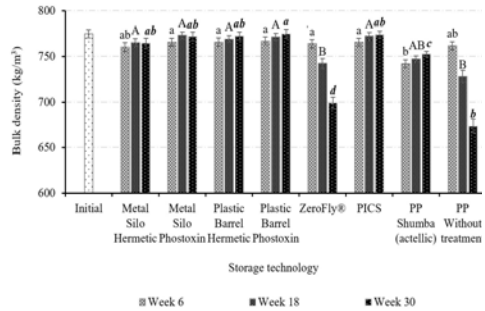

Fig. 2: Grain bulk density ((mean ± SE) in the storage technologies over 30 weeks.
Significant difference at Week 6 denoted by different lower case letters (F=3.16, P=0.0038), significant difference at Week 18 denoted by different upper case letters (F=11.23, P<0.0001), significant difference at Week 30 denoted by different bold lower case letters in ***italics*** (F=49.85, P<0.0001).

3.4 Insect population

Two major maize spoilage insects were identified: *S. zeamais* and *T. castaneum*. We did not find *P. truncatus* throughout the storage period. The population of live adult *S. zeamais* in the grain increased rapidly in ZeroFly® and PP bags (Fig. 3) but reduced in all the airtight containers. The insect was completely absent in PP *Shumba* (Actellic).

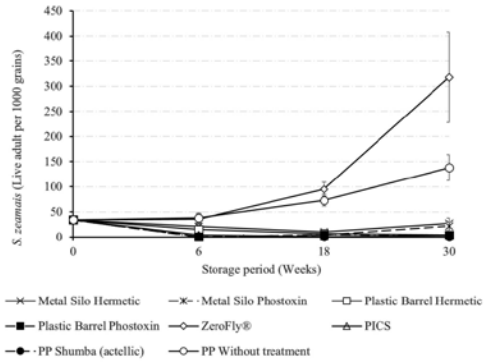

Fig 3: Number (mean ± SE) of live *S. zeamais* adult polupation in the storage technologies over 30 weeks.

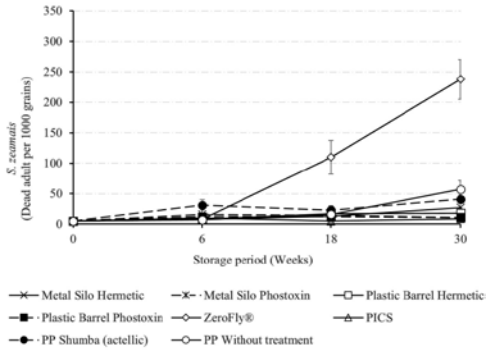

Fig. 4: Number (mean ± SE) of dead *S. zeamais* adult population in the storage technologies over 30 weeks.

At the end of storage the number of dead *S. zeamais* adults was highest in ZeroFly®, and in PP bags (Fig. 4). PICS had the lowest number of dead *S. zeamais* adults, significantly fewer than in other treatments (F = 28.01; $P < 0.0001$). Adult *T. castaneum* was not detected at the time of storage but later detected during storage (Fig. 5&6). At week 30 of storage, the population of live *T. castaneum* adults was low in all airtight containers and insecticide-treated grain while it was significantly higher in ZeroFly® and PP bags(F = 33.98; $P < 0.0001$). Dead adult of *T. castaneum* was found in ZeroFly® and PP bags, maximum of one was found in hermetic storage containers and also in grain treated with insecticides.

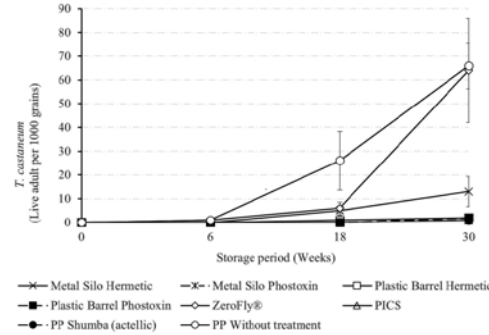

Fig. 5: Number (mean ± SE) of live *Tribolium Castaneum* adult population in the storage technologies over 30 weeks.

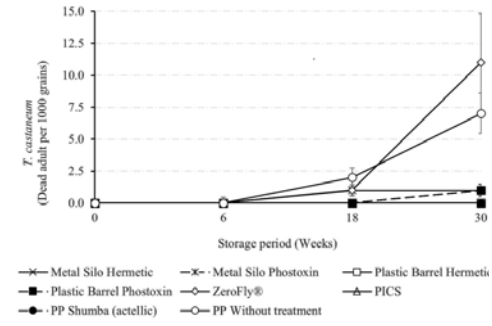

Fig. 6: Number (mean ± SE) of dead *Tribolium Castaneum* adult population in the storage technologies over 30 weeks.

3.5 Grain damage (DG)

Fig. 7 reveals very crucial patterns of insect behavior concerning the destruction of grain and the consequent food loss during storage if farmers would adopt the various storage technologies tested. The results reveal the implication of poor shelling methods that break the grain before storage and how this could accentuate insect damage. Significant difference at Week 6 denoted by different lower case letters (F=3.17, P=0.0037), significant difference at Week 18 denoted by different upper case letters (F=25.06, P<0.0001), significant difference at Week 30 denoted by different bold lower case letters in ***italics*** (F=89.09, P<0.0001).

During storage, there was an initial decrease in DG at week 18 after which DG values increased.

The increases were highest in PP bags (PP without treatment) and in ZeroFly® bags at week 30 of storage, and were significantly higher (F = 87.09; $P < 0.0001$) than the DG percentage in all the other

storage treatments. No significant differences were observed among the remaining treatments irrespective of the use of insecticide whether combined with hermetic storage or not.

3.6 Weight Loss (WL)

The consequence of the increase in DG and other factors was that average WL in PP bags (PP without treatment) and ZeroFly® bags continuously increased but did not change significantly in any of the remaining storage treatments (Fig. 8). At week 30 of storage, WL was significantly higher ($F = 10.31$; $P<0.0001$) in untreated grain stored in ZeroFly® (8.1 ± 0.6%) and PP bags (11.6 ± 1.7%) than in PP bags with insecticide treatment (PP *Shumba*; 4.4± 0.2%). There was hardly any WL in PP *Shumba* and the hermetic treatments.

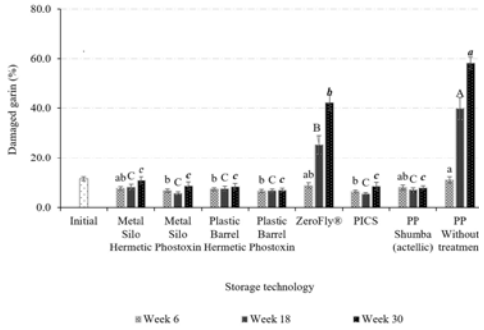

Fig. 7: Percent (±SE) of damaged grains in the storage technologies over 30 weeks

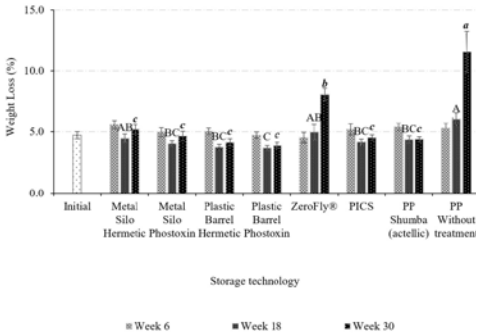

Fig. 8: Percent (±SE) grain weight loss during 30 weeks of storage No significant difference between means of weight loss (%) at Week 6 ($F=0.99$, $P=0.4379$), significant difference at Week 18 denoted by different upper case letters ($F=3.74$, $P<0.0005$), significant difference at Week 30 denoted by different bold lower case letters in ***italics*** ($F=10.31$, $P<0.0001$).

3.7 Agents of grain loss

Considering a batch that was damaged at base condition (before storage), the most critical causes were calculated to be grain breakages (32.2%), fungi infection (31.8%), and damage by insects (24.1%). After storage, the most economically important damage agents were insects: 25.4% for plastic barrel Phostoxin, 90.8% for ZeroFly®, and 91.4% for PP bags without treatment. Fungal coloration appears to constitute an important agent of grain defects in the hermetic containers. The increase in moisture in hermetic storage could promote fungi growth. Since a large insect population would cause more damage, therefore, preventing an increase in insect population is a critical factor for reducing DG and WL. In addition, *S. zeamais* seems to be more economically important in the Central Corridor of Tanzania than *T. castaneum* concerning damage to stored maize grain and food losses.

3.8 Farmers' perception

Farmers rated the hermetic storage technologies without insecticide application (metal silo hermetic, plastic barrel hermetic and PICS) as the most effective ways to control storage pests. However, contrary to trial results, PP *Shumba* was not rated as effective. Farmers also liked the same hermetic technologies best. Metal silos were preferred to plastic barrels.

Even though PP bags without treatment did not control storage pests, farmers still liked them as this was a cheap technology. PP *Shumba*, and above all ZeroFly® bags were liked the least. Farmers indicated that the PP *Shumba* treatment was not liked because it altered the taste of the grain. Field

observations revealed that farmers who store their maize with insecticide avoid using such grain as much as possible for household consumption but prefer to sell it.

4.0 Conclusion

This study showed that hermetic storage techniques could be used to store grain for 30 weeks without a significant effect on the quality and germination of the grain. Storage of maize treated with Actellic Super in PP bags, a traditional practice in Tanzania, was effective in controlling insect damage. However, for public health reasons, the application of insecticides to staple food should be avoided especially in locations where trained personnel to supervise the use of insecticides are absent. Hence hermetic storage without the application of insecticides is preferred, but the storage materials need to be made affordable to the smallholders. Sound handling and management of the technologies by farmers must also be ensured, i.e., proper placement and hermetic sealing of lids should be ascertained; insect infestation from the field should be as low as possible; grain must be properly dried before storage, and re-infestation during the intermittent opening of airtight containers should be prevented as much as possible.

DOI 10.5073/jka.2018.463.198

Abstract

Hermetic containers have been promoted in recent years for chemical-free grain storage among smallholder farmers. In the context of grain quality, the influence of maize storage and pre-storage practices (harvesting time, dehusking, drying, and shelling method) on performance of air-tight bags was investigated in the semi-arid regions of south eastern Kenya and northern Tanzania. Completely randomised trials were conducted in farmer-own stores; shelled maize was filled in air-tight bags or woven polypropylene (PP) bags and stored for 30-35 weeks. Insect damage, physical grain quality, mould infection were evaluated at 6-7 weeks intervals, and mycotoxin contamination was examined at onset, mid, and end of storage. Maize stored in hermetic bags was generally free from insect infestation, while PP bags permitted profuse build-up of insect populations causing grain damage of up to 82%. Total aflatoxin contamination of maize stored at moisture content below 14% increased significantly in the PP bags (5 - 8 folds) but not in the air-tight ones. Harvesting, drying and shelling practices significantly influenced the quality of maize stored in hermetic bags, resulting in sorting losses of 6-23 kg/100 kg after 6-8 months of storage. Since sorting is an important operation for improvement of food value and market quality, such losses would significantly lower the benefits of air-tight storage. Pre-storage practices of sorting, cleaning and moisture verification by farmers have impact on overall performance of air-tight storage.

On-Farm Maize Insect Pest and Mycotoxin Levels in Ghana

Abstract

Maize post-harvest losses are perennial in Ghana but reliable comparative information on on-farm losses of maize produced in the Middle and Northern Belts of Ghana is lacking. Two studies were conducted from September 2015 to February 2016 to identify factors contributing to on-farm losses of maize in these two Belts. In the Northern Belt, the study was conducted in six communities including Adubiyili, Diari, Pong-Tamale, Savelugu, Toroyili and Zamnayili; and in the Middle Belt, in Ejura, Sekyedumase and Amantin communities. Moisture content, percent weight loss, percent insect damaged kernels (IDK) on numerical basis (%IDK_{nb}) and percent IDK by weight basis (%IDK_{wb}), insect pest abundance, and mycotoxin levels were estimated. Moisture content values of maize at pre-harvest and heaping stages in all nine communities were below 15%. *Sitophilus zeamais*, *Sitotroga cerealella*, *Cathartus quadricollis*, and *Carpophilus dimidiatus* were found to attack maize on-farm in communities in the Middle Belt, but no adult insect pests were collected on pre-harvested maize in the Northern Belt. The %IDK_{nb} values on-farm in all nine communities were < 2% per 250 g. Mean aflatoxin levels below 15 ppb were obtained from pre-harvested maize in both regions but levels above 15 ppb were obtained from heaped maize on-farm. Fumonisin levels of maize were below 4 ppm on pre-harvested and in heaped maize in both regions. Results show that heaping maize on-farm increases aflatoxin levels beyond the acceptable threshold level and should not be practiced.

Keywords: insect infestation, aflatoxin, fumonisin, maize post-harvest loss, food security

1. Introduction

In Ghana, maize accounts for 50–60% of cereal production, with major producing areas located within the middle to southern parts of the country (CSIR-SARI/AGRA, 2014). Maize post-harvest losses in Ghana are estimated to be 35% (Edusah, 2007) which is a threat to food security. The major causes of maize post-harvest losses are grain moisture content, environmental conditions and biological agents, mainly insect pests and mold. Insect pests cause both qualitative and quantitative losses to maize and can facilitate dissemination of fungal spores (Hell et al., 2010). Mold and fungal infections can lead to mycotoxin contamination and this may occur throughout the maize value chain (Enyiukwu et al., 2014). From 2015 to 2016, separate surveys were conducted in the Middle and Northern Belts of Ghana to assess post-harvest losses of maize on-farm and at post-drying stages in order to identify mitigating strategies. This paper sought to provide comparative information on the factors contributing to post-harvest losses of maize on-farm in the two Belts (Middle and Northern Belts).

2. Materials and Methods

In the Middle Belt of Ghana, the study was conducted in three principal maize growing districts of Ejura, Sekyedumase and Amantin. The study covered the periods September–mid-October 2015 and late-December 2015–mid-February 2016. These periods corresponded with harvest time for the major and minor cropping seasons, respectively. A three-factor factorial-RCBD design of the factors cropping season, district and sampling stage with 2x3x3 levels (two cropping seasons: major and minor; three districts: Ejura, Sekyedumase and Amantin; and three sampling stages: field, ground-pile and post-drying) was used. Farmers within sampling location represented replications for the district in a cropping season. White maize varieties (Obatanpa,aborohomaand OBT) the most widely cultivated varieties in the Middle Belt of Ghana were sampled from selected farmers. Samples were taken from 51 maize farms. The three sampling stages were assigned to each randomly selected maize farm for a maize cropping season. In the Northern Belt, the study was conducted in farms in two districts of Central Gonja and Savelugu-Nanton in the Tamale area of Northern Region, Ghana. The locations selected were Adubiyili, Toroyili and Zamnayili in Central Gonja district; Diari, Pong-Tamale and Savelugu in Savelugu-Nanton district. Five farmers were chosen from each location. This study spanned the period October to December 2015 in the Northern Region, and this period corresponded with harvest time for the single maize season in the Northern Belt. In both belts, field sampling was performed by sampling mature cobs either before or during harvesting. From each farm 30 cobs were randomly collected from three parts of the field. Cobs from each part of the farm were de-husked and kept in three sealed and labelled plastic bags (39 cm x 25 cm) with each bag containing 10 de-husked cobs. De-husking was carefully done to avoid escape of insects on cobs. Cobs in each bag were hand shelled into a basin, mixed thoroughly and 500 g weighed out for moisture content, insect and aflatoxin and fumonisin data. Maize samples for mycotoxin test were kept in a portable cooler to reduce further growth and development of fungi. For ground-pile/heaping stage sampling, similar protocols as the field sampling stage were used for sampling and data collection, however, samples were taken from heaps of cobs piled on the ground in the farm fields after harvest. With respect to post-drying sampling stage, maize was sampled after cobs had been mechanically shelled and kernels sun-dried for storage or market. Dried maize grains either on tarpaulin or in store were divided into three different sections. A 2-kg sample was taken from each division by sub-sampling ten 200 g of maize from a sampling section. Three 500 g sub-samples were taken from each of the three 2 kg samples, kept in sealed and labelled plastic bags for data collection. Mycotoxin (aflatoxin and fumonisin) analyses were performed using AgraStrip® WATEX (aflatoxin) and AgraStrip® Total Quantitative Fumonisin (COKAS3000A) test kits provided by Romer Labs®, Inc. Union, MO, USA. In both tests, sample grinding, extraction, solute preparation and test procedures were done in accordance with the manufacturer's instructions (Romer Labs Methods, romerlabs.com). Complete details of these surveys can be found in Danso et al. (2017).

Statistical analyses were performed with SAS Version 9.4 (SAS Institute, Cary, NC). Data were analyzed by location (district) because interest was primarily understanding the effects of stage and cropping season on response variables whose data were collected.

3. Results

In both Belts, moisture content of maize at all three sampling stages was < 15%. In the Middle Belt, *Sitophilus zeamais* (Motschulsky), *Sitotroga cerealella* (Olivier), *Cathartus quadricollis* (Guerin-Meneville) and *Carpophilus dimidiatus* (Fabricius) were the dominant insect species that were recovered from maize on-farm but in the Northern Belt, there were no insect pests on maize at the field stage and only a few larvae were found in heaped maize. In both Belts, mean percentage insect damaged kernels (%IDK_{nb}) recorded across locations were below the 5% threshold set by Ghana Standard Authority (GSA) for commerce. The %IDK_{nb} values on-farm in all nine communities were < 2% per 250 g and mean maize weight losses of < 1% were recorded in all the communities. In the Middle Belt, mean %IDK_{nb} recorded across the locations in both cropping seasons ranged between 0.35–0.82% while 0.35–1.82% were recorded in the Northern Belt. However, in both Belts, %IDK_{nb} was significantly lower at field stage than at both the heaped and post-drying stages. Mean aflatoxin levels below 15 ppb were recorded from pre-harvested maize in both Belts but levels above 15 ppb were recorded from heaped maize on-farm. Fumonisin (ppm) levels of maize were below the recommended threshold of 4 ppm on pre-harvested and in heaped maize in both Belts.

4. Conclusion

The data presented in this comparative study show that more insect pests attack pre-harvested maize in the Middle Belt compared to the Northern Belt of Ghana. Interestingly, comparable insect damage and weight loss of maize occur in both Belts. Data also show that heaping maize on-farm increases aflatoxin levels beyond the acceptable threshold level and should not be practiced.

Abstract

Effective post-harvest management of crops could significantly contribute to food security by improving the availability and quality of food. In Burkina Faso, new concerns have emerged as a result of the growing importance accorded to sesame (Sesamum indica), roselle (Hibiscus sabdariffa), "zamnè" (Acacia macrostachya), and sorghum (Sorghum bicolor). The insects identified as storage pests on these crops belong mainly to the order Coleoptera and families of Chrysomelidae, Curculionidae and Bostrichidae are the most representative. The studies carried out allowed a better knowledge of the pests as well as their economic importance. Losses due to insects, estimated up to 100% depending on the crop and protection methods used, are frequently observed after a few months of grain storage. Several alternatives to the use of chemicals including biological control, biopesticides and hermetic storage are being promoted. The triple bagging technology is one of the promising alternatives that can adapt to the post-harvest storage of a wide range of crops. Despite its proven effectiveness for several commodities, there is need to verify its efficiency against a diversity of insect pests with differing behaviour and evolution. The importance of the challenges is such that the strategies to be implemented must be conceived in a comprehensive, integrated approach, even at the regional scale.

Keywords: Post-harvest concerns, Promising crop sectors, Grain beetles, Storage alternative methods, capacity building, Burkina Faso, regional integrated strategies.

Introduction

Persistent food insecurity in sub-Saharan Africa is a complex and multifactorial phenomenon (FAO, 2017). While it is true that food insecurity is related to the inadequacy of agricultural production in general, it is also important to recognize the role of inappropriate post-harvest management practices. In 2011, post-harvest losses were estimated by FAO and the World Bank in sub-Saharan Africa at around $ 4 billion a year for an estimated total annual production of $ 27 billion (World Bank, NRI and FAO, 2011). In addition, it is estimated that lost food could meet the minimum annual needs of at least 48 million people.

In Burkina Faso, agriculture is booming with growing interest in some crop sectors. To overcome food and nutritional insufficiency and reduce poverty, it is important to support the efforts made by farmers and government policies to increase crop productivity through appropriate post-harvest management strategies. The promising sectors mainly include food crops, legumes and/or oil crops, which are increasingly considered as cash crops. For the most part, these crops are important for food security of the majority of the population in the country and are an essential element of the livelihoods of smallholders.

Sorghum (*Sorghum bicolor* (L.) Moench) is one of the most important cereals in the semi-arid tropics providing a major source of dietary energy and protein for nearly a billion people living in semi-arid areas (Belton and Taylor, 2004; Awika and Rooney, 2004). In Burkina Faso, sorghum serves as the major staple food crop with a total annual production of 1,435,640 tons in 2015-2016 (INSD, 2016). Burkina Faso is the third largest African producer of sorghum after Nigeria and Sudan (FAOSTAT, 2016). Cowpea (*Vigna unguiculata* L. Walp.) is the most widely grown legume in Burkina Faso. All the parts of the plant are useful but the seeds, by their richness in proteins (23-30%), play an exceptional role as food. Burkina Faso is the third largest African producer with a production of 571,304 tons in 2015-2016 (FAOSTAT, 2016). "Zamnè" (*Acacia macrostachya*) is an example of a non-timber forest product of food interest in Burkina Faso. The nutritional value of seeds makes them the foods of

choice to produce nutritional improvement formulations (Hama-Ba et al., 2017). They contain nutrients that are essential for human health (Sawadogo et al., 2011). The increasing interest in this wild legume is such that «zamnè» is used in the preparation of prestigious dishes served in receptions of religious and customary ceremonies (Ganaba, 1997) where they are consumed in the form of ragout and dishes associated with cereals. (Hama-Ba et al., 2017). In economic terms, seed marketing generates substantial income for the rural population (Hagberg et al., 1996). Most of the production comes from harvests in the wild, but the importance of the plant has allowed the development of a research program to facilitate its wider domestication. Sesame (*Sesamum indicum* L) is an oilseed crop grown in several countries around the world for its seeds that are traded internationally (Amoukou et al., 2013). In Burkina Faso, sesame production has increased significantly in recent years, from 25,060 tons in 2005-2006 to more than 321,837 tons in 2014-2015 (FAOSTAT, 2016). This places Burkina Faso among the top three sesame producing countries in Africa after Sudan and Ethiopia and is the third largest agricultural export product after cotton and peanut (INSD, 2016). Unfortunately, since that date, the sector has been experiencing difficulties which are dropping production, which in 2016 was only 235,079 tons (INSD, 2016). In Burkina Faso, peanut, (*Arachis hypogeae*) is both an important food crop and a cash crop. Peanut production is becoming increasingly important with an average production increase of 9.7% compared to the five-year average, which makes a total production of 365,887 tons of unshelled peanut in 2016 (FAOSTAT, 2016). In West Africa and particularly in Burkina Faso, Roselle (*Hibiscus sabdariffa L*. Malvaceae) is receiving increasing attention as a crop with potential for making great socio-economic impacts. The Sabdariffa variety, the most important one, is grown for the production of calices, which are used in the preparation of Bissap, a high nutritional value and commercial drink (Egharevba and Law-Ogbomo, 2007; Lepengue et al., 2007; Sanou et al., 2004; Babajide, 2004).

Despite their importance, the seeds of all the above mentioned plants face post-harvest storage and management constraints, leading to variable post-harvest losses negatively impacting their availability, accessibility, and income that could result from their commercialization. In this paper, we focus on the problems, their causes, their impact and we will end up giving an overview of the solutions that are currently available or expected.

Major storage insect pests and damage caused

Post-harvest losses are correlated with economic losses since grain quality is an important determinant of market prices (Langyintuo et al., 2003). The above described crops are generally producing grains that have in common to be attacked by several species of insect pests (Tab. 1). We will describe for each of them the insects as well as the damages associated with the level of losses when possible.

Sorghum

An inventory of insects associated with sorghum storage in Burkina Faso revealed that fourteen species divided into eight families of Coleoptera and two families of Lepidoptera were recorded on the sorghum stores (Waongo et al., 2015). The most representative families included Bostrichidae, Silvanidae, Tenebrionidae, Cucujidae and Curculionidae. The Family Gelechiidae dominated the Order Lepidoptera (Waongo et al., 2015). Rhyzopertha dominica (Bostrichidae), representing 39.53% of the total number of individuals collected was the more important species responsible for the grain damage. Insects of the R. dominica species develop and feed on sorghum grains. This biological activity results mainly in a loss in weight and a production of flour from perforated and crushed grains (Waongo, 2016). After 6 months of storage in polypropylene bags, the perforated grains are estimated to 11.73% for a total grain loss of 2.87% (Lankoandé, 2017).

Cowpea

Several species of the subfamily Bruchinae (Chrysomelidae), and specifically Callosobruchus maculatus Fab., have been identified as insect pests of stored cowpeas in Burkina Faso (Ouédraogo

et al., 1996, Sanon et al., 2005). The overlapping generations of flightless form C. maculatus during cowpea post-harvest storage in West Africa are responsible of grain damage (Ouédraogo et al., 1996). Infested seeds become increasingly hollow resulting in weight loss and perforation, adult insect emergence holes at the end of larval growth. Previous studies have shown that farm storage for six months was accompanied by 70% seed infestation and about 30% weight loss and virtually unfit for consumption (Singh and Jackai, 1985).

Tab. 1. Summary information on the major insect pests and their damage in stored grains for crops under consideration, Burkina Faso.

Roselle (Hibiscus sabdariffa L.)	Spermophagus niger Motschulsky	Seed perforation and weight loss	Koussoube et al. (2016) Sanon et al. (2017)

Peanut

Sampling of peanut stores in the farm environment identified four families of insects (Ouédraogo et al., 2017) including three families of Coleoptera, Tenebrionidae, Chrysomelidae, Silvanidae and a family of Lepidoptera (Pyralidae). Among these insects, Caryedon serratus (Chrysomelidae, Bruchinae) seems to be the predominant and the most damaging species to stored peanuts (Ouédraogo et al., 2017). Monitoring peanut stores in several localities in western Burkina Faso showed a variation in the level of infestation according to localities and a rapid increase during storage. For example, in the locality of Toussiana, the rate of perforation of the peanut pods was almost zero at the beginning of storage but this increased significantly during storage to 53.7, 81.8, 89.8 and 100% after 2, 3, 4 and 6 months of storage, respectively. Another consequence of peanut

infestation by insects is the association of insect attacks with the production of aflatoxin, which causes severe food poisoning.

The "zamnè"

Recent studies of Acacia macrostachya grain storage have identified six insect pest species belonging to three families, Chrysomelidae (Bruchinae), Tenebrionidae and Silvanidae. The last two families contain mostly secondary pests. The subfamily Bruchinae, with 3 species, represents about 98% of insects collected in stores. These are Bruchidius silaceus, Bruchidius spp. and Caryedon furcatus and responsible for the damage (Sanon, Personal observation). The main damage caused by these pests to A. macrostachya includes weight loss and seed perforation.

Sesame

From the samples of sesame seeds collected from storage, two species of Coleoptera/Tenebrionidae (*Tribolium castaneum* and *T. confusum*) and one species of Lepidoptera/Pyralidae, *Ephestia cautella* were identified as storage pests (Sanou et al., 2011). The infestation of sesame during storage by these insects causes a rancidity of the seeds rendering them unfit for human consumption. Insects also cause the loss of germinability and promote the establishment and development of mycotoxins (Sanou et al., 2011) whose consequences remain to be clarified.

Roselle

Spermophagus niger (Coleoptera: Chrysomelidae: Bruchinae) is the main pest of roselle seeds stored in Burkina Faso (Koussoubé et al., 2016, Sanon et al., 2017a). Roselle infestations by S. niger occur in the field at calyx maturity with an estimated infestation rate of 67% of the samples examined. Like other Bruchinae, development takes place in the seeds and successively passes through an egg stage, four larval stages and a pupal stage (Sanon et al., 2017a). At the beginning of grain storage, infested seeds generally had only one insect emergence hole, with seed perforation rates ranging from 1.8% to 4 % depending on their origin (Sanon et al., 2017a).

Insect control strategies during post-harvest storage

The need to protect grain during post-harvest storage is imperative to ensure the availability and quality of food commodities that are limited resources. Increasingly, crops grown for export must also meet post-harvest quality standards to compete in the international market. Although synthetic insecticides have played a key role in post-harvest grain storage, their use by farmers is nowadays criticized worldwide (Williamson et al., 2008). Furthermore, a survey of cowpea traders in Burkina Faso found that 77% of the insecticides used were neither registered nor intended for food preservation (Zongo et al., 2015). The consequences of inappropriate usages of chemicals include health and environmental risks (Idrissi et al., 2010; Zongo et al., 2015), and sometimes induce resistance in storage insect pests populations (Leontieva et al., 2006; Oyedemi et al., 2006; Opit et al., 2012). To minimize the negative effects of chemicals, many studies have investigated some components of integrated pest management with a view to developing alternatives to systematic chemical control. In Burkina Faso, studies carried out on post-harvest storage of the crop sectors considered in this paper can be grouped into three categories: biological control, botanicals, and hermetic storage.

Biological control has often been considered at the experimental level without a method of producing biological control agents and large-scale application being developed. Studies on the biological control potential of the main cowpea pest, C. maculatus, have identified the parasitoid Hymenoptera Dinarmus basalis Rond. (Pteromalidae) and Uscana lariophaga Stephan (Trichogrammatidae) as the best biocontrol agents (Sanon et al., 1998; Amevoin et al., 2007) without cost-effective methods of mass production of these biocontrol agents being available. The recent discovery of four (4) families of Parasitoids, Eulophidae, Pteromalidae, Eupelmidae and Eurytomidae associated with Bruchinae pests of A. macrostachya (Personal communication) opens interesting

perspectives of research on the possibilities of biological control of these insects. Although an important component of integrated pest management, success stories of biological control under stored food conditions are rare.

The use of botanicals is by far the most explored field of research in Burkina Faso. The data collected mainly concern cowpeas and peanuts. In Burkina Faso, since the early 2000s, several scientific investigations have focused on the control of C. maculatus using botanicals considered as promising and safe alternatives to chemicals (Sanon et al., 2017b). Extensive studies were carried out on six (6) plant species from three families including Capparaceae, Lamiaceae and Verbenanceae, through bioassays on C maculatus and cowpea storage trials. The set of data analyzed shows that several plants materials, including powders, crushed plants and essential oils (EO) were active against eggs, larvae and adults of C. maculatus, through dose-dependent mortality responses. However, EO extracted from native aromatic plants have yielded the most promising results, specifically EO from Ocimum canum (Lamiaceae) appeared as the best candidate control agent (Sanon et al., 2017). With regard to peanuts, Ouédraogo et al (2016) also tested several essential oils on eggs and adults of C. serratus. The results also showed a variable dose dependent biological activity depending on the origin of the essential oil. The current stage of research on essential oils is the conduct of toxicity tests towards humans and animals and the optimization of their use in storage conditions. For example, it is envisaged to have the essential oils carried by supports which would facilitate the treatment and improve the remanence (Ilboudo et al., 2015).

Hermetic storage is an old technique but more recently revalorized through triple bagging technology, known as PICS bags (www.ag.purdue.edu/ipia/pics). Since previous research of Sanon et al. (2011) who validated the effectiveness of a triple bag prototype in post-harvest storage of cowpeas in Burkina Faso, the effectiveness of triple bagging has been demonstrated for many commodities in Africa and around the world. Grains that are effectively preserved with triple bagging include other legumes such as bambara groundnut, peanut or pigeon pea (Baoua et al., 2014a; Sudini et al., 2015; Vales et al., 2014) cereals such as maize, rice, sorghum, wheat (Njoroge et al., 2014; Williams et al., 2017; Martin et al., 2015; Baoua et al., 2014b, 2016; Lankoandé, 2017); roselle seeds (Amadou et al., 2016). Promising crop sectors such as sesame and "«zamnè»" have been the subject of very few studies regarding post-harvest management strategies. Moreover, recently, the use of insecticides on sesame above the maximum residue limits has resulted in seizures and destruction of export grains from Burkina Faso (Personal Communication), anything that calls for greater vigilance in the production and post-harvest management of this important cash crop. In the meantime, advice is provided to producers who also have the opportunity to use or experiment with airtight containers such as PICS bags.

Prospects of future research

Post-harvest issues are a global concern. Limiting post-harvest losses throughout the food chain must be an important part of food strategies to achieve food and nutrition security. In addition, effective post-harvest management, limiting losses and improving the quality of food, can help reduce poverty through increased incomes. The diversity and the multitude of the species of insect pests of grains in the described crop sectors highlights the predominant role of this taxonomic group in the occurrence of losses in post-harvest. That is why it is crucial to find the most appropriate solutions while minimizing the use of chemicals. Concerns about crop sectors such as sesame, roselle and «zamnè» are relatively new and deserve rapid action to address them. The components of IPM already tested on other models could also be extended to these emerging sectors. In view of the proven effectiveness of triple bagging for the preservation of several grain commodities, this technology should be quickly tested and validated for the above mentioned sectors. However, the different insects identified have different ecological and biological requirements, which necessarily involve a permanent evaluation of the technology vis-à-vis the targets for efficient and sustainable post-harvest management. Any control strategy, to be effective, should be part of a comprehensive

integrated pest management approach based on the natural potential offered at national and regional levels.

Abstract

Knowledge of the diversity of arthropod pests infesting stored maize value chain in Uganda is very scanty to guide the development and implementation of management strategies. From a cross-sectional study conducted in north western, eastern and central regions of Uganda during 2017/2018, the diversity and economic importance of storage arthropod pests of maize in farmer storage, trader/retailer stores in villages and townships, and in milling and processing facilities is presented. A total of 11 insect pests were recorded feeding internally and externally on stored maize. Rhyzopertha dominica, Sitophilus zeamais and Sitophilus oryzae were the primary insect pests followed by Tribolium spp., Cryptolestes spp., Sitotroga cerealella, and Oryzaephilus mercator. The highest insect diversity and damage was recorded when maize was stored with husked cobs in farmers' houses, a practice farmers use to store seed for next planting. Meanwhile the distribution pattern of the pests in trader/retailer stores in villages and townships, and in milling facilities indicate waves of insect infestation occurring with stocks of grain being brought in storage. The maize grain at the peak of harvesting was in excellent quality but later stocks brought in several months after harvest were infested with diverse insects. Re-drying at farm level and use of chemical dusts at trader/retailer stores in villages and townships were the most common pest management practice. However, the lack of a differentiated market, whereby better quality would fetch premium price, discourages investment to reduce postharvest losses. Subsequently, most farmers sold their grains immediately after harvest and most traders sold their stocks as soon as there was the next bulk buyer. The critical point for pest management is at farm level where pest diversity and damage is greatest, and at the village/ township stores where the grain may be held in anticipation of improvement in price.

Introduction

Maize is the important cereal crop grown in most parts of the Uganda for food, feed and income, (Asea. et al, 2014). The maize sub-sector in Uganda is estimated to provide a livelihood for about 3 million farm households, close to 1,000 traders and over 20 exporters (UBOS, 2017; UBOS and MAAIF. 2011). As elsewhere in eastern and southern Africa, maize is increasingly the staple food of choice in many parts of the country, providing over 40% of the calories consumed in both rural and urban areas (Mason and Smale, 2013; Byerlee et al., 1994). Nutritionally, maize whole grain of 100g contain 10g of protein (poor in trytophan and rich in leucine) and 4gm fat, and provitles 360 calories; the germ (12% by weight of the whole grain)) contains 22% of the total protein and 80% of the oil (Nuss and Tanumihardjo, 2010; Shah et al., 2016).

Smallholder farmers dominate maize production in Uganda, generally characterized by small farm acreage (0.5- 5 ha) (MAAIF, 2013), low yields (1.0 -1.8 MT/ha) and high production costs and consequently low returns. Unfortunately, poor post harvest handling and storage practices have led to low grain quality reducing potential income for smallholder farmers by ~$300/ha per annum and limiting market volume potential. The inefficient traditional drying methods, high moisture levels and lack secure storage have led to low quality grain susceptible to fungal diseases and insect pests. It is estimated that 5-15 % of the maize produced each year is lost over a period of 3-6 months during storage as a result of storage pest damage (Affognon et al., 2015). Elsewhere, comprehensive lists of insect fauna infesting maize are available, for example Ethiopia (Tadese 1996; Walker and Boxall 1974.), Malawi (Schulten, 1974), Saudi Arabia (Rostom, 1993). However, very little work has been conducted in Uganda to understand the population structure of insect fauna infesting stored maize along its value chain in order to guide the development of management strategies.

Materials and Methods

A survey was conducted between December 2017 and March 2018 when there was grain in storage and when infestation and grain damage levels were most likely to be serious after maize grain spending at least 5 months in storage since harvest. A total of 150 farmers, 30 trader/retailer stores in villages and townships, and 15 maize milling facilities were randomly selected from north western, eastern and central regions of Uganda, and sampled for presence of storage pests. From a maize storage facility at each sampling point, grain was collected from the top, on the sides, in the centre, and at the bottom, combined and a subsample of 100g of grain taken. The subsamples were each put in a sealed plastic-bottles punctured with pinholes and labelled with sample number. At each sampling point, specific information such name of farmer/ trader/retailer/mill, date of sampling, time of grain spend in storage, treatments to control pest infestations, and which pests among those sighted or otherwise the respondent perceived as most important, were recorded.

In the laboratory, each grain sample was sieved over a 2 mm mesh sieve and all fractions were examined. Insects were removed, counted and grouped according to order or genus and were preserved dry as pinned collections or in 75% alcohol. The different fractions of grain samples were reconstituted, re-bagged, and were held at room temperature to determine any internal infestation or parasitism. After about one month, these samples were re-examined and any emerged insects were recorded as previously. Based on their relative abundance in grain samples, the status of insects of each species was noted as being: very common when they were numerous and recorded from all samples; common when they were few but recorded from all samples; uncommon when they were few in number and recorded from some of the samples only; uncertain when it was not possible to handle for counting (for example mites); and unusual when the species is not known as a pest of stored products and was recorded from one or two samples only. The samples of insects and other arthropods obtained during both inspection periods are kept at the School of Agricultural Sciences Makerere University for further confirmation of identification.

Results and Discussion

The species of arthropods recorded on stored maize are listed in Tab. 1. Five species of Coleoptera and three species of Lepidoptera were preliminarily identified at the School of Agricultural Sciences Makerere University. Among Coleoptera, *Sitophilus* spp., *Tribolium* spp., *Rhizopertha dominica* and *Cryptolestes* spp. were the most common and widespread pests. One species of Coleoptera was vaguely identified as *Prostephanus truncatus* (large grain borer) but only one insect in one sample was recovered. The species of Lepidoptera that were recovered from the maize samples included *Sitotroga cerealella*, *Ephestia cautella* and *Plodia interpunctella*. These were dominant but only widespread in maize grain samples collected from village trader/retailer/milling premises. There were many other coleopteran pests, possibly mites, thysanura and diptera that were recovered in store refuse within the farmer stores and village trader/retailer/milling premises that were considered mostly secondary pests, and were not identified.

Sitophilus spp. was the most common and perhaps the most destructive of all the insect pests recorded (Tab. 2). Most of the pest species were recovered from grains that have been broken or damaged by *Sitophilus* spp., *S. cerealella* and *R. dominica* that are the primary pests, and thus considered secondary pests. These species that were recovered are cosmopolitan pests in stored products and not unique to Uganda. However, nationwide surveys may be necessary to determine the diversity of species of pests associated with stored maize and other stored produce in Uganda. This study did not attempt to estimate the exact losses caused by the major pest species in maize. It is important to determine the losses associated within the different types of stored produce so as to guide development of integrated pest management system.

Tab. 1: List of arthropod pests and their status in maize stored at on-farm and in village trader/retailer/milling premises in north western, eastern and central regions of Uganda between December 2017 and March 2018

Sitophilus spp	+++	+++	+++
Tribolium spp	++		+++
Prostephanus truncatus		?	?
Lepidoptera			
Ephestia cautella	+	+++	++
Plodia interpunctella	+	++	+++
Sitotroga cerealella	+	+++	+++
Others		++	+++

Re-drying at farm level is the common practice for managing pests, as most farmers reported that it reduces insect populations, with many of the winged insects flying away and the coleopteran insects crawling away from the grain under the hot sun. However, this practice exposes the grain to re-infestation, and increased damage in continued storage. The lack of a differentiated market, whereby better quality would fetch premium price, discouraged farmers to invest in postharvest loss reducing technologies. Depending on the quantities produced and the desperate need of income by the farmer, most farmers to sell their grains immediately after harvest whereby the drying process may also be hurried through. Subsequently poor quality produce enters the trading component of the value chain and thus the commodity fetching very low prices. At trader/retailer stores in villages and townships, grain was not held at all early in the season due to demand, and most traders sold their stocks as soon as there was the next bulk buyer. This was also a way to build capital to buy more grain later in the season. Where grain was held for some time in anticipation of improvement in price, there was no partitioning of the maize grain brought into storage the peak of harvesting that was in most cases in excellent quality from the later stocks brought in several months after harvest that were infested with diverse insects. At trader/retailer stores in villages and townships, chemical dusts either spread on the bags or admixed with grain before bagging was the most common pest management practice. No milling premise was observed to hold stocks of maize grain. The pests recovered within these sampling points were in grain dust on the floors, walls and roofs of the premises.

Tab. 2: Mean number (per 100g) of insect pests recorded from stored maize samples collected at on-farm and in village trader/retailer/milling premises in north western, eastern and central regions of Uganda between December 2017 and March 2018

	Central	North western	Eastern
Coleoptera			
Sitophilus spp	85.3 ± 7.6	63.1 ± 6.8	51.4 ± 6.8
Rhizopertha dominica	33.1 ± 7.2	37.0 ± 3.2	82.4 ± 6.8
Tribolium spp	10.8 ± 2.6	50.0 ± 1.7	19.5 ± 3.7

Based on the insect species diversity, dominancy, spread, and greatest potential for damage, the critical point of pest management is at the farm level. Postharvest control of insect pests should be an integral part of maintaining safe, high quality, abundant produce domestically and for trading in the country. For example, the necessity to variously demonstrate appropriate postharvest technologies such as mechanical crop shelling, solar dryers, and improved storage (e.g. hermitic bags and insecticide incorporated polypropylene bags) to farmers and traders. In order to promote adoption of these technologies, there is need for behaviour change communication campaign, and to conduct short-term trainings to create awareness and build a cadre of local postharvest specialists among extension workers as part of long-term capacity building in on-farm grain handling and storage; stored grain management; and application of basic food safety principles. There is also need to improve the operation environment, for example, strengthening farmer associations/community-based organizations to increase access to postharvest tools, equipment, packages, supplies; and facilitate development of well-structured commodity value chains and postharvest management and handling operations in the country. These associations/community-based organizations would establish postharvest service centres and Agribusinesses which offer a combination or all of the following services: harvesting, de-husking, drying, shelling, cleaning, storage, provision of agricultural inputs, and credit facilities. These postharvest handling services could make it possible to produce large quantities of consistently high quality commodities which would then facilitate value addition and bigger profit margins for the smallholder farmers. At trader/retailer stores in villages and townships, there is need for improved sanitation in the stores, and ability to rotate the produce in store according to the "first in - first out" principle in order to prevent over-storage.

Abstract

The efficacy of essential oils extracted from fruits of *Piper capense* and *Xylopia parviflora*, and roots of *Echinops giganteus* and *Mondia whitei* were evaluated against *Acanthoscelides obtectus* and fungi isolated from bean seeds in laboratory conditions in Cameroon. The essential oils were extracted by water-distillation and their chemical composition identified by Gas Chromatography-Flame Ionization Detection (GC-FID) and Gas Chromatography-Mass Spectrometry (GC-MS). Toxicity assays of essential oils against *A. obtectus* were carried out by fumigation in which insect pests were exposed fumes of the essential oils, and mortality recorded after 6, 12, and 24 hours. Additionally, the toxicity by contact of the essential oils was evaluated through coating grains with essential oils or impregnating the essential oils onto the filter paper, allowing the insects to physically get in contact with the essential oil, and assessing weevil mortality recorded after 1, 2, 3, and 4 days. The essential oils from *P. capense* and *X. parviflora* consisted mainly of hydrocarbon monoterpenes (56.5% and 50.0% respectively), whereas the essential oils from *E. giganteus* was mostly constituted of sesquiterpenes (94.3%) in which the tricyclic compounds are more abundant. A major compound identified in the essential oil from *M. whitei* was 2-hydroxy-4-methoxy-benzaldehyde (81%). The essential oil from *X. parviflora* was the most effective as contact and fumigant against *A. obtectus,* causing 100% mortality within 1 day at low lethal concentrations. On the other hand, the essential oil from *M. whitei* exhibited the best anti-fungal activity. These essential oils could play an important role in pest protection of stored beans and reduce the risks associated with use of synthetic insecticides especially in low income small holder farming systems.

Keywords : Essential oil, Insecticide, Fungicide, biopesticides, Integrated Pest Management

Background

Bean crops (Phaseolus vulgaris L.) occupy a prominent place in medium and large farming units in Cameroon (Pessoa et al., 2016). Most of the time, the availability of this crop depends on, among other factors, strict quality control, timely harvesting, and appropriate storage. During storage, bean seeds may be destroyed by insects mainly Acanthoscelides obtectus SAY which consume substantial quantities of the beans, and their respiration increases temperature and intergranular humidity which in turn facilitates fungal growth (Rupolho et al., 2006) and production of mycotoxins. Stored grain pest infestation is controlled by various methods amongst which the application of chemical pesticides remains the most effective. However, because of the negative side effects of most synthetic insecticides on environment and human health, alternative control methods are gaining importance. Over the last decade, essential oils from plant origin and other botanicals (plant powders, plant extracts and non-volatile oils) have been developed as potential alternatives for pest control. They are often of low mammalian toxicity, readily biodegradable and pose low danger to the environment if used in small amounts (Regnault-Roger et al., 2002). This research evaluated the insecticidal and fungicidal activities of essential oils from fruits of Piper capense and Xylopia parviflora, and roots of Echinops giganteus and Mondia whitei against Acanthoscelides obtectus and fungi isolated from bean seeds. These plants were selected among others because they are locally available and used as spices in some camerounian traditional foods.

Materials and methods

Toxicity assays of essential oils extracted from Piper capense, Xylopia parviflora, Echinops giganteus *and* Mondia whitei against *the bean weevil (*Acanthoscelides obtectus*)*

Adult insects were obtained from stock cultures maintained in the laboratory and reared on common bean grains. They were kept in a controlled chamber under a 10-h light, 14-h dark photoperiod at 26.08 ± 0.2 °C and 70.8 ± 0.4% relative humidity (RH). After two weeks of oviposition, parent insects were removed by sieving and the glass bottles containing bean were held under the same conditions until the emergence of F1 progeny. For activity testing, one or two days old adult of unsexed insects were used. The different plant materials were collected from Dschang market where they are sold as spices. Essential oils of *Piper capense* and *Xylopia parviflora* fruits, of *Echinops giganteus* and *Mondia whitei* roots were extracted by hydro-distillation and analyzed by Gas Chromatography-Flame Ionization Detection (GC-FID) and Gas Chromatography-Mass Spectrometry (GC-MS). Toxicity assay of essential oils against *A. obtectus* was carried out by fumigation in which insect pests were exposed fumes of the essential oils, and mortality recorded after 6, 12, and 24 hours. Additionally, the toxicity by contact of the essential oils was evaluated through coating grains with essential oils or impregnating the essential oils onto the filter paper, allowing the insects to physically get in contact with the essential oil, and assessing weevil mortality recorded after 1, 2, 3, and 4 days. Percent mortality was calculated using the Abbott correction formula for natural mortality in controls (Abbott, 1925). The Bliss (1938) method based on the regression of the probits of mortalities (Finney, 1971) was used to determine the 50% lethal concentration (LC50) based on the decimal logarithms of the oil concentrations. After the above contact toxicity tests, the remaining living adults were removed, discarded and the glass jars containing beans were kept under the same experimental conditions until the emergence of F1 progeny. The emerged F1 insect's was counted to evaluate the effect of essential oils on the progeny production of *A. obtectus* adults. Percentage of reduction in progeny production was calculated and the damaged seeds were weighed to assess weight loss.

Evaluating antifungal activity of essential oils extracted from Piper capense, Xylopia parviflora, Echinops giganteus and Mondia whitei against different fungi isolated from market bean seeds

Thirty-six samples of bean were collected from three markets in Dschang town, at the rate of 12 from each market. To isolate post-harvest pathogens, 10 seeds of each sample were placed in Petri dishes on potatoes dextrose agar (PDA) for 7 days at 21±2 °C. The pure isolated fungi were morphologically identified according to the documented keys in fungal identification (Champion, 1997; Mathur and Kongsdal, 2003) and were subcultured and stored in a fridge (4 °C) until needed. Among these, 8 filamentous fungi (*Aspergillus flavus, Aspergillus niger, Fusarium oxysporum, Fusarium moniliforme, Fusarium nivale, Fusarium solani, Fusarium crookwellense,* and *Penicillium* sp) were used to evaluate the antifungal activity of essential oils. The antifungal activity of the essential oils was performed following the procedure described (Ngono et al., 2000). The minimal inhibitory concentration (MIC) which inhibits the visible growth of fungi was recorded. For confirmation of the fungistatic or fungicidal activity, all wells showing no visible growth after 7 days were subcultured onto potatoes dextrose agar medium and incubated at 25°C for 10 days and the minimal fungicidal concentration (MFC) was recorded as the lowest concentration where no fungal growth was observed.

Results

Chemical composition of the essential oils

The essential oils of *P. capense* and *X. parviflora* consisted mainly of hydrocarbon monoterpenes (56.5% and 50.0% respectively), followed by hydrocarbon sesquiterpenes (17.8%) for *P. capense* and oxygenated monoterpenes (20.7%) for *X. parviflora*, whereas *E. giganteus* was mostly constituted of sesquiterpenes (94.3%) in which the tricyclic compounds are more abundant. A major compound, 2-hydroxy-4-methoxy-benzaldehyde (81%) was identified in the essential oil of *M. whitei* (Tab. 1).

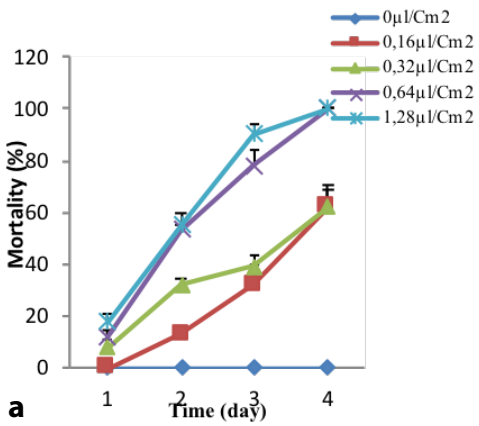
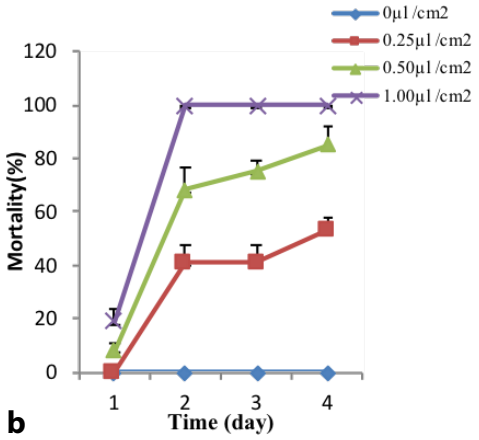
Toxicity of extracted essential oils to Acanthoscelides obtectus

The toxicity of essential oils applied on filter paper was dose-dependent because weevil mortality increased with concentrations of the oils, except for *M. whitei* which did not show any activity against *A. obtectus* (Fig.1). Essential oil extracted from *X. parviflora* fruits was the most effective at all concentrations evaluated. At the highest concentrations (0.31 and 0.47µl/cm2), it caused 100% mortality within the first day, whereas the essential oils from *E. giganteus* and *P. capense* caused weevil mortality after 2 and 4 days exposure, respectively. The LC50 of essential oils extracted from *E. giganteus, P. capense* and *X. parviflora* when used as physical contact poisons against *A. obtectus* were 0.35 µl/cm2, 0.31µl/cm2 and 0.17µl/cm2, respectively.

After 24h, the lowest concentration of all fumigated essential oils had strong toxic action (between 98 and 100% mortality) against *A. obtectus* (Fig. 2). Between 6h and 12h, the mortality induced by all the concentrations was significantly different ($P<0.05$). The LC50 values after 12h were 0.15 µl/cm3, 0.08 µl/cm3 and 0.05µl/cm3 for *M. whitei, P. capense* and *X. parvflora*, respectively. The essential oil from *E. giganteus* was not effective against *A. obtectus* at all the tested concentrations when used as a fumigant. The mortality of *A. obtectus* due to fumigation with essential oils also increased with the dosage of oil and the exposure time. Essential oil *of X. parviflora* was the most effective against A. *obtectus* on beans. Indeed, its highest doses (0.04 and 0.06µl/g) caused 100% mortality on the first day. The LD50 of the essential oils calculated after 2 days of exposure when used as fumigants against *A. obtectus* adults were 0.80µl/g, 0.60µl/g and 0.19µl/g for *M. whitei, P. capense* and *X. parvflora*, respectively.





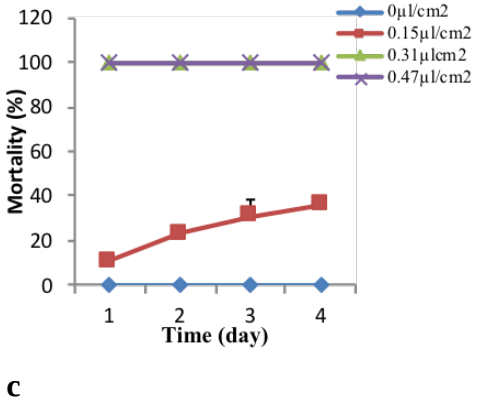


Fig 1: Mortality percentage (CM±SD) of *Acanthoscelides obtectus* as a function of time and concentration of essential oils of *Echinops giganteus* (a), *Piper capense* (b) and *Xylopia parviflora* (c) on filter paper. CM: corrected mortality; SD: standard deviation

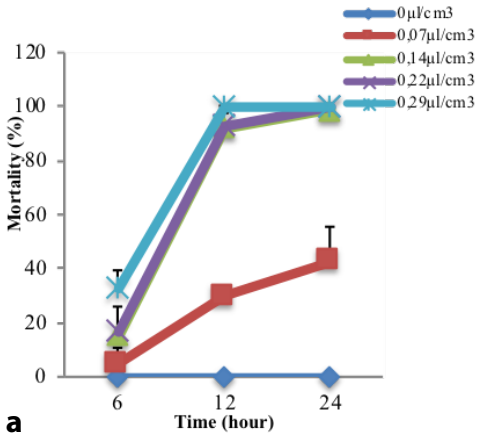

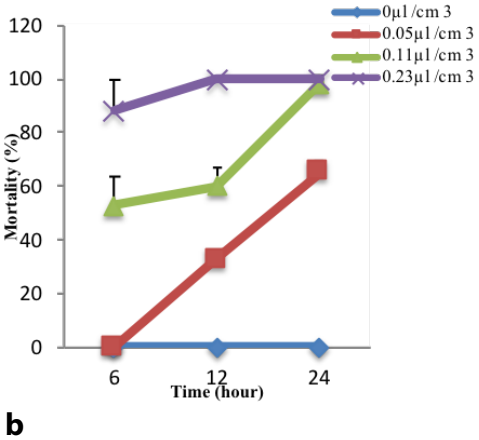

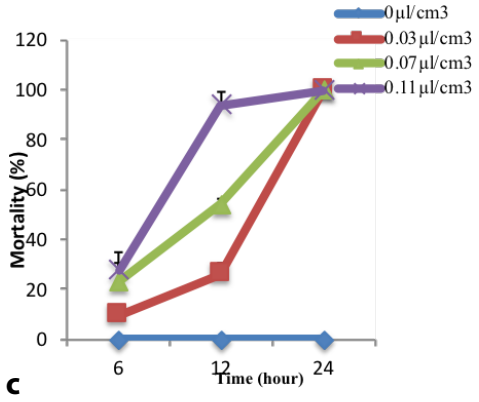

Fig 2: Mortality percentage (CM±SD) of *Acanthoscelides obtectus* as a function of time and concentration of essential oils of *Mondia whitei* (a), *Piper capense* (b) and *Xylopia parviflora* (c) fumigated. CM: corrected mortality; SD: standard deviation.

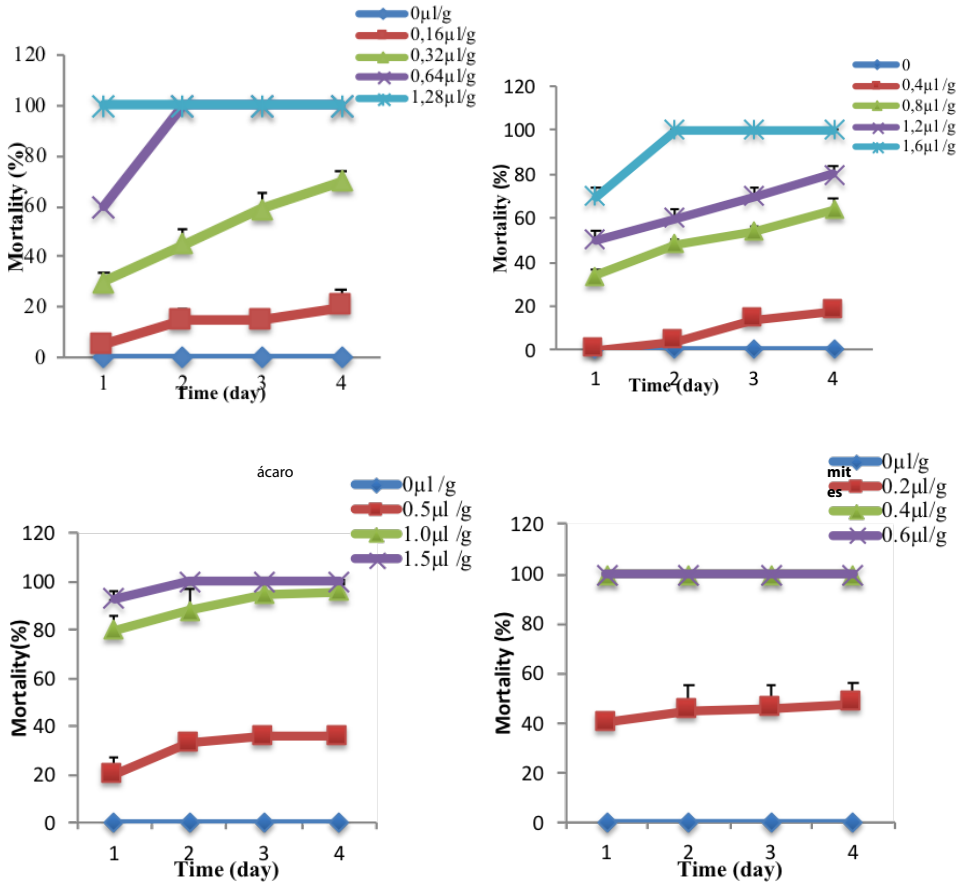

Fig 3: Mortality (CM±SD) of *Acanthoscelides obtectus* as a function of time and concentration of essential oils of *Echinops giganteus* (a), *Mondia whitei* (b), *Piper capense* (c) and *Xylopia parviflora* (d) on bean grains. CM: corrected mortality; SD: standard deviation

Effect of essential oils on F1 progeny production of Acanthoscelides obtectus infesting stored beans

All doses of essential oils caused significant reduction in F1 progeny of *A. obtectus* (Tab. 1). No progeny emerged in grains treated with the highest dosages of the four essential oils. Subsequently, all the doses of the oils reduced the grain weight loss, since it is proportional to the number of insects that emerge.

Tab. 2: Effect of dosage of essential oils of *Echinops giganteus*, *Piper capense, Mondia whitei* and *Xylopia parviflora* on F1 progeny production in stored beans and weight of beans after emergence.

Anti-fungal activity of extracted essential oils

Several fungal species were isolated and identified on bean seeds collected in Dschang town; the main species were *Aspergillus flavus, Aspergillus niger, Fusarium oxysporum, penicillium sp., Rhizopus stolonifer, Rhizoctonia solani* and *Mucor* sp. The genus *Aspergillus* is most prevalent (58%) followed by the genera *Fusarium* (16%), *Penicillium* (12%), while the genera *Mucor* (6%), *Rhizopus* (3%), *Rhizoctonia* (2%) and others (3%) were the least prevalent.

Mondia whitei essential oil showed the best antifungal activities (MIC = 0.06 – 1.02 mg/ml). Among the eight fungal species tested, *A. niger* was the most sensitive to the treatment, while *Penicillium* sp., *F. oxysporum* and *F. moniliforme* were the most resistant. *Piper capense*, *D. glomerata* and *X. parviflora* showed low antifungal activity on all fungal isolates tested with MIC values between 4.1 and 16.32 mg/ml while *E. giganteus* did not show any antifungal activity.

Tab. 3: Minimal Inhibitory Concentrations (MIC) and Minimal Fungicidal Concentrations (MFC) results for antifungal activity of essential oil from *Mondia whitei.*

	Mondia whitei		**Mancozeb**	
Fungi species	**CMI(mg/ml)**	**CMF (mg/ml)**	**CMI(mg/ml)**	**CMF(mg/ml)**
A. flavus	0.51	0.51	0.51	1
A. niger	0.06	0.51	0.51	1
F. solani	0.25	0.51	0.25	1
F. nivale	0.51	1.02	0.25	1
Penicillium sp.	1.02	2.04	0.25	1
F. oxysporum	1.02	2.04	0.12	1
F. crookwellense	0.51	2.04	0.12	1
F. moniliforme	1.02	1.02	0.51	1

Conclusion

A good level of control of *A. obtectus* was achieved with essential oils of *E. giganteus*, *M. whitei*, *P. capense* and *X. parviflora*, which successfully reduced *A. obtectus* progeny production and bean loss. At the same time, the antifungal activity of these essential oils gives new opportunity for the control

of bean pathogens. Overall, essential oils extracted from these spices could play an important role in stored bean protection and reduce the risk associated with the use of synthetic insecticides.

Sustained effective use of phosphine in stored product protection in India: Role of UPL Limited

Ujjwal Kumar*

UPL Limited, Mumbai, India
*Corresponding Author: ujjwal.kumar@uniphos.com
DOI 10.5073/jka.2018.463.203

Phosphine has a predominant role in stored products protection in India since more than 4 decades. Its use has gained further prominence ever since methyl bromide has been withdrawn (except QPS applications) on environmental concerns. Accordingly, the use of phosphine is being expanded to QPS treatment of certain commodities. Phosphine has several merits and as a stored product fumigant. However, there is a concern about occasional failure to achieve desired 100% mortality of insect pests during phosphine treatment in the country. Hence the factors contributing for control failures have been identified. Also there are reports about need to improve existing fumigation practices and to create awareness about the required parameters to ensure successful treatments. In this context UPL Limited, a leading manufacturer of metal phosphide formulations in the world took important steps: A. To create awareness about proper sealing of fumigation enclosures, phosphine dosage, exposure period and target terminal concentration parameters B. To impart practical demonstrations to the stakeholders in across the country details of phosphine fumigation workshops, demonstrations and industry & end user & farmers interactions conceptualized, funded and executed by UPL Limited in coordination with other lead agencies, will be discussed. Furthermore, focus on the use of on-site phosphine generators which has the advantage of rapid generation and even distribution of the gas facilitating successful treatments by way of demonstration to different end users has also been presented.

Recent Developments in the Global Application of ECO2FUME® and VAPORPH3OS® Phosphine Fumigants

Abstract

ECO2FUME® (2% phosphine, 98% CO2 by weight) and VAPORPH3OS® (99.3% phosphine average by weight) are cylinderized gas formulations of phosphine that have achieved significant growth in commercial applications for the disinfestation of food and non-food commodities in the last two decades. The expansion in the global application of these two cylinderized phosphine fumigants is driven by increasing concern for safety, efficacy, unreacted powdered residue and disposal associated with aluminium phosphide tablets, which are promoted as alternatives to methyl bromide, and the concern of insect resistance to phosphine in both developed and developing countries. This paper describes recent developments in the global application of ECO2FUME® and VAPORPH3OS® in terms of commercial in-transit fumigation of grains and logs in ships, fumigation of export distiller's dried grain with solubles (DDGS) in containers and shiphold, best practices in the management of phosphine resistance of insects in grains, and establishment and application of quarantine and preshipment (QPS) phosphine fumigation protocols for selected fresh fruits, vegetables, dried fruits and cut flowers as an alternative to methyl bromide. The growing issue of powdered residue from unspent aluminium phosphine tablets and the use of cylinderized phosphine as an effective solution are discussed.

Keywords: ECO2FUME®, VAPORPH3OS®, cylinderized phosphine, Horn Diluphos System, fumigation applications, aluminium phosphide tablets issue, alternative to methyl bromide, phosphine resistance management

1. Introduction

Among the existing fumigants commercially available in the market, phosphine is considered the most cost-effective and widely used fumigant for protection against stored product pests worldwide. Although using phosphine in a solid metal phosphide formulation has drawbacks --it is slow acting, self-ignites when exposed to air, and requires deactivation and disposal of unspent residue--these disadvantages have been overcome with the introduction of ECO2FUME® and VAPORPH3OS® cylinderized phosphine fumigants.

ECO2FUME® is a cylinderized formulation of a nonflammable, ready-to-use liquefied gas mixture of 2% phosphine and 98% carbon dioxide (CO2) by weight. It is packaged in high-pressure aluminum or steel cylinders with a net fumigant weight of 31 kg and 620 grams of phosphine. Though the phosphine/CO2 mixture is liquefied inside the cylinder, it is converted immediately to gaseous form upon release into the atmosphere. The formulation requires simple dispensing equipment made of either a stainless steel double-braided hose or a high-pressure hydraulic hose designed to deliver the fumigant as quickly or slowly as required by individual applications. VAPORPH3OS® is 99.3% average phosphine purity by weight and is designed for use with approved blending equipment for safe on-site dilution with CO2 or air in nonflammable proportions. It comes in steel cylinders with a net fumigant weight of 22 kg. Due to the larger amount of phosphine contained in a cylinder, VAPORPH3OS® is most suitable for larger volume applications for which it is not practical to store, handle or transport large numbers of cylinders; for price-sensitive applications such as grains; and for locations that conduct frequent fumigations (Tumambing et al., 2012).

ECO2FUME® and VAPORPH3OS® offer numerous benefits. The conduct of fumigation can be completed safely because it is applied externally to the fumigation structure, thereby removing confined space entry, reducing worker exposure and eliminating retrieval of 3 – 5% unspent powdered residue associated with metal phosphides (van Graver 2001). Due to its gaseous form, there is no residue that requires waste deactivation or disposal. When phosphine gas is vented into the atmosphere during aeration, it will react with oxygen in the air and, in the presence of sunlight, will readily convert to phosphoric acid. It is environmentally friendly as it is non-ozone depleting and does not contribute significantly as a greenhouse gas. It has a non-phytotoxic property and, therefore, does not damage sensitive commodities such as cut flowers, fruits and vegetables during fumigation. Required fumigation time is considerably faster using a phosphine gas than a metal phosphide formulation because the gas mixture can be easily applied to quickly distribute and uniformly achieve the target concentration. Compared to methyl bromide, the dose level for phosphine gas is at least 20 times less in terms of g/m3 application rate for phosphine

environmental and safety benefit. Additionally, phosphine gas is more penetrating and has extremely active molecules, which will enable the gas to distribute quickly and uniformly inside the fumigation structure without the help of a blower. Better gas distribution results in more effective control of target insects. Target concentration can be maintained quickly and safely anytime during the fumigation by top-up, which also decreases the amount of phosphine that needs to be applied.

Through the years and over nearly two decades, ECO2FUME® and VAPORPH3OS® have achieved significant growth in commercial application for the disinfestation of food and non-food commodities. The expansion in the global application of these two cylinderized phosphine fumigants has been driven by increasing concern for safety, efficacy, unreacted powdered residue and disposal associated with aluminium phosphide tablets; alternatives to methyl bromide; and the spread of insect resistance to phosphine in both developed and developing countries.

Application for In-Transit Fumigation of Grains and Logs in Ships

In-transit fumigation of grains and logs in ships has been practiced for several years around the world using aluminum phosphide tablets or blankets. However, the use aluminum phosphide in ships has been associated with risk of ignition, fire and explosion, particularly during aeration or gas venting due to ingress of high-humidity air and exposure of still-active fumigant inside the hold, which leads to quicker generation of phosphine gas, exceeding the low flammability limit. Additionally, the use of aluminum phosphide tablets leaves unspent powder residue that contaminates the fumigated commodity in the ship.

Due to safety issues and residue contamination of fumigated commodities in ships, in recent years ECO2FUME® and VAPORPH3OS® have been utilized in commercial fumigation of grains and logs in ships during in-transit journeys at sea. In Turkey, ECO2FUME® is being used for in-transit fumigation of exported corn and soy beans in the Black Sea region. A typical cargo ship with approximately 45,000 m3 volume capacity containing about 30,000 tons of corn and soy bean can be fumigated while in transit for 14 days using a phosphine dose of 400 ppm. As shown in Fig. 1, the complete setup for dispensing ECO2FUME® involved the following (Goztas et al., 2015):

1. A perforated drainage pipe was placed at the bottom of the ship hold.
2. The drainage pipe and a recirculation pipe were connected via a “T” connection.
3. A blower was attached to the recirculation pipe to ensure movement of the gas.
4. After loading of the commodity, the recirculation pipe was placed on top of the commodity.
5. ECO2FUME® cylinders were secured and connected to the system via a standard manifold (Fig. 2).
6. ECO2FUME® was then dispensed into the hold.

In Australia, VAPORPH3OS® in combination with the Horn Diluphos System (HDS) has been used for in-transit fumigation of export grains destined to the Middle East as a mitigation measure. The option of using VAPORPH3OS® instead of aluminium phosphide tablets was prompted when the importing country rejected fumigated grains contaminated with powdered residue. The fumigation protocol and overall setup of gas dispensing and gas distribution is similar to ECO2FUME® except for using VAPORPH3OS® and an HDS fumigation machine. Fig. 3 and 4 show a setup using VAPORPH3OS® and HDS 200 inside a trailer and dispensing the gas through a flexible distribution hose into a hatch in the shiphold (courtesy of Ball, 2016).

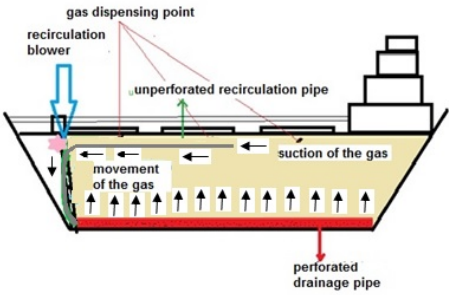

Fig. 1 Schematic of setup of ECO2FUME® during gas dispensing and distribution inside the shiphold.

Fig. 2 Eight ECO2FUME® cylinders secured and connected in manifold during gas dispensing through the hatch.

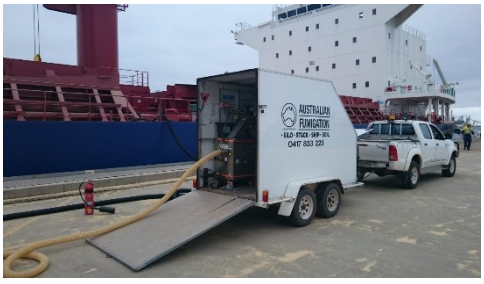

Fig. 3 VAPORPH3OS® and HDS 200 inside a trailer ready for dispensing gas into a shiphold.

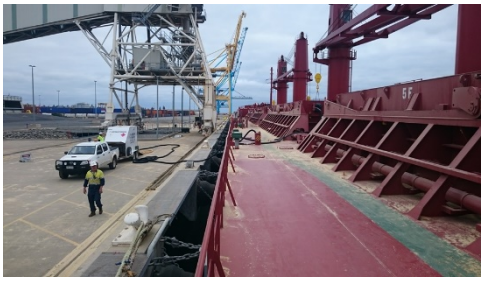

Fig. 4 Setup of flexible gas distribution hose between the trailer and hatch in a shiphold.

For additional safety when using ECO2FUME® and VAPORPH3OS®, guidelines on the use of pesticides applicable to fumigating cargo in ships set by the International Maritime Organization (IMO 2010) are being followed. IMO guidelines have specific instructions for pre-inspection of shipholds for the presence of cracks, and gas monitoring for the presence of gas leaks outside the shiphold and inside the cabin of the crew.

Fumigation of logs with VAPORPH3OS® and HDS destined to China has been practiced in Uruguay in the past two years. Previously, China has accepted the use of phosphine from aluminium phosphide tablets and blankets for in-transit fumigation of logs using a fumigation protocol of 2 g/m3 of phosphine as an initial dose at the wharf and a second dose of 1.5 g/m3 of phosphine as a top-up 5 days later while on the ship to maintain a phosphine concentration of 200 ppm for 10 days (Zhang and van Epenhuijsen, 2005). Chinese authorities have accepted the use of VAPORPH3OS® for in-transit fumigation of logs from Uruguay. In the case of VAPORPH3OS® the fumigation time is cut in half to 5 days using a one-off dose of 3.5 g/m3 of phosphine conducted while the ship is at wharf. With the use of VAPORPH3OS® and HDS, fumigation of logs is accomplished safer and quicker, eliminating the risk of having a fumigator on board to open the hatch and do complete top-up 5 days into the sea journey. The added benefit of using VAPORPH3OS® for in-transit fumigation of logs is the elimination of unspent powdered residue from aluminium phosphide tablets, which is currently not accepted by Chinese authorities.

Fumigation of Export Distillers Dried Grain with Solubles

Distillers dried grain with solubles (DDGS) as a by-product of ethanol production from corn is produced in large quantities in the US and became popular as a feed ingredient for export. However, in the past, as the Vietnamese quarantine authority banned the export of DDGS from the US due to

repeated insect infestation when the grain reached the destination port in Vietnam. The insect infestation issue was resolved with the establishment of fumigation protocols for phosphine gas for complete treatment against insect pests. With new protocols in place, the Vietnam Plant Protection Department lifted the ban on imported DDGS from the US effective September 2017 (Trung, 2017). The new protocols combine phosphine concentration, exposure time and temperature, as indicated below:

- 750 ppm for 3 days at >20°C
- 750 ppm for 4 days at 15 - 20°C
- 750 ppm for 5 days at 10 - 15°C

These protocols are applicable to both DDGS in shipping containers and larger bulk quantities in a shiphold with a gas recirculation system.

Best Practices in the Management of Insect Resistance to Phosphine in Grains

Insect resistance to phosphine has become a major concern in many countries where grains are harvested and stored for a period of 6 months or longer under high temperature and relative humidity favorable for insect growth and reproduction. The phosphine resistance issue emerged due to the use of leaky structures and poor fumigation practices associated with aluminium phosphide tablets. Aside from the common strong resistant strains of the lesser grain borer (Rhyzopertha dominica), rice/corn weevil (Sitophilus sp.), red flour beetle (Tribolium castaneum) and saw toothed grain beetle (Oryzaephilus surinamensis) another strongly resistant rusty grain beetle (Cyptolestes ferrugineus) is added to the list. This particular insect pest is a concern in Australia, China, India, Thailand, Vietnam, the Philippines and Brazil, among other countries. A series of efficacy studies and field validation trials conducted by the Postharvest Grain Protection Unit of the Queensland Department of Primary Industries have identified the strong resistant rusty grain beetle and established effective fumigation protocols for complete treatment of this insect pest (Kaur and Nayak, 2014; Nayak and Kaur, 2016). The fumigation protocols for the strong resistant rusty grain beetle are shown in Tab. 1 and are now part of the ECO2FUME® and VAPORPH3OS® label in Australia.

Tab. 1 Fumigation protocols for the strong resistant rusty grain beetle as part of the ECO2FUME® and VAPORPH3OS® Australian label

Commodity	Minimum Application Rate (g/m3) & Minimum Phosphine Concentration (ppm)		
Temperature	0.5 g/m3 (360 ppm)	1.0 g/m3 (700 ppm)	1.4 g/m3 (1000 ppm)
20 – 24°C	30 days	23 days	na
25 – 29 °C	27 days	18 days	12 days
30 - 34°C	na	na	10 days
35°C or higher	na	15 days	6 days

In the US, the USDA Agricultural Research Station conducted phosphine resistance management studies entitled "Technical Framework for Using Cylinderized Phosphine for Managing Phosphine Resistance" and presented the following findings (Walse et al., 2017).

Resistant pests can be effectively controlled with the right dose of phosphine.

- More is not always better - there is a "Sweet Spot" Phosphine concentration, such as 500 – 1000 ppm for lesser grain borer and red flour beetle.
- Narcosis threshold for eggs of major grain insects treated with phosphine is generally ≥ 1000 and ≤ 2000 ppm depending on the insect species.
- Phosphine concentration higher than the threshold concentration will result in narcosis, and much longer time is required to kill the egg stage.
- As shown in Fig. 5, the sweet spot phosphine concentration for the egg stage of susceptible and resistant strains of red flour beetle (RGB) is similar; however, eggs of resistant strains take

relatively longer time to kill compared to eggs of susceptible strains at a given phosphine concentration.

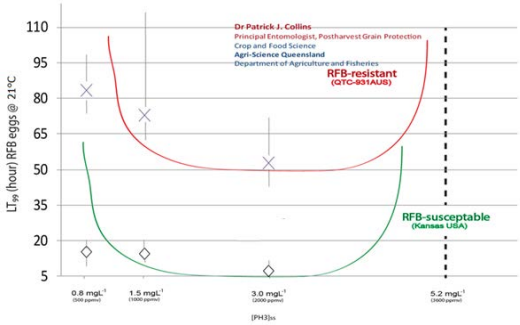

Fig. 5 Time in hours to reach LT99 of susceptible and resistant strains of red flour beetle (RGB) at different phosphine concentrations and 21°C temperature.

Phosphine fumigation protocols for quarantine and pre-shipment

Over the years, phosphine fumigation protocols have been developed in different countries as alternatives to methyl bromide for quarantine and pre-shipment application for selected fruits and vegetables, cut flowers, dried fruits, pine timber and associated nematodes, coffee and cocoa beans. These protocols were established under lab and field scale efficacy studies as conducted by accredited research institutions in different countries. Tab. 2 shows the different phosphine gas fumigation protocols for QPS treatment of selected commodities and corresponding research institutions.

Tab. 2 Phosphine gas fumigation protocols for QPS application of selected exported and imported commodities in different countries.

Commodity	Plant Pest Type	Phosphine Conc. (Minimum)	Exposure Time	Temperature	Reference
Pineapple	Purple scale, Citrus mealy bug	1400 ppm	24 hours	5 oC or higher	NPQS Korea 2015

Conclusions

1. ECO2FUME® and VAPORPH3OS® phosphine fumigants offer advantages over methyl bromide in terms of lower dose for phosphine environmental and safety benefits, greater gas penetration and quicker gas distribution into bulk commodities without the need for recirculation blower and without the need for a heater/vaporizer to dispense the fumigant in form.
2. ECO2FUME® and VAPORPH3OS® phosphine fumigants offer greater benefits over metal phosphide than metal phosphide formulation in terms of reduced worker exposure, no need of deactivation and disposal in unreacted residue, non-phytotoxic to sensitive commodities and quicker fumigation time.
3. The application of these two cylinderized phosphine fumigants has expanded to commercial fumigation of grains and logs in ships during in-transit journeys at sea and fumigation of export distiller's dried grain with solubles (DDGS) in containers and shipholds.
4. The emergence of phosphine resistance insects particularly in grains and oilseeds can be better addressed with the use of cylinderized phosphine fumigants due to its ability to be controlled and maintained at higher dose and longer exposure time.
5. There is sweet spot phosphine concentration that should be used for effective control of resistant insects. Above the sweet spot phosphine concentration narcosis effect could set in resulting in much longer time to kill the egg stage.
6. Phosphine gas fumigation protocols have been developed as alternative to methyl bromide for quarantine and pre-ship treatment of selected fruits and vegetables, cut flowers and nursery trees, dried fruits and pine timber and associated nematodes.

Efficacy of *Myristica fragrans* and *Alpinia conchigera* oils were evaluated against *Callosobruchus maculatus* at Post-harvest Technology on Field Crops Research and Development Group, Post-harvest and Processing Research and Development Office during October 2014 to September 2015. Seed of *M. fragrans* and rhizomes of *A. conchigera* were extracted the essential oils. It was identified the chemical composition by GC-MS which 10 and 12 constitutes were found on *M. fragrans* and *A. conchigera* oils. The major component of *M. fragrans* and *A. conchigera* oils were sabinene and 1,8-cineole, respectively. Contact toxicity assay on filter paper of both essential oils, the LC50 value of *C. maculatus* adults when treated with *M. fragrans* oil at 72 h were 4.6 µL/cm2 while 1.7 µL/cm2 for *A. conchigera* oil. Furthermore, the number of laid egg and adult progeny production of *C. maculatus* were inhibited by treated with *M. fragrans* and *A. conchigera* oils at 8 and 10% under laboratory condition. In additions, the efficacies of both essential oils were conducted for 6 months at warehouse of Lopburi Agricultural Research and Development Center. The results showed that insect pests and natural enemies were more found in the mung bean treated with *M. fragrans* oil than *A. conchigera* oil and *C. maculatus* was the major pest. Furthermore, *C. maculatus* was found on mung bean that coating with *M. fragrans* oil than *A. conchigera* oil. Both essential oils were control insect pests for 1 month.

Insecticidal and larvicidal activities of Cinamic acid esters isolated from Ocimum gratissimum L. and Vitallaria paradoxa leaves against Tribolium castaneum Hebst (Coleoptera:Tenebrionidae)

Insect pest of stored products is one major threat to food safety globally. Various techniques are being employed to address these pest problems. Pest management using botanicals have been widely practiced in recent times. The natural compounds present in these botanicals have been known to be responsible for the protection they offer against insect pests. Some of these compounds may act as single compounds to produce an effect or may be synergistically effective. In the present study using a bioassay guided approach, two cinnamic acid derivatives; Methyl cinnamate and Sitosterol cinnamate were isolated from the leaves of O. gratissimum and V. paradoxa respectively. Adults and a week old larvae of T. castaneum were dipped in the samples and transferred into clean petri dishes containing wheat flour and observed for mortality or larval growth activity. These compounds show high levels of insecticidal, larvicidal and larval growth inhibition activities against T. castaneum. The LC50 of methyl cinnamate was determined to be 26.92 mg/mL against the adult, 8.31mg/mL against the larvae whiles the LC50 of sitosterol cinnamate was determined to be 6.92 mg/mL against the adult and 3.91 mg/mL against the larvae. Generally, the susceptibility of adult T. castaneum to these cinnamic acid esters can be directly associated with the concentration as well as time of exposure to the compounds. Several studies have confirmed the safety of cinnamic acid esters by evaluating acute toxicity, skin irritation and genotoxicity and therefore can be used safely for stored product protection.

Assai (Euterpe oleracea Mart.) fruit: Green method development by Andiroba oil (*Carapa guianencis* L.) for Hemiptera control

Cristiano W.R. Ribeiro, Carlos E.S. Soares, Milena O. Dutra, Marco Dominici, Bárbara C.F. Ferreira, Vildes M. Scussel

Mycotoxicology and Food Contaminants Laboratory, Food Science & Technology Department, Center of Agricultural Sciences, Federal University of Santa Catarina

The assai (*Euterpe oleracea* Mart.), in Portuguese açaí, is a Brazilian fruit grown mainly in the Amazon forest (Northern region) and Cerrado (Northeastern region) which has a quite high staple & economic importance to the country. It is part of the region's culture and the fruit is consumed in salty dishes (mixed with cassava or tapioca flour and also with fried fish) by the natives. Although the main consumption is in those regions, its frozen pulp is the best-known worldwide available product (exported to the United States & European Union, mainly) and has increased in recent years. Apart from Amazon forest natives high lipid and protein food source, assai fruit is rich in antioxidants (anthocyanins & flavonoids), with high levels of vitamin C and fibers - that makes it highly consumed by the youngsters and sports people (as diet supplement - frozen pulp / ice-cream). Despite that, insects (Hemiptera *Triatoma brasiliensis*) infestation with subsequent disease development caused by *Trypanosoma cruzi* (parasite present in the mosquitoes faeces) may take place at the assai fruit stage. Considering the lack of information on assai fruit contamination and mosquito (parasite vector) control, the current study aimed to develop a green method through Andiroba oil (*Carapa*

guianencis L.) to control/repel that Hemiptera from the fruits (thus replacing chemical insecticides exposure). Andiroba oil and assai fruits utilized were from Belem city, Para state, Northern region of Brazil. They were divided into 2 main groups: treated (Treated Group - TG) and not treated (Control - C). The TG was sub-divided into TGI, TGII, TGIII, TGIV and TGV for the application of oil at different concentrations (10, 25, 30, 50 e 100%, respectively) and time of exposure (n=3). After oil treatment under controlled environment, the assai fruits insects were left standing 24 h, with their behavior variation observed (each 2 h) and the most effective concentration registered by decreasing order of efficacy was selected. As expected, on the assai surfaces`, the insect movements (distance) and speed reduced with the percentage of dead ones reaching to 100% as the oil concentration raised. The Andiroba oil green method could be a safe treatment to be utilized for assai insect infestation (instead of chemical insecticides) as the whole fruit is utilized n the de-pulping process.

Colour changes in pulses fumigated with different metal phosphide formulations

Gerhard Jakob[1]*, Renate Steuerwald[1], Dennis Ryman[1]

[1]Detia Freyberg GmbH, Dr.-Werner-Freyberg-Str. 11, D-69514 Laudenbach

DOI 10.5073/jka.2018.463.208

Abstract

Many phosphine-emitting products are used globally to control insect pests in dried vegetables, grains and pulses. However, variation in phosphide formulations is associated with colour change in many pulses. This study evaluated the effect of fumigation using Mg_3P_2 containing ammonium carbamate; AlP containing no ammonium carbamate and pure ammonium carbamate on colour of diferrent pulses. Different pulses showed different reactions towards fumigation with phosphine. A distinctly darker discolouration was observed in broad beans and lentils when fumigated with ammonium carbamate containing Mg_3P_2 and pure ammonium carbamate, whereas there were no apparent colour changes in white kidney beans, soybeans and green peas. The use of ammonium carbamate-free AlP resulted in no changes in any of the pulses. Therefore, formulation type of the phosphine product plays a major role in the visible colour change of the pulses.

Keywords: phosphine, ammonium carbamate, pulse varieties, colour change

Introduction

In many fields of stored product protection one of the most important substances in use worldwide to control stored product pests is the fumigant phosphine. The most established method of distribution is the use of solid-based aluminium phosphide and magnesium phosphide products in the form of tablets, pellets, bags or plates. After distribution, existing stored product moisture or ambient moisture contribute to the release of the actual active substance itself: phosphine gas. The advantages of this gas are its excellent penetrative ability and its extraordinarily high rate of efficiency against all stock-damaging insects. In this respect, all developmental stages of storage insect pests can be easily controlled; these properties even deal reliably with those developmental stages living hidden within the stored products.

Phosphine also has favourable properties regarding innocuity and the formation of no residues in treated food and animal feed products. The gas has no negative impact on the treated products and volatilizes quickly after use. Therefore, no residues are to be expected in fumigated goods. Besides, quality parameters such as germability or taste are not negatively influenced by the gas. However, according to oral reports, colour changes have arisen in different types of pulses after fumigation with metal phosphide products. This present study emonstrates the extent phosphine is may be responsible or the circumstances under cwhich certain changes in product colour may be triggered by substances emitted from the product formulation enhancers.

Materials and Methods

Five types of pulses were selected for the studies: green peas (*Pisum sativum*), broad beans (*Vicia faba*), lentils (*Lens culinaris*), white kidney beans (*Phaseolus vulgaris*) and soybeans (*Glycine max*)

while the fumigants used were: MAGTOXIN Pellets (active substance Mg_3P_2, contains ammonium carbamate) at a dosage of 3.3 g PH_3 / m^3, DETIA-GAS-EX B (active substance AlP, contains no ammonium carbamate) at a dosage of 3.3 g PH_3/m^3 and pure ammonium carbamate.

The bioassays involving ammonium carbamate were carried out in a glass dessicator (diameter 320 x height 235 mm) with a perforated plate. A dish filled with ammonium carbamate was placed at the bottom of the dessicator below the perforated plate, and petri dishes containing the pulses were placed on the perforated plate. This arrangement allowed ammonia vapour escaping from the ammonium carbamate to circulate around the perforated plate unhindered. The dessicator was kept closed for 8 days. In parallel, fumigation assays using metal phosphide products were carried out in two fumigation chambers each with a volume of 0.5 m^3. The relevant amount of fumigant was introduced together with the dishes filled with the pulses. The designated period of exposure time was 8 days. The test conditions were 20°C and 65% relative humidity.

Results

After treating the various pulse seeds with ammonium carbamate (and the ammonia released from it), distinct colour changes were observed in some of the pulse varieties. Whilst white kidney beans, soybeans and green peas didn't show any apparent changes, a distinctly darker discolouration was observed in broad beans and lentils in comparison with the untreated pulses.

In the fumigation trials both products used achieved the expected maximum phosphine concentration of between 2,000 – 2,500 ppm after 48-60 hours. After the exposure time of eight days, the ammonium carbamate containing product MAGTOXIN Pellets resulted in the same colour changes which were observed when using pure ammonium carbamate. Again, broad beans and lentils were distinctly dark discoloured after the treatment whereas no changes were evident in the white kidney beans, soybeans and green peas. In contrast, the use of ammonium carbamate-free DETIA-GAS-EX B resulted in no changes in any of the pulses.

Discussion

The most important active ingredient worldwide used for controlling stored product pests is phosphine gas. Through its positive properties with regard to eco-toxicity as well as its good penetration properties and the associated excellent effectiveness against stored product pests, phosphine has become indispensable for successful stored product protection over decades. The fumigant is also known as a substance, which has no serious effects on the treated goods with regard to residues and quality.

The present trials therefore raised the question as to whether phosphine actually is responsible for apparent colour changes in pulses following their fumigation with metal phosphide products; or whether other substances in the composition of metal phosphide formulations might be held responsible for such changes.

Consideration should be given in particular to the ammonium carbamate often deployed in compressed formulations used to improve compressability and to regulate the outgassing behavior. This ammonium carbamate leads to the release of ammonia during the degassing process.

The results of comparable trials using pure ammonium carbamate as well as metal phosphide formulations with and without ammonium carbamate clearly show that to a large degree of certainty it may be assumed that the colour changes are caused by ammonia and not by phosphine.

Whereas no changes occured in the pulses following fumigation using the ammonium carbamate-free metal phosphide product 'DETIA-GAS-EX B', dark discolouration in various pulses was observed following treatment with the product containing ammonium carbamate "MAGTOXIN Pellets" as well as following treatment with pure ammonium carbamate.

RYMAN (2017) reported similar results after having treated various pulses with metal phosphides which contained or did not contain ammonium carbamate. After treatment with formulations

containing ammonium carbamate on a few pulses, he likewise reported dark changes in colour whereas none of the varieties displayed changes after having been treated with the ammonium carbamate-free product DEGESCH PLATE.

It is known that especially tannic woods display discolouration in the presence of ammonia and on contact with the substance darken in colour (SELL AND KÜHNE, 1967). This circumstance is consciously utilized, for example when "smoking" oakwood, in order to modify the colour of the wood (MARQUARDT, 2005).

MARQUARD (1998) describes that pulses might also contain tannic acid and tannins. The amount can vary from species to species and from type to type and ranges from more or less no tannic acid up to 4.5% in the dry weight of the pulses.

In this respect, it can therefore be assumed that the colour changes in individual pulses are caused by the reaction of the ammonia from metal phosphide formulations containing ammonium carbamate with the tannin contained in the various pulses.

In order to avoid visual changes in the form of dark discolouration in pulses after treatment with metal phosphide formulations the use of formulations which do not contain any ammonium carbamate is recommended for such treatment.

DOI 10.5073/jka.2018.463.209

Abstract

The Postharvest Education Foundation (PEF) was founded to address postharvest losses through education and training. Postharvest expertisewas identified as a key weakness in many developing countries. The PEF provides innovative programs that motivate and empower people to reduce food losses and waste. At the heart of the PEF is a structured e-learning program that provides a practical curriculum to address the causes of postharvest losses, as well as methods to minimize these losses for horticultural crops and staple foods. E-learning is an efficient and cost-effective way to reach interested parties globally, and keeping costs low enables PEF to train and mentor a large number of candidates in developing countries. The curriculum entails several assignments and participants can conduct these assignments on a crop of their choice, making the training relevant to their situations. Most of the 154 people who have completed the program have in turn trained hundreds of farmers, traders and marketers in their own regions inhandling fresh produce, crop storage, and food processing, thereby delivering maximum impact with minimum input. In addition to its e-learning program, the PEF provides education on improved technical practices along the postharvest chain and on extension education. This training includes a wide range of topics from measuring postharvestlosses to designing demonstrations on storage, pest management, packaging and temperature management, from building and using low cost cold storage systems to calculating return on investment of changes in handling practices. The PEF also provides advice on designing postharvest training and service centers. This information is available on the organization's website. In addition, mentoring is provided through social media sites, continuing with the philosophy of providing distance education and training.

Keywords: E-learning, fresh produce handling, storage

Introduction

The Postharvest Education Foundation (PEF,www.postharvest.org) was founded as a non-profit organization in 2011 by Dr. Lisa Kitinoja with the assistance of a small group of like-minded colleagues. The aim of the PEF is toprovide innovative programs that motivate and empower people to reduce food losses and waste through education and training. At the heart of the PEF is a structured e-learning program to train participants in how to teach farmers, traders, processors and marketers on handling produce and crops after harvest to maintain quality and reduce postharvest losses for horticultural crops and staple foods. In addition the PEF provides postharvest tool kits, mentoring, access to information through its website, and practical education via hands-on workshops and conferences.

E-learning program

E-learning is an efficient and cost-effective way to train and mentor a large number of candidates in improved postharvest technologies, extension skills and outreach practices. Participants in the e-learning program include trainers in non-governmental organizations, governmental employees, horticulture companies, extension workers, research scientists, postharvest professionals and graduate students, and are predominantly located in developing countries (Tab. 1). Most of the 154 graduates of the PEF postharvest e-learningprogram have in turn trained farmers, traders and marketers in their region, extending the impact of the program.

From 2011 to 2016 the 'Global Postharvest E-learning Program' was offered as a mentor-guided learning program. Participants enrolled in January and worked through the assignments at their own pace using a crop of their choice. This allowed those working or studying fulltime to participate and complete the program by the end of December. As of November 2016, the PEF Postharvest E-learning Manual was posted online so individuals or groups can participate at no cost, and on their own schedules (Kitinoja, 2016).

The course consists of 12 chapters and up to 12 assignments (some are optional) as summarized here:

1. Introduction to the PEF training of postharvest trainers e-learning program and the manual
2. Assessing the learning needs, skills and experience of the postharvest trainer/extension worker (Assignment 1)
3. Investigating available resources in the field of postharvest technology (Assignment 2)
4. Performing a commodity systems assessment (CSAM) and identifying the causes and sources of postharvest losses and quality problems for any crop of interest (Assignment 3) (Fig. 1) (La Gra et al., 2016)
5. Identifying and prioritizing research, extension and advocacy needs for the crop based on the CSAM report (Assignment 4)
6. Assessing the suitability of 'best postharvest practices' and appropriate technologies for their respective communities (Assignment 5)
7. Determining the costs and benefits of using improved practices and technologies (Assignment 6) (Tab. 2 and 3)
8. Designing postharvest demonstrations for local farmers, traders, processors and marketers (Assignment 7)
9. Setting measurable goals and objectives for a postharvest training program (Assignment 8)
10. Using postharvest extension methods, simple postharvest tools and basic equipment for quality assessment and as training aids (Assignment 9)
11. Designing local postharvest training and extension programs for various audiences (Assignment 10)
12. Evaluating the effectiveness of postharvest training programs (Assignment 11).

There is an optional assignment (12) of designing a Postharvest Training and Services Center (PTSC) (Kitinoja & Barrett, 2015).

Conducting a CSAM (Fig. 1) helps to highlight crop-specific needs for training, research and advocacy. For example a CSAM conducted on French beans grown in Rwanda by Kangondo (2017) reached the following recommendations for growers, the government and other stakeholders on training, research and advocacy needs.

Training needs:

- Best agricultural practices to increase the quality and quantity of French bean production.
- Postharvest handling, especially after harvesting and during transportation.
- Evaluating affordable storage and transportation solutions for this perishable crop.
- Food safety.

Research needs:

- Evaluating new varieties, in particular, varieties suited to the Rwandan climate and those resistant to pests and diseases,
- Processing methods to prevent waste if the beans are not consumed fresh.

Advocacy needs:

- The government should assist, or facilitate private investors to assist, the industry in developing processing facilities for adding value and minimizing waste.
- Improved infrastructure including roads and constructing collection centers near production areas.

Assignment 6, where costs and benefits of adopting a new practice are evaluated, is a valuable exercise. Tab. 2, prepared by an e-learner, demonstrates the cost of constructing a Zero Energy Cool Chamber (ZECC) for storing passion fruit (Nantambi, 2016). The result was much lower water loss resulting in greater salable weight, and better quality fruit. In addition, the use of the ZECC strengthened the bargaining power of the small farmer and extended their revenue period providing them with a market advantage. The construction of a ZECC takes a few hours of time and labor (neither of which were included in Tab. 2) but the relative profit of this new practice compared to the current practice is clear (Tab. 3).

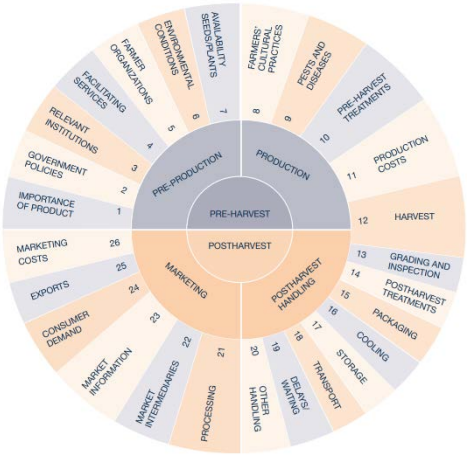

Fig. 1 The 26 principal components of the Commodity Systems Assessment Methodology (CSAM) presented in a figure (LaGra et al., 2016).

Other roles of the PEF

In addition to the e-learning program the PEF provides access to a wide range of postharvest information. Training materials are available on the website and are used by those involved in extension work and training of farmers, produce handlers and small-scale food processors. The resources site of the webpage provides white papers on relevant topics such as the use of returnable plastic crates (Kitinoja, 2013), and measuring postharvest losses of fruits and vegetables (Kitinoja and Kader, 2015).

A postharvest toolkit is available at a discounted price and includes a pulp temperature thermometer, produce caliper and gauges, pH and chlorine test strips, color charts for produce maturity and quality assessment, produce knife, refractometer and digital scale. A smaller version of the Postharvest toolkit is given to those that complete the e-learning program. The PEF website provides links to videos on using these postharvest tools in the white paper on 'Creating fruit and vegetable postharvest videos' (Barrett, 2014).

In addition, the website provides instructional videos and designs for building solar dryers, evaporatively cooled storage structures, cold rooms, hermetic storage of grains, transportationoptions and reduced energy use, to name a few. PEF e-learning graduates also provide links to their journal articles, research publications and extension materials e.g. 'Mycotoxins contamination in maize alarms food safety in sub-SaharaAfrica' (James &Zikankuba, 2018), 'Commodity systems assessment methodology of postharvest losses in vegetable Amaranths: The case of Tamale, Ghana'(Osei-Kwartenget al., 2017), Vegetable handling, distribution, and wholesale profitability in "Abinchi" night market, Kumasi-Ghana (Zu et al.,2014) and 'Zero Energy Cooling Technology for Storage of Cavendish Banana Fruits' (Abdul-Rahaman et al., 2015).

The PEF organizes postharvest workshops for e-learners who successfully complete their online programs, offers long-term mentoring for participants in e-learning programs via social networking websites, conducts short courses, study tours, and workshops and provides advice and guidance for establishing local postharvest training and services centers. As a consequence, postharvest training and services centers have been established in several African countries including Arusha, Tanzania (Kitinoja & Barrett, 2015) as well as 16 additional sites in Tanzania as a component of the Market Infrastructure, Value Addition and Rural Finance support project (World Bank), and in Guinea, BurkinaFasoand Rwanda as part of Feed the Future projects managed by the Horticulture Innovation Lab.

Conclusions

The impact of the PEF in training is not limited to the e-learning graduates but has benefited those trained by graduates, plus the many users of the PEF website. This impact was achieved with a small budget by passionate andcommitted professionals. Although the focus of The Postharvest Education Foundation is on fruits and vegetables, similar principles can be applied to improved

handling, drying, packing, pest protection, storage and processing of grains and cereals.

Abstract

Maize is a staple food in Ghana where there is ever increasing demand for its use to also support poultry and livestock production. However, post-harvest loss of maize is high in Ghana. This study evaluated the effectiveness of plastic and steel bins as bulk storage structures to reduce maize post-harvest loss in Ejura, Ghana during the period from February 2016 to January 2017. Maize pre-disinfested with a solar biomass hybrid dryer was stored in the following treatments: i. a white 7-ton plastic bin filled with untreated maize, ii. agreen 7-ton plastic bin filled with untreated maize, iii.a 6-ton Kikapu steel bin filled with untreated maize, iv. six 50-kg polypropylene (PP) bags filled with maize treated with Betallic Super (80 g pirimiphos-methyl and 15 g permethrin per liter as an emulsifiable concentrate (EC)), and v. six 50-kg PP bags filled with untreated maize ascontrol. Moisture content, insect pests, insect damaged kernels (IDK), grain weight loss, aflatoxin and fumonisin levels data were collected monthly. *Sitophilus zeamais*, *Triboliumcastaneum, Cathartusquadricollis*, and *Cryptolestesferrugineus* were the dominant insect species collected from maize samples. At the end of 12 months of storage, % IDK in the control was >17% while IDK values in the other treatments were <3%. Mean grain weight losses of <1% were recorded in the bin treatments. Mycotoxin levels in the control were above the allowable threshold of 15 ppb. Our data suggest that use of plastic and steel bins has potential to reduce post-harvest loss of maize during storage.

Key words: Storage bin**,** post-harvest loss, aflatoxin, fumonisin, grain storage.

1. Introduction

Maize is a staple food for about 1.2 billion people in sub-Saharan Africa (SSA) (IITA, 2009). In Ghana, there is ever increasing demand for its use to support poultry and livestock production. However, measurable quantitative, qualitative, and economic losses of maize grain occur along the post-harvest system (Tefera, 2012). And, the Food and Agriculture Organization of the United Nations and World Bank data estimated that post-harvest loss (PHL) of cereals in SSA ranged between 5–40%, and worth approximately $4 billion (Zorya et al., 2011).

Insect pest infestation constitutes the major threat; these infestations can cause losses of approximately 20–50% of stored maize in most African countries (CABI, 2012). Although synthetic insecticides can be effectively used to manage stored-product insect pests, the majority of resource-poor farmers in developing countries do not use these chemicals because of inability to afford them, along with the associated environmental and health concerns among others. Therefore, farmers resort to the use of traditional storage techniques including bag storage, and warehouses (FAO, 1994; Adejumo and Raji, 2007). However, bag storage is the most preferred storage technique in developing countries (Koona et al., 2007; De Groote et al., 2013) even though post-harvest losses in bagged commodities are high.

Therefore, there is a need to explore the use of alternative technologies for the protection of grains. In Ghana, little research has been undertaken in bulk storage of maize in plastic and steel hence this study which evaluated the effectiveness of two 7-metric ton plastic storage bins (white and green color) and a 6-metric ton steel bin to protect maize against infestation by stored grain insect pests as compared to farmers' current practice of using PP bagswith or without pesticide.

2. Materials and Methods

This study was conducted in Ejura, located in the Middle Belt of Ghana. The site selected for the study was near a maize market where insect pressure was expected to be high. The study spanned the period from February, 2016 to January, 2017. Maize pre-disinfested with a solar biomass hybrid dryer was stored in the following storage types as experimental treatments: i. a 7-ton white plastic bin filled with untreated maize, ii. a 7-ton green plastic bin filled with untreated maize, iii.a 6-ton Kikapu steel bin filled with untreated maize, iv. six 50-kg polypropylene (PP) bags filled with maize treated with Betallic Super (80 g pirimiphos-methyl, and 15 g permethrin per liter as an emulsifiable concentrate (EC), and v. six 50-kg PP bags filled with untreated maize (control).

No insect pest-control measures were conducted during the 12-month storage period of the study. The experimental design used was completely randomized design (CRD). However, the bin treatments could not be replicated because of budgetary constraints arising from the cost of plastic and steel storage bins and quantities of maize used. However, there were six replicates for the bag treatments. White maize variety "Obaatanpa" sourced from a single farmer was dried to a moisture contentof 12.5% using a solar biomass hybrid dryer. Initial and monthly maize samples were collected from storage bins and bags. Three out of six bags from the control and Betallic-treated maize were randomly selected and 250-g sample taken from each bag during each sampling month. For the storage bins, 250 g samples were taken from three different sections along a vertical profile (top, middle and bottom sections). In each section of the profile, grains were collected from six random positions. Moisture content (MC) and temperature of maize in each selected bag and each section of the storage bins were determined using a John Deere moisture meter and PHL moisture meter developed by the USDA-ARS. Maize samples were transported to the insect laboratory of the Department of Crop and Soil Sciences of Kwame Nkrumah University of Science and Technology (KNUST), Kumasi, Ghana in 17-liter Koolatron® 12-V Compact Portable Electric Cooler for mycotoxin analyses. Insect species and numbers and percentage insect damaged kernels (%IDK) were also determined. Mycotoxin (aflatoxin and fumonisin) analyses were performed using a standard Romer Labs test kit (romerlabs.com). Weight loss due to insect damage was assessed using the count and weigh method of Harris and Lindbald (1978) and Boxall (1986) as:

$$\text{Weight loss (\%)} = \frac{[(WuxNd)-(WdxNu)]}{Wux\,(Nd+Nu)} x\ 100$$

Where, W_u= Weight of undamaged grain, N_u= Number of undamaged grain, W_d= Weight of damaged grain, and N_d= Number of damaged grain.

Statistical analysis was not performed on the data because the storage bins were not replicated. Only means and standard error were calculated using SAS version 9.4 (SAS Institute, Cary, NC).

3. Results

The results showed that initial mean moisture content (MC) of maize in bins was 15.9–18.0% compared to the bags (10.1–10.5%); however, MC in the bins declined to 12.6–12.9% in March. Grain MC subsequently fluctuated in all the treatments reaching 14.0–14.3% and 13.8% in the bins and bags, respectively at the end of the experiment. No live insect species was observed during the first 6 months of storageprobably because pre-storage disinfestation was effective against the adults and re-infestation was virtually nil? Temperaturesrecorded were between 26.6 and 39.7 °C whiles relative humidity ranged 22.9-73.1%. The dominant insect species found after the sixth-month period were *Sitophilus zeamais*Motschulsky, *Triboliumcastaneum*Herbst, *Cathartusquadricollis*Guerin-Meneville, and *Cryptolestesferrugineus*Stephens. *Sitophilus zeamais* was the most dominant insect species with a mean total 34.3 ± 6.7 per 250 g in the control; other treatments had < 4 per 250 g) (Table 1). The highest total number of *C. quadricollis* (10.83 ± 3.55 per 250 g) was recorded in the Betallic treatment while the bin treatments had <1.00 per 250 g. With the exception of the white plastic bin which had 1.17 ± 0.41 live *Cryptolestesferrugineus*per 250 g, all other treatments had < 1.00. Percentage insect damage kernels (% IDK) was highest in the control (17.9 ± 5.2) than the other treatments (<3%) (Fig. 1), which is below the 5% threshold set by Ghana Standard Authority (GSA) for commerce (Reference). Mean grain weight losses recorded in the bin treatments were < 0.5% throughout the storage period. However, ~1.6% mean grain weight loss was recorded in the control (Fig. 1). Mean aflatoxin levels of maize in the storage bins were below 15 ppb which is the safe threshold set by GSA (year?). However, in the control, mean aflatoxin level was over 47 ppb at the end of the study (Fig. 2). Similarly, mean levels of fumonisin in the control was 5.3 ppm which is above the safe threshold of 4 ppm; mean levels of fumonisin in the bins and the betallic treatment was < 2 ppm.

Tab. 1. Mean total number (±SE) of *Sitophilus zeamais*(SZ), *Triboliumcastaneum* (TC), and *Cathartusquadricollis* (CQ) per 250 g of maize sampled from five storage types in Ejura, Ghana from September to January.

Storage type	SZ	TC	CQ
Control	34.28 ± 6.75	2.28 ± 0.68	1.28 ± 0.45
Betallic	0.28 ± 0.14	0.11 ± 0.08	10.83 ± 3.55
White plastic bin	0.94 ± 0.26	0 ± 0.0	0.78 ± 0.47
Green plastic bin	1.72 ± 0.38	1.06 ± 0.32	0.22 ± 0.13
Steel bin	1.11 ± 0.34	2.83 ± 0.69	0.06± 0.06

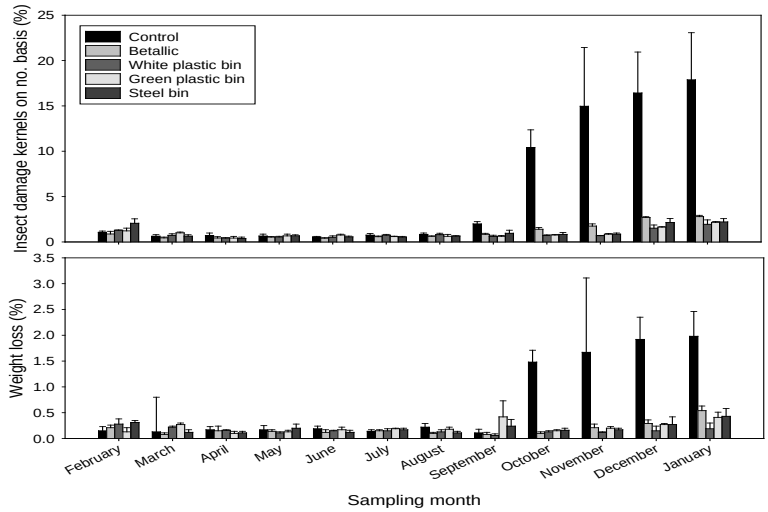

Fig. 1.Percentage insect damage kernels on number basis and percentage weight loss (Mean ± SE) per 250 g of maize obtained from five storage types in Ejura, Ghana.

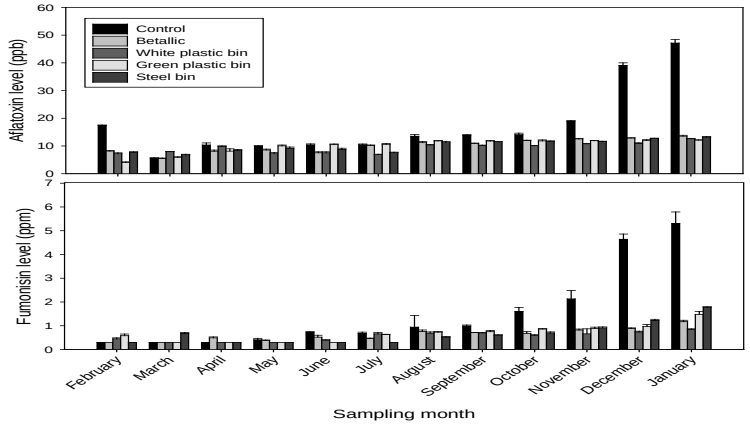

Fig. 2. Aflatoxin (ppb) and fumonisin (ppm) levels (Mean ±SE) in maize sampled from five storage types in Ejura, Ghana.

4. Discussion

The results of this study demonstrate that storage bins can keep the quality of maize for a reasonably longer period of time than the PP bags if they are properly designed and managed. It must be noted that during sampling a lot of insects which otherwise might have entered to infest maize inside the bins were found dead on the lid on the plastic storage bins**.**

Post-harvest losses are economically significant in Ghana for a broad range of commodities, resulting in a substantial negative impact on food security and livelihoods. Maize grains are the main food crops that provide staple diet for the majority of the population. A nation-wide survey was conducted in the three different geographical zones of Ghana (Northern savannah, the semi-deciduous middle belt and the coastal zones) to determine insects infesting major staples and evaluate the damage and losses caused. At each sampling, 1 kilogram of grain was sieved. Insects, frass and grains were collected separately. A random sample of 100 grains was taken from each sample for the determination of moisture content, percentage damage, weight loss and the number of insects per kilogram. The Thousand grain mass method was used to determine dry-weight loss. The levels of grain damaged were significantly different among the samples. Maize from markets in the Central region recorded the highest mean damages (14% and 17%) while the least (0%) was from Tinga in the Northern region. *Sitophilus zeamais* was the predominant insect in all maize stores and farms across the country. Its damage was lower than that caused by *Prostephanus truncatus*. Several parasitoid Hymenoptera, and an anthocorid predator were also collected in this survey. The parasitoids will be identified to species level to help us understand their biology and consequently develop rearing models for mass release to curb the injuriousness caused.

In a project supported by funds of the German government (PT BLE), we test a mobile camera system, scanning surfaces in storage warehouses or food processing industry. If insects are detected they are compared with morphological data in store to decide if the detected individual is a target pest. In case a target pest is determined with high probability, a laser beam is directed to the target to eliminate the insect by heat. The concept is to develop a system that is able to learn and identify more and more different species over time. First aims of the project are to improve reliability of species detection and identification in contrast to the grain with different light spectra and camera parameters. Reaction tests under different light conditions of the two exemplary insects grain weevil *Sitophilus granarius* (Col., Curculionidae) and Indianmeal moth *Plodia interpunctella* (Lepid., Pyralidae) will be carried out. Further the project will investigate laser beam wavelengths and intensities not damaging surfaces and items beneath or next to targets. The system could be utilized to support IPM in well-sealed structures for storage or processing of food and feed stuffs.

Keywords: camera insect surveillance, light, laser control, Sitophilus, Plodia.

1. Introduction

Stored product insects may be found in a given premise for three different reasons:

1. The insects came with infested raw materials, palettes or machinery.
2. The insects have been present for some time and developed in residual products accumulated in unattended areas of the building or within the machinery.
3. The insects found a way to enter from outside, attracted by light, temperature, moisture or volatiles.

In any case it is worth-while to determine the cause why insects can be found inside a storage or food processing facility in order to improve the situation and to reduce the frequency of insects as potential contaminants of food. If insects invaded a premise in infested raw materials, packaging materials such as card-board boxes, tarpolin, palettes, or in infested machinery an improved inspection of all goods prior to bringing them in would be advisable (Adler 2015).

A residual infestation in the building can be detected by regular inspection or by heat-treatments when insects start leaving their favorite hiding spaces. To prevent the immigration of insects from outside one needs to check the seal of windows and doors, the quality of gaskets between frames and movable parts. The air movement could be important, too, as around openings to the outside a reduced pressure in the building could prevent the development of a gradient of attractive odours and thus the orientation of stored product pests (Adler 2016). However, no preventive measure except low temperatures can keep premises permanently insect-free. If insects entered in spite of preventive strategies, they should be detected and controlled as early as possible. One study

developed a laser system called "photonic fence" to identify, track, and shoot down small flying insects in the wild (Keller 2016).

Our project outlined here aims to test an automatized camera surveillance of surfaces, combined with a determination of insect genera and a method of pest control using laser beams as a physical control device. Such an automated surveillance could be used in the reception of raw products and storages of finished products, in areas without laborers or at hours when there is no production. Ideally, an insect could be detected and controlled prior to oviposition or other damage.

Questions to be answered are:

1. At which wavelength and light intensity stored product insects are not disturbed in their normal activity but can easily be detected by camera surveillance?
2. Can the utilized optical system detect and determine stored product insect genera with sufficient accuracy?
3. Is the coordination between optic detection and laser control sufficiently fast and accurate for pest-control?
4. Can laser beams be used for insect pest control without damaging goods or surfaces next to the target?

2. Materials and Methods

In a first study the following species resembling crawling beetles and flying moth are tested:

Granary weevil *Sitophilus granarius* (L.) (Col., Curculionidae)

Indianmeal moth *Plodia interpunctella* (HÜBNER) (Lep., Pyralidae).

We test at which wavelengths and light intensities insect movement is not influenced by a sudden flash from a certain angle, critical wavelengths and light intensities will be determined. Specimens for testing come from our own laboratory culture at defined conditions and on defined substrates. All experiments will be carried out in a stationary testing environment. Later on, a mobile camera detection unit will be used.

The principle of the recognition software is based on pattern analysis (Deep learning) and is illustrated in figure 1. The motion patterns of insects on grain surface, under the different light wavelengths and intensities are recorded in high resolution pictures and videos. The comparison of the pictures results in a probability value for a certain pest insect. The image acquisition of the grain surface and pattern matching are running permanently, creating an automated surveillance system. If a pest insect is determined with a minimal probability of 80 %, laser control is initiated and the process is also transmitted via a data interference to a central pest monitoring center. Is the pest insect on the image not in the database, a new species connected with image and video data can be entered and saved as specimen for the new species. Hence, the pest insect database can be extended.

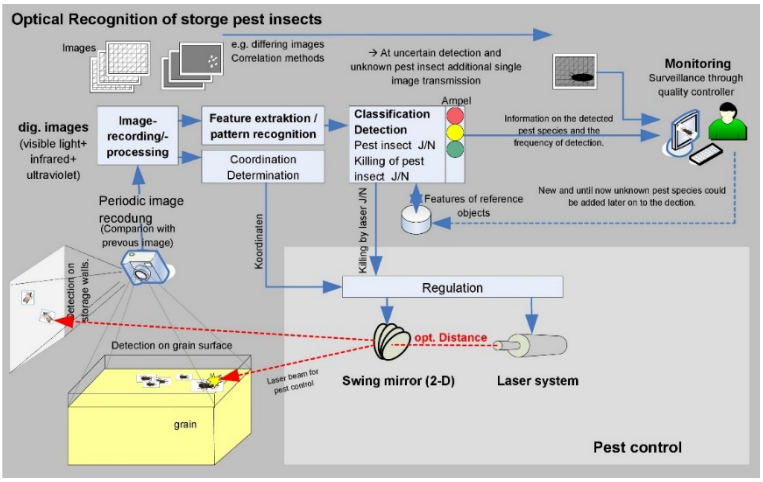

Fig. 9 Scheme of the complete system with detection and pest control

3. Outlook

This study will evaluate the probability of the early detection and pest control and will be a foundation to develop a prototype system. The detection of pest insects facilitates the installation of a model database under diverse environmental conditions and camera angles. The database will be improved if the information of different capture systems (storages) with diverse conditions and will be saved here altogether. With this detection unit a centralized monitoring can be established to lower the personnel costs for inspections and to facilitate a prompt action. Industry partners are integrated early on, starting in the development stage, to guarantee the incorporation of commercial demands. With the results of this study, an industry partners can develop a suitable scanner (light source & camera) in the evaluated spectral region. Preprocessing of video data could be implemented in the camera hardware, hence the transmission of big data amounts (video data) could be minimized drastically.

Web-Based Phosphine Fumigation Monitoring with Active Sensor Validation Confirms Lethality in Stored Grains

D. Glennon[1*], A. Caravello, S. Ottmar, C. Sweet

[1] Spectros Instruments, Inc., 17D Airport Rd, Hopedale, MA 01747 USA
*corresponding author: dglennon@spectrosinstruments.com
DOI 10.5073/jka.2018.463.213

Abstract

The predominant measurement technologies for fumigation gases over the past 60 years include colorimetric tubes, photoionization detectors, and electrochemical sensors. Their limitations and inaccuracies are well documented. Spectros Instruments has shown non-dispersive infrared monitoring (NDIR) to be a superior analytical tool for the practical measurement of fumigation gases as shown in Table 1. Any compliant fumigation

monitor must be accurate, reliable and affordable. Stored Product Protection has additional requirements in remote regions such as Central China and Western Australia. In these cases, the value of real time access via the internet to fumigation data collected with NDIR Technology from a remote location adds heretofore unknown benefits. Allocation of manpower and materials resources are optimized by access to information about fumigant gas levels in grain storages via the internet. Data is automatically transferred to a central database that can be accessed in real-time from any location with internet access. Intelligent monitors with built-in diagnostics tracking barometric pressure, temperature, sample flows and detector voltages are described. This data collection, data warehousing and reporting platform maintains measurement traceability to certified compliance with secure, encrypted electronic notebook format. Knowing REAL phosphine concentrations allows informed decisions to be made to achieve required CxT and avoid situations leading to target pest phosphine resistance.

Key words: NDIR, phosphine resistance, fumigation monitors, phosphine, internet, remote sensing

Introduction

Stored Product Protection requires a compliant fumigant to be applied as a gas and achieve penetration within the grain mass. Control of insect populations necessitates precise phosphine fumigation control and accurate gas concentration measurements. Phosphine has achieved premier status as the fumigant most used worldwide. It is inexpensive, offers good results when used correctly and leaves no residues but also has unique requirements for accurate measurement.

Currently, stored grain is heavily reliant on phosphine to eradicate infestations. The warmer climates have increased likelihood of more widespread insect occurrence in stored grains. Countries such as Australia have used phosphine since the 1950s. As the need for low chemical residues on grains was mandated on international markets through the 1980s; phosphine became the viable solution and its use increased significantly through the 1990s. World-wide, some estimate that phosphine is used over 80% of the time in grain storage/pest control applications.

Phosphine Resistance

Along with the increased use of phosphine there has been a well-documented increase in the frequency of global resistances of major target pests. This resistance to phosphine is a major challenge to the worldwide grain market. Insect resistance to phosphine occurs because of improper application of the product usually applied as aluminum phosphide tablets under various trade names. In grain storages these react with moisture in the air to release phosphine gas. The gas moves around by diffusion and in air currents inside the silo. Phosphine leaks in non-gas tight silos are quite common.

The widespread use of phosphine gas fumigation in unsealed silos in farm, merchant, and bulk handling facilities has significantly contributed to insect resistance to phosphine fumigations. Frequent exposure of insect populations to sub-lethal dosages allows some insects with a new resistance gene to survive treatment and continue breeding, passing on their resistance. Repeat fumigations favour the insects that carry the resistance gene by allowing them survival, but killing normal, susceptible insects.

When strongly resistant insects are present, phosphine fumigation in an unsealed silo will have virtually no effect on the insects. One key to success is the ability of a silo to pass a pressure test. Compliant Silos that can be sealed well enough will hold the required concentration of phosphine for long enough to kill all stages of the insects, including resistant insects.

Monitoring Phosphine Fumigation Gas Concentrations

Accurate measurements of phosphine gas concentrations will increase the likelihood of successful fumigations. A precise, measured concentration level is desired. Dosage IS NOT concentration! Monitoring done correctly helps avoid situations where either too little or too much gas is used. Real-time web-based diagnostics of measured physical parameters confirms proper monitor

performance and in turn defends traceability to compliance in matters of concentration documentation. (Figure 1.)

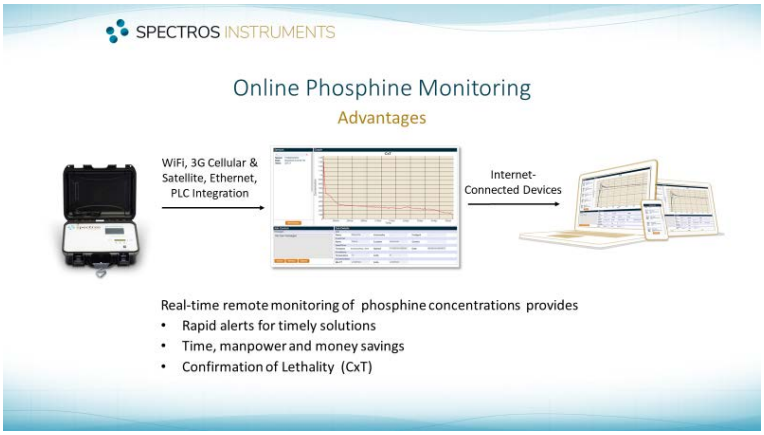

Figure 1: Spectros Instruments Phosphine Monitors Onboard Active, Real-Time Diagnostics assures correct monitor performance and validates phosphine fumigation data

Infrared Spectroscopy measures absolute physical constants and compensates for changes in temperature; barometric pressure; relative humidity as well as other interfering gases. The Spectros Instruments Phosphine Web Based Monitors provide communication protocols (3G cellular, WiFi, ethernet, Modbus RTU) for remote collection, organization, and reporting of fumigation data that the phosphine monitor collects as well as any alerts generated. Goals of increased efficiency, secured electronic records, compliance proof (traceability) and financial savings have been realized. Confidence in target CxT is achieved. (Figure 2.)

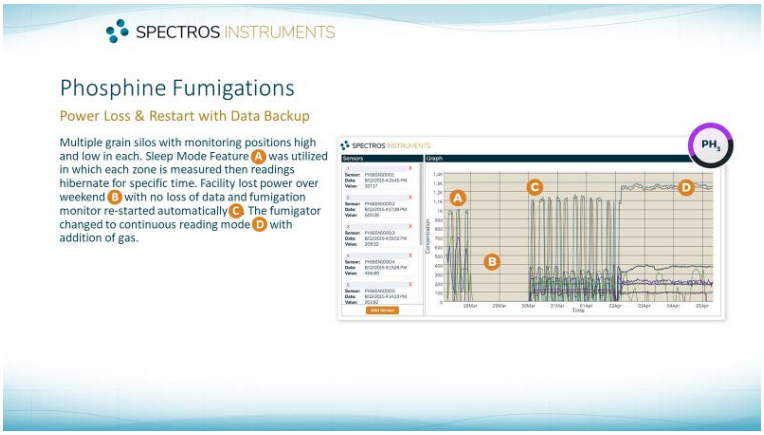

Figure 2: Spectros Instruments Architecture for secure web portal communication, warehousing & analytics of phosphine fumigation data

Table 1 History of Fumigation Gases Monitored by Spectros Instruments

Year	Fumigation Gas	Development Partners
1996	Ethylene Oxide	Johnson & Johnson
1998	Phosphine	Lorillard; RJR
2004	Sulfuryl Fluoride	Dow Chemical
2005	Methyl Bromide	USDA APPROVED
2009	Ethanedinitrile	Linde

Conclusions

Accurate, traceable to compliance and accessible phosphine concentration web monitoring provides immediate actionable data (**Figure 3)** to deliver safeguards that address potential insect resistance. If implemented, these demonstrable advantages allow an expanding global market to reasonably rely on a higher quality, uninterrupted supply chain for stored grain stuffs. Data accuracy, warehousing and easy access of data is key for informed decisions.

Abstract

Farming sustainably and protecting gross harvest production correctly provides growers with "health care, school fees and peace-of-mind" (net benefits). Reducing Postharvest and input loss sustains the components of agriculture's triple-bottom-line which are "accessible nutrition, reduced green-house emissions, and foreign exchange reserves". Lacking storage that stops grain PHL, agriculture suffers critical problems like the Aspergillus fungi that leaves grain contaminated with invisible aflatoxin that growers cannot consume or market. The objective of the Ghana pilot study was to understand why new ideas/findings like, applying biologicals to the soil before harvest, gross production inputs, virtual markets and especially the spread of stationary grain warehouses have failed to improve the net benefits of farming or agricultures' triple-bottom-line in sub-Saharan Africa. Qualitative comparison methods were used to identify roadblocks to improvement as scientific monitoring and storage eliminate grain Postharvest loss on the drylands in many parts of the world. Observations suggest net benefits are being ignored as reviews and assessments of primitive or council storage exchange scientific rigor for Stationary Warehouse Prejudice. Scientific rigor illuminates how the qualitative cost of aflatoxin, and quantitative expense of pests, recycling plastic, and empty stationary warehouses impact end-user-cost per unit stored per month. We conclude that Postharvest loss is expensive, and that relatively inexpensive mobile metal storage assets would improve net benefits and the triple-bottom-line.

Key words: grain, aflatoxin, storage, postharvest loss, triple-bottom-line.

1. Introduction

Staple, pulse, and legume (grain) farming means harvesting sustainably as much as possible from

production inputs, arable land (ecosystem services), and protecting what is harvested correctly so surplus provides for "health care, school fees and peace-of-mind" (net benefits). Reducing "Postharvest loss sustains the important components of agriculture's triple-bottom-line which are "accessible nutrition, reduced green-house emissions, and foreign exchange reserves".

Of course, not all sub-Saharan Africa (SSA) farm production is the same, so it is impossible to lump all Postharvest loss together. Some Postharvest loss is of "fruits, vegetables, and meat" (dense nutrition) and some is dry, high calorie and protein grain. However, grain provides most of the calories that power animal and human hard labor to "plant, grow, harvest, thresh, clean, dry, aggregate, store, monitor and process" grain and densely nutritious food. At the farm level, especially in the field, many biotic pests like fungi, insects, rats, birds, or abiotic groundwater, flooding, wildfire, and theft are difficult or impossible to control without protective storage. Historically Postharvest loss means SSA grains are contaminated by rats, insects, and fungi that cause Postharvest loss like aflatoxin. Aflatoxin "increases morbidity and mortality" (IARC, 2016) and small-scale grain growers' cannot safely consume or market grain.

Development often confronts Postharvest loss with production packages that temporarily increase gross grain production. For example, guaranteeing a price 10% above market premium for all compliant product. When there is typically a great deal of Postharvest loss, first season sourcing from local growers' results in 70% out of tolerance product, mostly from aflatoxin. When a lab test determines contamination, grains are simply turned back, and growers must fend for themselves. Some contaminated product goes to animal and fish feed formulators, which take half of the rejected product. Same growers then sell another quarter to mill operators, who do not test or care about quality. The remainder is consumed by growers (Lamb, 2017).

Objectives

Our objectives were to strengthen knowledge about why the spread of inputs and stationary warehouse storage for surplus grain have failed to reduce Postharvest loss. For example, knowing why International Crops Research Institute for the Semi-Arid Tropics (ICRISAT, 2017) says application of biologicals like harmless strains of Aspergillus fungi to the soil have had very limited success reducing SSA Postharvest loss in storage, is critical (Kumar, 2017). Exposing this aspect of Postharvest loss would help development experts guide research and outreach by HarvestPlus, International Fertilizer Development Corporation (IFDC), International Institute for Tropical Agriculture (IITA), Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ), Ghana's Social Enterprise Development Foundation (SEND-Ghana), Adventist Development and Relief Agency (ADRA), Mennonite Economic Development Associates (MEDA) and Center for Agricultural Rural Development (CARD) for example.

2. Materials and Methods

The three qualitative comparison methods were:

- evaluate the scientific rigor used to assess storage by organizing, reviewing, and comparing research
- field test mobile storage (Fig. 1) by observing adaptive learning at four of many locations
- identify any potential roadblocks for growers' rights to reduce Postharvest loss with mobile storage.

Figure 1. Mobile metal storage has utility for storing many crops, monitoring and primary proccesing surplus grain. Image: Unknown and modified by author.

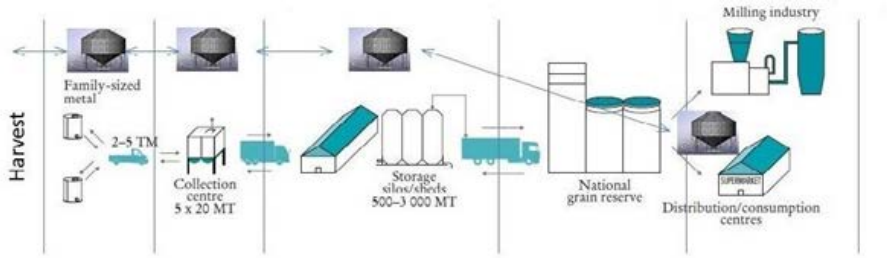

Figure 2. Mobility lets growers optimize storage at many locations. Image: FAO 2015 D. Mejla and modified by author.

3. Results

Qualitative comparison is relevant as scientific improvements (Butler, 1907), research (Proctor, 1999), storage testing (Opit, 2016), and grain moisture content measurement (Armstrong, 2016) etc., permit judicious adjustments to the timing, choice, and intensity of control actions, timely chemical pest control measures, in grain storage. Adjustments that are expedited using "Integrated Pest Management" (IPM) are often not only the cheapest but also the most reliably efficacious of the possible options and reduce Postharvest loss to insignificant levels on the drylands of the world that provide SSA with a staggering 83% of the food it consumes, though SSA holds nearly 50% of the land available worldwide" (Juma, 2016).

The key results suggest that solutions to the aflatoxin challenge that plagues SSA farmers, other agri-entrepreneurs, and governments are ignored. Kaminski, (2014) describes how reviews and life-cycle assessments of African storage, exchange scientific rigor for "Stationary Warehouse Prejudice" (Adjei, 2017). While Kumar (2017), and Ampuko (2018) mention aflatoxin, they ignore innovation storage solutions that their "Archer Daniel Midland Institute for the Prevention of Postharvest Loss" at University of Illinois and "1st All Africa Postharvest Congress and Exhibition", at University of Nairobi, respective research organizations exposed for peer review in conference proceedings. These and other reviews also ignore how sealed storage requires additional stationary infrastructure (Fig. 1) to mitigate condensation, handling to monitor for grain damaging insects that bore into plastic bags, and that rodenticides are not chemical free and soft plastic needs to be recycled. Examples of life-cycle assessments are the World Food Program (WFP) Global Postharvest Knowledge Center (Rierson, 2017) which ignores that that growers and refugees are often tenure-insecure. Michigan Institute of Technology (MIT) Comprehensive Initiative on Technology (2016)

merely evaluates the end-user-cost per unit stored annually, assuming all storage is full for the same number of months, instead of a per unit per number of months perspective that illuminates the cost-effectiveness of storage that is full for longer periods.

During pilot study field tests, we observed Ghana's agricultural business environment and witnessed adaptive learning that suggested mobile storage addresses the needs of tenure-insecure growers. While field testing at four locations we observed that rights to storage shifted benefits to growers and away from patriarchs wielding land-tenure, opportunistic traders setting prices or councils that are unresponsive (Easterly, 2015).

Roadblocks that the pilot study identified were Stationary Warehouse Prejudice, Development Packages, and Purchase Price of mobile storage.

Stationary Warehouse Prejudice Roadblock

University of Ghana's Egyir (2017) questions the competence of most of the current stationary warehouse management to source working capital, or network to accomplish IPM. Lack of management means Postharvest loss increases with storage period and capacity. However, empty, or full, with or without market access, prejudice for stationary warehouses provide protocol fees or services that facilitate cooperation by grain councils in East Africa or Ghana. This kind of cooperation makes implementation of production package blueprints easy for any "non-Governmental Organization" (NGO), even though NGO cultural advisors know that Postharvest loss will continue to impact advisor extended families in rural communities.

Agribusiness lobbies globally to set the agricultural research and education agenda to facilitate profits through the sale of inputs like mechanization, seeds, fertilizers, and pesticides (gross production technologies). Input agribusiness sees little profit in the preservation of food once it is produced. In fact, SSA agribusiness profits from Postharvest loss in warehouses as this loss reduces the food supply thus creating the perception that inputs to plow new land (extensification) and/or for irrigation (intensification) are needed to produce more food (Wilson, 2016). SSA agribusiness ignores that when Postharvest loss drives intensification or extensification, ecosystems are degraded and soon limit net benefits and the triple-bottom-line.

SSA research and outreach assess grower-controlled storage with wheels, as disruptive and suggest already proven off-the-shelf "Mobile storage needs basic research and testing if we are to share/promote [for growers to evaluate] it widely" (Essegby, 2017). Agribusiness and councils lobby so research and outreach delay Postharvest loss solutions and so annual grain summits and USAIDs' ADVANCE Preharvest events or forums exclude innovation from local agendas. Excluding innovation from local agendas discourages grower evaluation of inputs and protocol.

Development Package Roadblock

Development often confronts PHL with gross production packages and support councils to blueprint stationary warehouses for average local production. As averages are rare, council managed warehouses are either almost empty or overflowing and often far away from Postharvest loss control locations. On the other hand, the dynamic nature of farming and chronic Postharvest loss it is risky for tenure-insecure growers to build and maintain warehouses at optimal locations.

Many development packages attempt to move growers up by implementing warehouse receipt systems (WRS). However, if the receipt system warehouse is "too far away or does not scale to production for cost-effective IPM" (unresponsive), WRS are soon "rusting" monuments to Postharvest loss (Armah, 2006). Kula (2017) suggests development experts should learn the lesson that WRS based on stationary warehouses do not even out supply or help growers (World Bank, 2013).

"Tackling [stationary] WRS Challenges" by Mugano (2017) explains precisely, the familiar lack of suitable infrastructure or requisite skills, legal and regulatory issues, missing or weak complementary market institutions, disabling elements in the policy environment that discourage key stakeholders especially bankers from financing agriculture in SSA.

An example of a Development package is Financing Ghanaian Agriculture Project (FinGAP) Incentive grants. FinGAP assists "Financial Organizations" (FO) to focus on areas that will never support commercialized farming where the "most vulnerable growers are" (World Vision). One of these FOs is the Center for Agricultural and Rural Development (CARD). Incentive grants allow CARD to provide credit-in-kind for inputs to approximately 10,000 vulnerable growers in exchange for bags of "maize, rice and soy" (produce). The credit-in-kind is more likely put to good use by growers for approved production practices than cash which could be diverted to unapproved uses. Middlemen from target districts assist CARD activities by delivering approximately 500 MT of loan repayment produce which is then aggregated, stacked on pallets and covered by tarps anticipating price appreciation. FinGAP reports that supporting FOs activities leads to increased gross production and 100% loan repayment.

Although easy to move pallets and tarpaulins are at first attractive option to stationary warehouses, they do not stop Postharvest loss from flourishing throughout the stack during the 6-8 months the repayment produce anticipates price appreciation. Ground water and termites weaken pallets and allow sacks to contact fungi in the soil. Manually removing/replacing the tarpaulins daily is needed to prevent condensation that allows fungi, insects, rats, and birds to feast. CARD's capacity to move up above grants and sustain the triple-bottom-line is limited by Postharvest loss (Shukla, 2017).

The surplus grain that remains with CARD growers at the farm level or council district warehouses will likely be rewetted (Trenk, 1970) and allow Postharvest loss like aflatoxin to impact the most vulnerable children (Cardwell, 2014). Postharvest loss is not approved production practice as the net benefits of credit-in-kind inputs are diverted to pests, middlemen and councils.

Development packages that use gross production to ignore the impact of Postharvest loss, miss an opportunity to approve storage practices so that net benefits drive the triple-bottom-line without further use of land, water, and other agricultural inputs (APHLIS, 2015).

Purchase Price Roadblock

Even though the cost of any metal grain storage decreases with increases in capacity and the number of months that capacity is full, the up-front purchase price of metal storage is a roadblock for grower storage rights that reduce Postharvest loss.

4. Discussion

Rights that secure access to land or tenure, reduce the risk to resources invested to build and maintain stationary storage like warehouses. However, SSA growers are often tenure-insecure. Lacking storage that meets their needs, growers are forced to sell quality surplus early or suffer significant Postharvest loss (Lipinsky, 2013).

North Carolina State University (NCSU, 2018) focus group discussion suggests crops are not stored in the field for fear of theft. As a result, farmers only harvest volumes that they can carry in any one day. Considering that the main means of transportation was by head, the amounts that can be transported within a given period is limited. As a result, the produce may be exposed to rewetting in case of rains. These findings seem to imply that a transport intervention that parks cost-effectively to store aggregated quality while heads, wagons or trailers haul heavy loads may go a long way in reducing the losses that occur at harvest before or as crops leave the fields.

Opportunistic traders or middlemen know growers lack storage and set low prices. Low prices reduce the net benefits of inputs like hard labor, ecosystem services, and especially gross production inputs like "FarmerLine (sms information), Tuluu (virtual market), AgriCorp (education), Oikocredit (micro-finance), Area Yield Index Crop (insurance), Hello Tractors and Solar powered irrigation (mechanization), HarvestPlus Biofortification (improved crop varieties), IFDC (fertilizers), IITA's AflaSafe fungi (biologicals)" and other process improvements like commodity marketing. The result is the tenure-insecure grower may experience "market failure" (Jones, 2011) after investing inputs, selling grain low, and then buying similar grain back at a higher price. Or, if the grower attempts to

gain the advantage by controlling assets that store grain in bulk, sack, or airtight metal can, hard plastic drum or soft plastic bag, they may "challenge the tradition" of patriarchs (Bott, 2005). In SSA the grower invests the important inputs and gets just enough to survive but not enough to move up, as "Postharvest and input loss" (PHL), middlemen and councils divert significant net benefits.

Simply, harvesting grain without storage means PHL is chronic and invisible aflatoxin stops growers from setting, or modifying, their own goals, so two farms with identical climates and soils may be managed with different aims to achieve the diversity needed to sustain the triple-bottom-line (FAO, 2015).

If SSA development experts realized that grain PHL is an integral part of the SSA agricultural system (Boa, 2016), innovative grain storage would initiate the 'golden age' of SSA agriculture (Pearce, 2016). The Great Grain Bin Adventure (Butler, 1907) is an example which justifies many calls for proposals that specify food chain policy innovations, as there are few positive outcomes if aflatoxin means small-scale grain growers cannot safely consume or market grain (Mendoza, 2016).

Solutions to the Roadblocks and PHL

When scientific rigor quantifies the role PHL played during "decades of grain net yield increases in other parts of the world, to keep SSA grain agriculture less mechanized, low-yielding, and insecure" (Juma, 2016), accountable development packages will finance agendas that are responsive to grower net benefit and improve SSAs' triple-bottom-line.

On the drylands of SSA, output agribusiness like Cimbria and African Grain Care etc., have built, validated, tested, sold and maintained 1000s of stationary metal vented, raised sloping floor silos for utility storage. If the storage was mobile the same storage could be relocated at any PHL control point and provide the practical utility needed to support IPM practices. So, should be easy for research and outreach to understand how storage with wheels, just like just like agricultural wagons and trailers will likely improve tenure-insecure growers' net benefits. Storage with wheels can be leased. Leased and/or purchased mobile storage can be parked cost-effectively at dynamic PHL control points so utility like vents will cost effectively mitigate condensation; wide-opening roofs reduce the labor needed to aggregate quality and monitor insects while also stopping rewetting; sloping floors reduce cleaning requirements and rise above groundwater and rats secure net benefits. Incentives for FOs to address the purchase price of an approved practice like storing and marketing safe surplus will move growers up to economies of scale and attract the working capital of local banks that will sustain agricultures' triple-bottom-line (Mugano, 2017).

To help focus the qualitative discussion we wanted to assess options like the airtight metal can (Fig. 3) versus mobile utility using the Granary Selector 'app' developed by the Natural Resources Institute at University of Greenwich under a contract with the Swiss Development Agency (Tran, 2016). However, the app does not allow users to organize, review and compare storage factors like lease or mobile types. We addressed this roadblock to financing by organizing a comparison based on practical field handling (Text Box 1.), storage (Text Box 2.), and marketing (Text Box 3.).

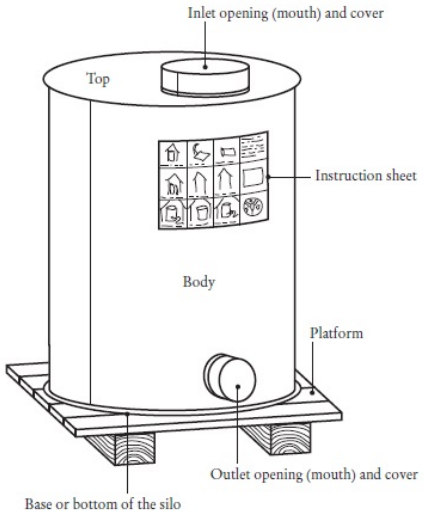

Figure 3. Airtight metal can capacities larger than 1.8 MT "become hard to operate" (George, 2011). Image: FAO 2015.

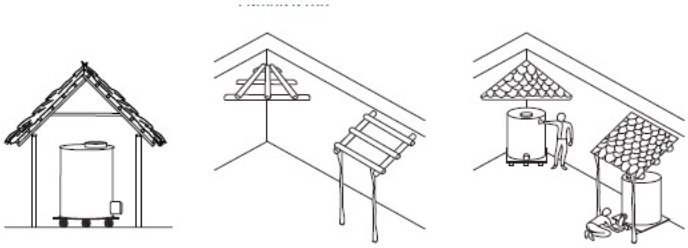

Figure 4. Airtight metal cans require additional infrastructure like floors, stationary platforms and roofs. Image: FAO 2015.

Text Box 1. Summary practical comparison of field handling to storage environments when significant PHL occurs (Lipinski, 2013). See Appendices A for detail.

Can (artisan, airtight, not for paddy rice)	Bin (mobile utility)
Field handling with cans prevents rodents, birds, insects, rain, and theft without walls. Cans do require platforms to exclude ground water and a roof to mitigate condensation caused by temperature fluctuations (day vs night). Cans do not allow air exchange and so condensation caused by temperature fluctuations can encourage fungi and insects and in turn lead to major losses in grain quality and volume. A hermetic or airtight seal is used to prevent fungi and insects. At first the cost of airtight insect and fungi control is low. However, the longer the grain is stored in airtight cans, the longer it will take for any metabolism to reduce the atmosphere. If the can is not filled, then the excess atmosphere may	Field handling mobile bins excludes rodents, groundwater, birds, rain, wild fire, theft and vents allow air exchange to mitigate condensation caused by temperature fluctuations (day vs night). Handling or "process solutions" (Rockefeller, 2015) have high utility when they mitigate fungi and insects by moving IPM into cropping systems for excellent value loss prevention/month/unit stored.

encourage any metabolism. Without the low oxygen atmosphere environment cans are less effective at suppressing insects and fungi.	

Text Box 2. Summary of storage where significant PHL impacts (Lipinski, 2013) the value of stored gross yield. A market-oriented growers' net benefits are a function of price seasonality, value loss prevention, and their opportunity cost of capital invested (Jones, 2011). See Appendices B for detailed practical comparison.

Can (in warehouse to stop condensation)	Bin (self-contained)
Storage will capture seasonality as IPM for value loss prevention/month/unit stored is good. However, artisan constructed cans with capacities larger than 1.8 MT "become hard to operate so this is the largest practical size" (George, 2011) and limits scaling for growers' cooperative storage.	Bins capture seasonality as leased capacity is a business expense and reduce the need for capital, transport, and tenure. Mobile storage is a value adding process solution, since utility with wide-opening-roofs mitigates abiotic and biotic problems with excellent IPM/month/unit stored.

Text Box 3. Summary estimation of the marketing incentives for optimal production as can or mobile bin utility counter act the "yield gap that may exist as the high costs of inputs or the low returns from intensification and/or extensification make it economically suboptimal to raise production to the maximum technically attainable" (Godfray, 2010). See Appendices C for detail.

Cans (in warehouses for primary processing)	Bin (primary processing)
Primary processing out to bowls, sacks, back to bulk and cleaning is assisted by gravity if the loaded cans are set up on platforms. Building and maintaining strategic roofs and platforms is capital that must be risked in anticipation of price appreciation and to ease primary processing. Maintenance of redundant roofs and platforms close to dynamic aggregation and marketing locations may limit surplus production.	Primary processing out by gravity matches demand for bowl, sack, bulk anywhere roads go. Leasing process solutions keeps maintenance costs per unit stored per month low, and reduce the scale needed to be economical. This primary processing utility is economical as units move when empty, and park cost effectively where storage is needed.

Conclusion and recommendations

PHL limits the net benefits that storage should provide grain growers and SSA agriculture is therefore insecure and production sub-optimal.

SSA research or outreach should conclude that PHL is expensive and recommend that relatively inexpensive storage assets should meet growers' needs, as well as democratize food supply decisions.

The pilot study recommends mobile utility be reviewed objectively and compared with roadblocks so

- growers have many IPM alternatives
- abiotic and biotic PHL becomes insignificant
- agricultures' triple-bottom-line benefits growers in an inclusive manner.

Qualitative Discussion about Reducing Grain Postharvest loss with Mobile storage in Ghana, West Africa is supported primarily by the Private sector and concerned stored grain and other Extension researchers. Also we sincerely thank: Ghana Investment and Promotion Center (GIPC), Ghana

Standards Authority (GSA), African Regional Standards Organization (Nairobi), Ghana Agricultural Engineering Services Directorate (AESD), and NeverIdle Farms (Canada).

Appendices

Appendices A.

Detail practical comparison during field handling to storage environments when significant PHL occurs (Lipinski, 2013) detail.

Can (artisan, airtight, not for paddy rice)	Bin (mobile utility)
Field handling with cans prevents rodents, birds, insects, rain, and theft without walls. Cans do require platforms to exclude ground water and a roof to mitigate condensation caused by temperature fluctuations (day vs night). Cans do not allow air exchange and so condensation caused by temperature fluctuations can encourage fungi and insects and in turn lead to major losses in grain quality and volume. A hermetic or airtight seal is used to prevent fungi and insects. At first the cost of airtight insect and fungi control is low. However, the longer the grain is stored in airtight cans, the longer it will take for any metabolism to reduce the atmosphere. If the can is not filled, then the excess atmosphere may encourage any metabolism. Without the low oxygen atmosphere environment cans are less effective at suppressing insects and fungi. If necessary, grain in the cans can be fumigated, with a caution that fumigation should never be done in cans that are located inside of living spaces. Flexible capacity for field handling to storage is poor because cans do not store cobs, groundnuts in the shell or sacks. There are mechanical options to the manual labor typically used to load, but flat-bottomed cans require manual cleaning. Cans are suited to smallholder field handling to storage because scaling to harvest is only limited by the roofs and raised platform on floors growers are willing to invest. However, relative to the surplus storage at dynamic PHL control locations needed to impact foreign exchange, cans will soon limit growers' benefits.	Field handling mobile bins excludes rodents, groundwater, birds, rain, wild fire, theft and vents allow air exchange to mitigate condensation caused by temperature fluctuations (day vs night). Handling or "process solutions" (Rockefeller, 2015) have high utility when they mitigate fungi and insects by moving IPM into cropping systems for excellent value loss prevention/month/unit stored. Leases effectively scale without warehouses, so "Growers whose scale of operation is too small to be able to produce SAFE FOOD" (Cardwell, 2015) can move up by participating in cooperative storage. Field handling to storage is excellent because bins with utility also store cobs, groundnuts in the shell or sacks and combinations of sacks and bags by multiple growers. Loading utility can be either manual or mechanical and sloping floors reduce manual cleaning. Mobile utility bins are very well suited to field handling to storage because leases effectively scale (location and capacity) to prevent PHL and secure harvest regardless of transport or land rights. If the bins are purchased, they become "mobile assets" (Growing Africa, 2013). 15+ year life cycle assessments must consider assets with the utility to store inputs (seed and fertilizer) at planting, optimal aggregation locations, proximity for monitoring, primary processing, and self-cleaning features.

Appendices B.

Detailed comparison of storage where significant PHL impacts (Lipinski, 2013) the value of stored gross yield. A market-oriented growers' net benefits are a function of price seasonality, value loss prevention, and their opportunity cost of capital invested (Jones, 2011).

Can (in warehouse to stop condensation)

Storage will capture seasonality if local water tank artisans build cans so capital requirements are medium. However, if airtight cans are opened for monitoring or to add or remove portions, the hermetic atmosphere that prevents fungi and insects, must be restored by metabolism. The longer the grain is stored in hermetic cans, the longer it will take for metabolism to restore and maintain the hermetic atmosphere. If a can is not filled, then the excess atmosphere may prevent the creation of hermetic environment. Without the hermetic environment cans are less effective at suppressing for example, residual fungi. If necessary, grain in the cans can be fumigated, with a caution. Due to the limits of artisan construction, fumigation should never be done in cans that are located inside of living spaces. IPM for value loss prevention/month/unit stored is good. However, artisan constructed cans with capacities larger than 1.8 MT "become hard to operate so this is the largest practical size" (George, 2011) and limits scaling for growers' cooperative storage. Investment is required to maintain and monitor a low atmosphere environment, roofs and the raised platform needed for gravity assisted processing and cleaning. Infrastructure for can storage is fixed relative to where large and small harvests or floods may occur, and tenure-insecure growers are less likely to invest if they consider surplus storage too risky.

Bin (self-contained)

Bins capture seasonality as leases are a business expense and reduce the need for capital, transport, and tenure. Mobile storage is a value adding process solution, since utility with wide-opening-roofs mitigates abiotic and biotic problems with excellent IPM/month/unit stored as, if necessary utility can be easily fumigated. Purchasing storage, a "process solutions" like mobile utility "are innovative ways of providing collateral" (Growing Africa, 2013) because asset with mobile utility make sense for on-site storage, security and proximity that replaces PHL with marketing for growers' net benefits. 15+ year life cycle assessments must consider the protocol fees and services for storage rights that impacts foreign exchange.

Appendices C.

Detailed estimation of the marketing incentives for optimal production as can or mobile bin utility counter act the "yield gap that may exist as the high costs of inputs or the low returns from intensification and/or extensification make it economically suboptimal to raise production to the maximum technically attainable" (Godfray, 2010).

Cans (warehouses for primary processing)

Secure warehouses at markets offer good return even though cans are fragile and difficult to transport and require building and maintaining redundant stationary roofs and platforms. Roofs must allow access by ladder to the lid for aggregating in. Processing out to bowls, sacks, back to bulk and cleaning is assisted by gravity if the loaded cans are set up on platforms. However, if opened for monitoring, growers must restore the hermetic atmosphere and

Bin (primary processing)

Mobile bin marketing offers optimal returns. When mobile utility secures the hard labor required to aggregate harvest quality and control abiotic and biotic problems, moisture testing and using the Sun to cook insect pests (solarization) prior to storing become relevant. On the drylands at aggregation, humidity is low enough for applications of Diatomaceous Earth. After grain is stored, utility means aeration to condition, and wide-opening-roof features that ease monitoring and secure collateral. Utility nearby means aggregation, monitoring fumigation or marketing decisions become judicious and will reduce PHL, especially insects. SSA temperatures are consistent, and so endemic parasitic wasps are likely effective in a vented bin to control moths and beetles (biocontrol). Since the vented storage is located nearby, the labor required to monitor biocontrol is reduced.

Primary processing out by gravity matches demand for

maintain platforms and roofs against termites and rotting. Building and maintaining strategic roofs and platforms is capital that must be risked in anticipation of price appreciation and to ease primary processing. Maintenance of redundant roofs and platforms close to dynamic aggregation and marketing locations may limit surplus production.

bowl, sack, bulk. In other words, mobile utility means capacity for growers' and their cooperatives can be adding value adding anywhere roads go. Leasing process solutions keeps maintenance costs per unit stored per month low, reduce the scale needed to be economical and enable access at any temporal or spatial link in the value chain. Self-contained primary processing utility is economical as units that move when empty, will park cost effectively where storage is needed. Mixing leases and purchases scale capacity to growers' requirements at harvest, aggregation, storing and processing at markets. 15+ year life-cycle assessments should consider how bins move to where storage is optimal, so capital investment provides the triple-bottom-line.

Abstract

A major concern for the Australian grain industry in recent years is the constant threat of resistance to the key disinfestant phosphine in a range of stored grain pests. The need to maintain the usefulness of phosphine and to contain the development of resistance are critical to international market access for Australian grain. Strong levels of resistance have already been established in major pests including the lesser grain borer, *Rhyzopertha dominica* (F.), the red flour beetle, *Tribolium castaneum* (Herbst), and most recently in the rusty grain beetle *Cryptolestes ferrugineus* (Stephens). As a proactive integrated resistance management strategy, new fumigation protocols are being developed in the laboratory and verified in large-scale field trials in collaboration with industry partners. To aid this development, we have deployed advanced molecular diagnostic tools to accurately determine the strength and frequency of key phosphine resistant insect pests and their movement within a typical Australian grain value chain. For example, two major bulk storage facilities based at Brookstead and Millmerran in southeast Queensland, Australia, were selected as main nodes and several farms and feed mills located in and around these two sites at a scale of 25 to 100 km radius were selected and surveyed. We determined the type, pattern, frequency as well as the distribution of resistance alleles accurately for two major pests, *R. dominica* and *T. castaneum*. Overall, this information along with the phenotypic data, provide a basis for designing key intervention strategies in managing resistance problems in the study area.

Keywords: phosphine**,** molecular platform, grain value chain, resistance management

1. Introduction

Protecting harvested grain from insect infestations is essential for facilitating domestic and international trade. In Australia, for example, the industry strictly adheres to a 'nil tolerance' principle for live insects to gain competitive advantage in international trade. Over the last decade, there has been significant progress in pest and resistance management in Australia in response to the development of high level of resistance to phosphine in key pest species, the primary fumigant used to disinfest stored grain (Nayak et al., 2013; Kaur and Nayak, 2015). While the alternative fumigants sulfuryl fluoride is being evaluated as a 'resistance breaker' to alleviate phosphine resistance problems (Nayak et al., 2016), efforts are ongoing to extend the usefulness of phosphine through development of higher application rates to control strongly resistant populations (Nayak et al., 2013; Kaur and Nayak, 2015).

In any resistance management program, key components include proper determination of strength of resistance and its distribution along the value chain, and appropriate and timely control of resistant populations. Researchers in Australia and India are collaboratively engaged in the

deployment of advanced molecular diagnostic tools to accurately quantify resistance to phosphine, assess risks along the grain value chain and to implement appropriate intervention strategies to manage them. It is important to note that Australia and India share similar sub-tropical and tropical climates conducive to insect infestations and both countries have a long history of use of phosphine to disinfest stored grain. Over the last decade, both countries have faced a constant threat to stored grain through widespread development of resistance to phosphine in key pest species, leading to risk to food security and market access. While losses to stored food grain due to insect problems are conservatively estimated around US$364 million (Boxall, 2001) in India, Australian losses are negligible. However, a 'nil tolerance' to live insects applies to all export and domestic grain trade, therefore, poor implementation of pest management practices can jeopardise the country's trade in grains worth AU$9 billion annually (https://www.graintrade.org.au).

Here we present a brief account of progress made in gathering critical resistance data in Australia using advanced molecular diagnostics. We used a molecular screening assay on pest populations collected along a pre-determined grain value chain that has two major bulk storage sites and numerous farms in Southeast Queensland. Our overall aim is to utilise the molecular resistance detection method as a decision-making tool for accurate determination of problematic sites within each node of the grain value chain and to facilitate timely implementation of resistance management tactics. The current study focuses on two major grain insect pests, the lesser grain borer, *Rhyzopertha dominica* (F.), and the red flour beetle, *Tribolium castaneum* (Herbst). Resistance data generated through both phenotypic and molecular methods are presented and discussed in the context of managing these two species.

2. Materials and Methods

2.1 Study sites and sample collection

Our area of focus was on a typical grain supply chain containing several grain handling nodes in the township of Millmerran, located in south-east Queensland, Australia. The supply chain contains a cluster of several on-farm grain storage silos, feed and stored product processing mills in and around two bulk grain depots, Millmerran, and Brookstead, each with the storage capacity of 30,000 tonnes (Figure 1). These depots are located 25 km apart and the distance between the farms and feed mills are approximately within 100 km. Grain samples were collected in a consistent pattern across all the selected nodes, representing the entire grain supply chain during 2017-18. For example, 3-5 sites within each node were selected, depending upon the storage size and the structure of the site. Within each site, 5-10 grain samples were collected, each weighing approximately 2 kg. The grain samples were screened in the laboratory for live adults and progeny (in the form of eggs and other immature life stages generated from the collected parent populations). Although several pest species were collected through this study, here we present data only on *R. dominica* and *T. castaneum*.

2.2 Phenotypic testing

The collected live adults were subjected to a phosphine discriminatory dose of 0.25 mg L^{-1} over 48 h for *R. dominica* and 20 h for *T. castaneum* to diagnose strongly resistant populations in each species as described previously for the resistance testing bioassays (Collins et al 2002 and Jagadeesan et al 2012). A cohort of approximately 150 insects were used for each site within each node for the resistance testing bioassays. In the case of eggs, all the eggs emerged as adults (progeny) after 6-8 weeks of incubation were fumigated. Both live and dead insects from the bioassays were subsequently preserved in 70% ethanol at -20˚C before DNA extraction and molecular resistance screening.

2.3 High throughput molecular screening of resistance alleles

2.3. 1 Genomic DNA extraction

Genomic DNA was extracted from individual insects using a modified Hotshot DNA extraction method described by Montero-Pau et al. (2008). Test insects in a 96 well PCR plate were lysed individually with 75 µL Alkaline lysis buffer (25 mM NaOH and 0.2 mM EDTA) (pH = 12) at 95 °C for 30 min, cooled down at 4 °C for 10 min and then neutralized by addition of 75 µL of 40 mM Tris–HCl (pH = 5). Samples were centrifuged and the supernatant containing *g*DNA from individual insects were stored at -20 °C for high-throughput sequencing. The susceptible and resistant reference strains in both *R. dominica* and *T. castaneum* were also included in each 96 well PCR plate in gDNA extraction for valid interpretation and used as positive controls.

2.3.2 Molecular resistance screening assay

The molecular assay is a genotyping-by-sequencing method comprising multiplex amplification and sequencing of the exons of the dihydrolipoamide dehydrogenase (DLD) gene of either *R. dominica* or *T. castaneum* (Schlipalius et al., 2012) using the Illumina Miseq™ next-generation sequencing platform. The assay encompasses nearly the entire protein coding sequence of the gene by employing multiple primer pairs to amplify the gene in segments that are subsequently sequenced together. The forward and reverse primers for each exon region were tagged with individual 10-mer index sequences during synthesis to facilitate bioinformatic sorting of the sequences to the individual from which they had been amplified.

Each forward primer was tagged to be specific to a 96-well plate that was assayed 96 tagged reverse primers were specific to individual wells of a 96 well plate. As a result, each DNA amplification product could be traced back to the plate and well in which it had been amplified.

2.3.3 PCR conditions to amplify multiple alleles

The PCR reactions utilised Terra™ PCR mix (Clontech), which amplifies directly from tissue and samples with high protein content. Each sample reaction contained: 3 µL template DNA (~5-10ng), 1X PCR Buffer, 10 µM of each primer (5 forward, 5 reverse), 0.6U Taq polymerase and water to a final volume of 22 µL. The PCR cycling conditions were: 98˚C for 2 min; 4 cycles of 98˚C for 15 s, 65˚C for 30 s, 68 ˚C for 60 s; with a final 36 cycles of 98˚C for 15 s, 55˚C for 30 s and 68˚C for 60 s.

Resulting amplicons were pooled and sent to the Australian Genomic Research Facility (AGRF) for sequencing on the Illumina MiSeq™ sequencing platform with the 250 bp paired-end read protocol.

2.3.4 Data processing and interpretation

Paired-end Miseq data were demultiplexed using CLC Genome Workbench V9.5.4 (CLCBIO) using the forward and reverse tags. The data for each sample was then aligned against a genomic reference sequence (JX434608 or KF032715) using the parameters: mismatch cost=2, insertion cost =2, deletion cost=3, length fraction=0.5. Variants were then called using the CLC Genome Workbench basic variant detection algorithm (minimum coverage=10, min frequency 25%, minimum variant count=2).

3. Results and Discussion

Our results on insect sampling clearly indicated the existence of both target pests, *R. dominica* and *T. castaneum* within the selected grain value chain at different density levels. For example, the average number of *R. dominica* per sample (1430.5) was higher than that of *T. castaneum* (728.5) (Tables 1 and 2). Comparison of number of insects identified in each grain handling node across the grain value chain confirmed that infestation *of R. dominica* was prevalent across the entire grain value chain, except for Depot 1 and the processing feed mill, whereas infestation of *T. castaneum* was prevalent only in farm storages (Tables 1 and 2). The average number of *T. castaneum* recorded

in the only mill sampled was double of that of *R. dominica* and far much higher than the *T. castaneum* collected on both depots (Tables 1 and 2).

Our phenotypic resistance screening in collected insect populations across the grain value chain identified three strongly phosphine resistant populations of *R. dominica* (one each from Depot 1, Depot 2 and Farm 1) and a single resistant population of *T. castaneum* (from Farm 1). The molecular screening for single nucleotide variants (SNV) (that confers strong resistance to phosphine), in both *R. dominica* and *T. castaneum* supported the results of phenotypic screening. In addition, the assay has identified two other strongly resistant *R. dominica* populations from Farm 2 and Farm 3, and one strongly resistant *T. castaneum* population from Farm 3, which were initially scored as 'not strongly resistant' in the discriminating phenotypic testing (Table 1). In total, molecular screening has identified three different SNVs, P>49>S, G>135>S and K>142>E in *R. dominica,* and a single SNV in *T. castaneum*, P>45>S (a homologue of P>49>S in *R. dominica*). These resistant alleles were also previously detected in farms and bulk storages in south east Queensland (Schlipalius et al., 2012, Kaur et al 2013), and bulk grain storages in India (Kaur et al 2015), and USA (Chen et al., 2015). Unlike our current high-throughput methods, however, the earlier studies relied on low-throughput DNA marker assays, targeting a specific resistance allele.

The accurate discrimination of multiple genotypes (*rr, rs and ss*) in each SNV (resistance allele) in selected populations of *R. dominica* and *T. castaneum*, identified allele frequency (R %) as well as percentage of actual carriers of resistance (R%) in each node (i.e. the proportion of individuals having at least one copy of resistant allele in the population). Comparison of resistance allele frequency between the grain handling nodes, indicated that frequency was higher in *R. dominca* in bulk storage depots (10.6-11.3%) compared to farms (2.5-3.95%) (Table 1). In an earlier study Kaur et al. (2013) estimated frequency of one specific variant, K>142>E in populations of *R. dominica* from farms in southern Queensland in 2011 using traditional CAPS (Cleaved Amplified Polymorphic Sequence) marker analysis, which showed a much higher range of allele frequency (3-26%) compared to the range established in our current study. Daglish et al (*in press,* in this Proceedings), using the same method estimated resistance allele frequency in *R. dominica* between (6.0-13.4%), that were trapped at the bulk storage depot sites of the same study site as ours, which supports the findings of the current study. In the case of *T. castaneum,* resistance was confined to farms, and frequency of resistance alleles remained relatively low (1.27-6.25%) (Table 2).

The observed variation in resistance allele frequency among the *R. dominica* and *T. castaneum* populations within the study area indicates that insect populations at each grain handling node have been exposed to differential selection pressure to phosphine. For example, the higher resistance observed in *R. dominica* at depots suggests that populations at this node might have had undergone stronger phosphine selective pressure than populations that were collected from farms and the feed mill. However, this trend was not observed with *T. castaneum* and, in fact, resistance in this species appeared to be prevalent only on farms. This difference, perhaps related to their inherent strength of expressing the resistance phenotype (Jagadeesan and Nayak, 2017) or probably related to species biology and habitat (Daglish et al., 2017). For example, Jagadeesan and Nayak (2017) showed that adults and eggs of strongly resistant *R. dominica* populations exhibit nearly 2-3 fold higher resistance level than that of *T. castaneum*. Thus, the fumigation strategies (concentration x exposure period) that are currently adopted at bulk storage depots to control resistant *R. dominica* could have been extremely high for *T. castaneum*, leaving no survivors after the phosphine treatment.

The grain value chain studied here is ideal in a sense that there has been a high degree of grain movement over the years between farms and bulk storage depots in the region. Our results led us to conclude that there is a high degree of possibility that resistance alleles, can migrate from farms to bulk storages and get exposed to higher selective pressures to phosphine. There is also the possibility of two way insect movement within the study area, which may aggravate the resistance problems in this region. Australian studies have demonstrated that *R. dominica* and *T. castaneum* flight occurs across the broader farming landscape (Daglish et al., 2017), and there is also the

potential for human-aided movement of insects along the supply chain (Hernandez Nopsa et al. 2015).

In conclusion, the current study established base-line information on pest populations and the type and frequency of phosphine resistance alleles for two key grain insect species in a typical grain supply chain in Australia using both phenotypic and molecular resistance tools. Currently, we are in consultation with industry collaborators for implementation of suitable intervention strategies for each grain handling node in a systemic pattern across our study area. We strongly believe that such approach will facilitate achievement of a sustainable pest and resistance management program for stored grains in Australia.

Table 1 Frequency of phosphine resistance in *R. dominica* within a selected grain value chain.

Abstract

Phosphine's continued use in Australia to control grain insect pests in on-farm and central storage systems is threatened through increased resistance in both frequency and strength in target insect pests. Effective fumigation combined with best practice integrated pest management is essential to the sustainability of grain biosecurity, food safety, quality assurance and market access for Australian post-harvest grain systems.

The National Stored Grain Extension Program (NSGEP) is an industry funded initiative developed to facilitate best practice in grain storage management within Australia's grains industry. The NGSEP uses a multi approach engagement strategy and a variety of adult learning principles and training techniques aimed at increasing awareness and knowledge to build capacity and support to enable farmers and industry to manage their grain storage systems and meet best practice and market requirements. These include: training workshops, field days, practical demonstrations, industry forums, multi-media and website development and building networks with grower groups, government agencies and agribusiness.

Various evaluation methods have shown that awareness and adoption of best practice in on-farm grain storage management has increased. Key outcomes include increased knowledge in insect identification and skills development and practice change in the management of grain hygiene, aeration, phosphine application, silo testing and planning of storage systems.

The NSGEP contributes to the positive on-going changes observed in Australia's on-farm grain storage systems, primarily through the specialized extension network of information, support and training provided that is highly regarded and in demand. It plays an instrumental role in building capacity and maintaining phosphine fumigation efficacy in the Australian grains industry.

Introduction

This paper reports on a Grains Research and Development Corporation (GRDC) sponsored project in extension for on-farm grain storage. The project was a national extension project, this paper focuses on the south eastern grain growing region of Australia, where the author is based and on-farm grain storage has increased significantly as a consequence of the deregulation of the domestic and export markets.

Phosphine fumigation is widely used to kill insect infestations in on-farm and central receival storages. When applied in unsealed storages poor results are typically attained which can lead to rejection at receival sites due to poor insect control and or detection of phosphine in the delivered grain. Use of phosphine in unsealed storages is a risk to the occupational health and safety of the user and increases resistance to phosphine. Safe phosphine application is essential to maintain the continued use of phosphine.

The project involved a multi approach to improve on-farm storage practises and the efficacy and safe application of phosphine for fumigation. The project consulted and worked with key industry stakeholders including state based departments of agriculture, research institutions, regulators, bulk handling authorities, silo and machinery manufacturers, training bodies, private agronomists and consultants, peak farmer representative bodies and farmer growing system groups.

Key elements of the project were delivery of best practise grain storage management and phosphine fumigation workshops and field days aligned to adult learning principles, information packages, media releases and communication, phosphine label changes and the introduction of an Australian Standard for gas-tight sealable silos.

Materials and Methods

The project involved using a multi approach to improve on farm grain storage management and phosphine fumigation practises including;

Workshops and field days were conducted for farmers, agribusiness and advisers on the principles of best management grain storage and fumigation practises. Grower, industry, silo and agricultural machinery networks were used to set up events in local areas. Events were advertised through these networks and local media and local grain storage issues were assessed to ensure the events were relevant to the immediate needs of participants as well as delivering the key messages around best practise fumigation and grain storage management.

Workshops and field days were developed and conducted using adult learning principles to create a positive learning environment for participants, build capacity in the industry to further support farmers and enable farmers and industry to implement ongoing changes in their grain storage systems. Typically the event would be for 3 to 4 hours depending on discussion and either started or finished with a meal and socialising to foster further discussion and knowledge transfer.

The events used a variety of delivery and training techniques, including auditory, sensory, visual and practical learning examples to cater for the different learning styles of the participants. Learning materials were supplied during the event and contact and further information details were given for participants to follow up on any questions.

Sessions would include presentations of best management practises combined with demonstrations and practical examples either at an on-farm grain storage or local grain storage site.

Group discussion and knowledge sharing was an integral component of each session, fostering learning and skills development for the participants.

A certified phosphine training course, "Responsible, Safe and Effective Use of Phosphine Generating Formulations on Farms" was developed with a chemical training provider (AusChem Training Inc) for on farm users. This course is available for training on-farm users of phosphine throughout Australia.

Best practise fumigation and grain storage management presentations were delivered at a variety of industry forums including GRDC Research and Grower updates, agribusiness and industry field days and seminars.

In consultation with industry a Strategy to manage resistance to phosphine was written to encompass the variety of grain storage systems in the Australian grain value chain. The strategy was written for use by small through to large central receival bulk handling authorities, grain growers and end users. This strategy has been adopted by the industry as a blueprint to manage phosphine resistance.

To support the training activities a variety of media articles were written and disseminated throughout local newspaper, journal and newsletter outlets. Articles were written in response to arising issues and as general information for growers and to promote best practise phosphine fumigation and management. A DVD was recorded on gas-tight sealed silos and phosphine use and distributed via the GRDC to all registered grain growers in Australia and uploaded onto YouTube and GRDC television. Radio interviews and discussions were also used to disseminate information and advice.

As an integral part of the nationwide project information packages and materials were developed and distributed through a variety of industry channels and were available at workshops and field days. Two written specifically for fumigant use were a GRDC factsheet called "Pressure testing sealable silos" and a booklet called "Fumigating with phosphine, other fumigants and controlled atmospheres. Do it right – Do it once".

Label changes to phosphine are currently being written to improve overall management of the product, safe use and to improve resistance management. Label changes have also been made to enable regulators to enforce breaches of the label, particularly in regards to what constitutes a suitable sealed structure.

In conjunction with SAI Global (formerly Standards Australia) the author convened a committee to write an Australian Standard for sealed silos. Prior to the Australian Standard (AS 2628-2010), there was no industry benchmark for sealed silos which growers could use to determine whether a silo they were purchasing was actually sealed and gas-tight when purchased. The committee was made up of representatives from State Department of Agriculture research scientists, the CSIRO, State and national farmer peak industry bodies and silo manufacturers. The committee consulted widely with industry, chemical registrants, the AVPMA and grower bodies and representatives.

All of these approaches were used to deliver a whole of industry extension program promoting best practise on-farm grain storage management and phosphine fumigation.

Results and Conclusions

Personal communication and anecdotal evidence in communication with the grains industry and value chain has demonstrated that on-farm grain storage management and the awareness and implementation of best practise phosphine fumigation has increased. Feedback from silo manufacturers has shown that growers are actively asking for Australian Standard compliant sealed silos when comparing and purchasing sealed silos. The Australian standard enables growers to purchase a sealed silo which meets a standard gas-tight pressure test, enabling them to have the correct system to fumigate. Prior to this standard being enacted growers found it difficult to benchmark silos in the marketplace, where a number of silo manufacturers claimed their silos were sealed but did not meet the standard pressure test.

The Australian standard alone does not ensure that efficacious phosphine fumigations can be administered; however it is the first step in ensuring a grower has the correct system in which to undertake an efficacious and safe fumigation.

Stakeholders across the grains value chain are asking for and disseminating best practise information through their networks and the many grower workshops and field days conducted through the national extension project and industry forums. Development of the various information packages covering best management practises for on-farm storage and fumigation provides a mechanism for growers and industry to support the training and knowledge development they have undertaken. The phosphine booklet "Fumigating with phosphine, other fumigants and controlled atmospheres" was a comprehensive and farmer friendly publication covering sealed storage management, silo testing and best practise fumigation. The Australian standard provided growers with the tools to select sealed storage, the extension program and information packages built on and supported best practise fumigation and grain storage.

At workshops and field days growers are taught the theory behind a successful fumigation and with practical demonstrations shown the features of a gas-tight sealed silo, how to maintain and replace seals and how to perform a standard pressure test to test whether they are sealed. A website www.storedgrain.com was developed to further provide a source for growers and industry to look for and download information.

Using mediums such as websites and the media allowed specific and timely information to be brought to the attention of growers and industry and to promote key messages when necessary. An example of this was a major media campaign using rural media and industry networks promoting and discussing the Australian standard for sealed silos, which was a great success and very quickly converted to growers actively asking whether silos being considered and or purchased met the standard.

Newspaper and newsletter articles and radio interviews are regularly released to promote best practise fumigation and grain storage practises when the information is timely and can be used to assist farmers in their storage management.

The accredited phosphine training module has had a minor uptake to date, largely due to growers still not being required to undertake training specific for the use of phosphine in all states except New South Wales. Currently New South Wales farmers are required to undertake phosphine training as a Work Cover (Occupational Health and Safety regulator) requirement. State regulators of chemical use are currently considering mandatory training for phosphine use, particularly in Victoria. The introduction of training is being considered as part of a response by regulators to the potential label changes for phosphine being proposed to the APVMA (Australian pesticides and veterinary medicines authority).

Overall the extension project has had a positive impact on improving the efficacy of phosphine fumigation in on farm fumigation. Growers are actively asking for Australian Standard Compliant sealed silos. Growers, industry and agribusiness are asking for and disseminating best practise information through their networks, and there has been a continuing demand for workshops and field days and addresses at industry forums.

Temporal and Spatial Patterns in Aerosol Insecticide Droplet Distribution: Modifying Application Strategies to Improve Coverage and Efficacy

James F. Campbell*, Frank H. Arthur, Daniel Brabec, Deanna Scheff

Abstract

With the phase-out of methyl bromide, treatment of food facilities with aerosol insecticides as part of management programs has increased. The physical layout of the structure, the distribution of equipment and other items within the space, and the application method and location may all cause spatial variation in how the insecticide is deposited, which can result in areas with insufficient or excessive amounts of insecticide applied. The impact of aerosol insecticide application position and dispersal method/formulation on the distribution of droplets was evaluated using a series of applications within the same flour mill room. The spatial pattern of droplet distribution and the effect of treatment on bioassay insects (*Tribolium confusum* Jacquelin DuVal) was evaluated. There was variation in aerosol concentration and droplet size distributions within room and application position had an impact on the spatial pattern of aerosol droplets. The further away and more obstructed by structural features a location was the lower the aerosol concentration, but concentration was also lower to the side and behind the release point. Evaluation of the temporal pattern in droplet deposition shows that most larger droplets settle out of the air relatively quickly, supporting that idea that shorter shutdown times are be possible. Efficacy was correlated with droplet concentration. The overall conclusion is that there can be considerable variation in distribution of aerosol insecticides and as a result considerable potential for improvement in the effectiveness of these applications.

Keywords: insecticide, aerosol, flour mill, *Tribolium confusum*, efficacy, spatial distribution.

1. Introduction

Some insecticides can be applied as aerosol treatments which involves atomizing the liquid insecticide and carrier and dispensing as small particles ranging in size size from 5 -50 µm. Use of aerosol applications using reduced risk insecticides such as pyrethinrs, pyrethroids, and insect growth regulators has increased with decreased use of structural fumigations in food facilities. Application of insecticides as aerosols offers the advantage over other spray methods in that more complete coverage of surfaces within a food facility can be obtained. However, information on the coverage that is actually achieved and the impact of variation in aerosol deposition on efficacy remains limited. Aerosol droplets have limited ability to penetrate into machinery or commodiites so they don't function like a fumigant and they also have limited ability to disperse under obstructions. This can generate areas with inadequate coverage with insecticide and can result in reduced efficacy (Campbell et al. 2014; Kharel et al. 2014; Arthur et al. 2018). Evaluations of spatial patterns in aerosol distribution can be done using bioassay insects (e.g., Campbell et al. 2014), but using particle size measuring equipment can improve our understanding of what is happening during aerosol treatments (e.g., Arthur et al., 2018). Understanding the spatial pattern in both aerosol droplet size and concentration is important given that droplet size impacts both dispersal but also efficacy, given that smaller droplet sizes tend not to be efficacious against insects (Arthur et al. 2014).

Previous research has shown that there is spatial variation in efficacy against stored-product insects within a facility, presumably due to uneven aerosol dispersal and deposition patterns (Arthur and Campbell 2008, Campbell et al. 2014, Arthur et al. 2018). When aerosol treatment with a combination of pyrethrin and insect growth regulator was applied from one location within a flour mill there were areas with high efficacy, typically in open areas in the center of the room, and areas with low efficacy, typically in corners, behind application point, obstructed areas, and locations farthest from application point and which had the most physical obstructions between point of release and where measurements were taken (Arthur and Campbell 2008; Campbell et al. 2014). As a result, a critical question is how can coverage of these treatments be improved so that get more even coverage and efficacy within a space. The aerosol formulation and delivery method are likely to be important variables, since velocity at release and droplet size distribution produced will impact the distribution and deposition of aerosols. Also, where the aerosol is applied within a space is also likely to impact coverage, given that barriers and distances that need to be traveled by droplets will vary with release point. In these tests, we evaluated the impact of application point and formulation type on coverage of aerosol treatments. Specifically, we used a combination of droplet size and concentration measurement and bioassay insects to evaluated spatial pattern in aerosol

applications when aerosols were applied from one of three locations or if aerosol application was split among all three locations.

2. Materials and Methods

Aerosol applications were conducted at the pilot scale flour mill at Kansas State University, on the third floor which is roughly L shaped, 13.5 x 21.0 m in main area and 7.5 x 6.5 m in the smaller offshoot of the main area (volume of approximately 1,504 m^3). Aerosol applications were applied by a commercial applicator using the label rates of (1) cylinderized formulation of a combination of pyrethrin and the IGR pyriproxyfen (TurboCide Py-75 with IGR, Chem-Tech Ltd., Des Moines, IA, USA) and (2) combination of pyrethrin (BP-100, BASF Corp., Research Triangle Park, NC) and the IGR methoprene (Diacon® IGR, Central Life Sciences, Schaumburg, IL, USA) applied using a portable handheld mechanical fogger hand applicator.

Each aerosol was applied from one of three locations within the mill, or the application was split equally among the three locations (Fig. 1). Treatments were replicated three times. Aerosol distribution was measured using bioassay dishes containing confused flour beetles, *Tribolium confusum*, and Aerodynamic Particle Sizer (APS) spectometer 3321 units (TSI Inc., Shoreview, MN, USA) placed at different locations within the mill (Fig. 1). After one hour of treatment, the room was vented and the bioassay insects collected and evaluated on whether they showed signs of being effected by the insecticide and then held for 14 days and assessed again and number alive, dead, or knocked down was recorded.

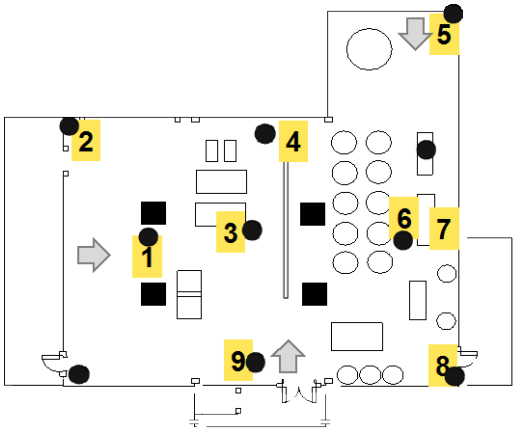

Fig. 1 Floor plan of the flour mill where the aerosol tests were conducted, with aerosol application release points and directions indicated with gray arrows, positions of the aerosol particle size analyzers indicated by numbers in yellow boxes, and positions of the bioassay dishes indicated by the black circles.

3. Results

Number of aerosol droplets, droplet size distribution, total concentration in air (mg/m^3), and estimated deposition on surfaces (ug/m^2) were calculated for each location/treatment combination. Example of the temporal and spatial pattern in total concentration and mean particle size is shown in Fig. 2. Total droplet concentration decreased with distance from application point and in more obstructed locations, and at all locations within the mill the total concentration had dropped to low levels after less than 20 min and remained unchanged until the end of the treatment. There was considerable variation in the estimated deposition on surfaces among locations, with greatest estimates near point of application and dropping as move further away or if more obstructed. Aerosol application location did impact which locations had higher concentrations of aerosol, but all application locations and formulations resulted in patterns of high and low deposition. Splitting

the application among three locations increased the number of locations with higher deposition but in all treatments had locations with low deposition.

There were significant differences in bioassay insect knockdown immediately after treatment and mortality after 14 days among application location/treatment combinations. Application location did result in differences in the pattern of efficacy but regardless of whether released from one of the three locations, or split among three locations, there continued to be zones where beetles survived treatments (Fig. 3).

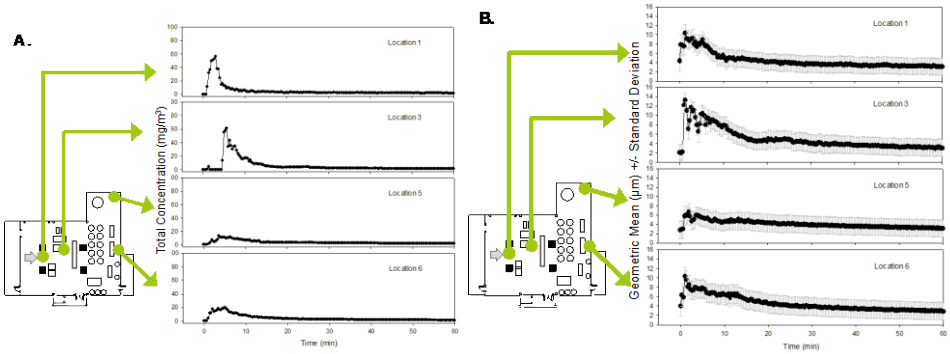

Fig. 2 Example of how total concentration (A.) and geometric mean droplet size (B.) varied among locations and changed over time after start of treatment, using results of one trial using the cylinderized formulation of pyrethrin and pyriproxyfen released at one location (only four the APS units shown for clarity).

4. Discussion

Results of this study show that there is spatial variation in the distribution of droplets that is impacted by release location and the insecticide formulation/application method. There was also a correlation between droplet deposition and efficacy using bioassay insects, suggesting that it is the droplet characteristics that are causing variation in efficacy. As expected, distance and physical barriers contributed to reduced droplet concentrations and droplet sizes, and were associated with lower efficacy. An exception to this pattern is that locations behind where the applicator stood often had reduced aerosol deposition and bioassay efficacy, suggesting that the release velocity of droplets resulted in limited drift of droplets back into the area of release. Unfortunately, none of the different application locations evaluated, including releasing aerosol split among all three locations, resulted in all locations having high efficacy. Further evaluation of other patterns of aerosol release and use of fans to facilitate movement of droplets is needed.

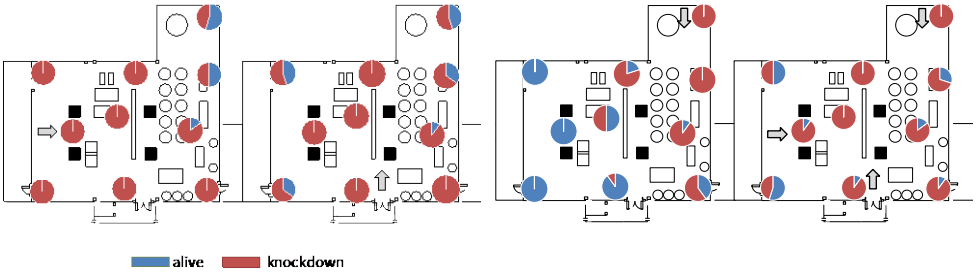

Fig. 3 Example of effect of application location on bioassay insects (*T. confusum*) immediately after exposure to aerosol at different locations, using results of one trial with cylinderized formulation of pyrethrin and pyriproxyfen. Each floor plan has an arrow to indicate the aerosol application location and direction and the pie charts represent the percentage of beetles alive or knocked down immediately after the treatment.

Our results bioassay results are meant to be used as indicators of aerosol concentration, not necessarily as an indicator of overall effectiveness of a treatment against a resident pest population. First, we did not include the impact of the insect growth regulator in the aerosol formulation. Initial evaluations indicate that because much smaller amounts are needed for efficacy that more consistent high efficacy is found using larvae exposed to surfaces at different spatial locations. Second, the spatial pattern of insects in the facility and how much of the population is hidden in areas aerosol cannot reach is not known. In most situations we would predict that large portions of the population will not be directly exposed to the droplets during an application. Contact with treated surfaces and materials after the aerosol application is likely to more important in terms of the overall impact of a treatment on the pest population.

Aerosol insecticide applications have tended to be a black box and little information was available on the impact of the treatments. Research presented here is part of a broader research effort to understand these treatments better, to make them more effective, and to be better able to predict the best strategies for using reduced risk aerosol insecticides.

Abstract

Phosphine is the most important commonly used fumigant for the control of stored product insects in warehouses and processing facilities globally. However, the improper and extensive use has led to reduced susceptibility to phosphine for several insect species and strains in many parts of the world. To evaluate and quantify this phenomenon, Detia Degesch developed the Detia Degesch Phosphine Tolerance Test Kit (DDPTTK) more than 10 years ago. The use of DDPTTK is based on the exposure of the insects on a high concentration of phosphine (e.g. 3000 ppm) for short exposure periods (e.g. 8-15 min). This kit can be used on site by the fumigation and food industry, and can provide immediate results on the tolerance status of the insect strains that are to be treated. So far, the instructions of DDPTTK refer only to a six insect species. In this work, data for

the expansion of knowledge about other species is provided, in order to broaden the spectrum of cases where the kit can be used. Moreover, certain improvements for the use of the kit are introduced, i.e. practical recommendations on the procedure and safety instructions.

Keywords: stored product insects, laboratory species, tolerance to phosphine, fumigation.

1. Introduction

The determination of insects´ sensitivity status towards treatments with phosphine has been a widely discussed matter all over the scientific world. As there have been many approaches to determine tolerance or even resistence as part of monitoring programs or other projects, a great discussion about validity, comparability and as a result, tendency of the development of resistence has been unleashed.

But as a scientific discussion is ongoing on a very different level as the actual fumigation work, a gap has developed between the results of various testing approaches and storage protection itself.

Due to this reason, Detia Degesch has developed a simple and easy-to-use testing kit, which can be utilized on-site and by basically anyone. In this way, the fumigator can have a fast and uncomplicated answer to his question: is there anything suspicious about the pests in my commodity?

The scientific basis for determining susceptibility in stored product pest insects has been described by REICHMUTH (1997), who discovered a relation between activity in a phosphine containing atmosphere with 3,000 ppm and narcosis with the narcotical effect showing direct proportionality to mortality.

The endpoint to be evaluated by the user is quite simple: Do the insects still walk? Have they become inactive or uncoordinated? How many of my 20 insects overgo their indicated time-to-immobility?

As the kit was released for the first time in 2007, time has come to relaunch an updated version, as most of the data was outdated. The basis of the sensitivity determination has been originally derived from laboratory reared insects, without prior contact to phosphine. Thus, the endpoint to be monitored has shifted for some species. The aim was to use actual monitoring data from the project "Tolerance/resistence of stored product insect pests to phosphine monitoring in Europe", which is the first project of its kind in Europe (SAKKA et al. 2017, AGRAFIOTI et al. 2017).

While the first kit included monitoring advice for six species, the new version contains information about 13 different species (to be presented during the conference).

2. Materials and Methods

The kit includes the following components:

100 mL syringe
2 canula, 1 with a rubber hose
5 L flexible plastic canister
Lid including a septum
5 x 2 test kit pellets
Instructions for use, containing determination of dilution

Additionally and not included in the kit, measuring equipment to determine phosphine concentration is required. It is advisable to use a pump and measuring tubes with a measuring range up to 10,000 ppm. To determine the time, a stopwatch or any clock should be at hand. The procedure of testing is as follows:

- Unfold the plastic canister
- Add 50 mL of water
- Add two test kit pellets and close with the lid, shake carefully (waiting for pellets to be completely dissolved)
- Connect the measuring device with the canister by using the canula and the ruber hose to determine phosphine concentration

- Use the diagram to determine the diltution for a target concentration of 3,000 ppm in the syringe
- Remove syringe piston, add 20 adult insects into the syringe and put back the piston without damaging the insects
- Adjust air volume in the syringe first (see figure 1 and table 1)
- Connect syringe with the canister and fill the syringe up to 100 mL with phosphine
- Start the clock
- Oberserve the behaviour/activity of the insects

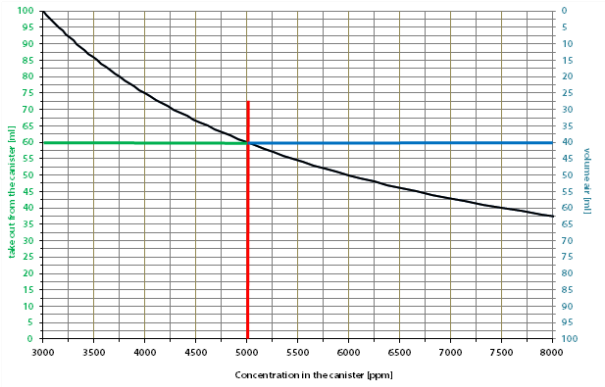

Fig. 1 Dilution determination scheme. To achieve 3000 ppm in the syringe, the concentration inside the canister has to be determined first. On the basis of this result, the volumes to be taken by the 100 mL syringe of normal air (first step) and phosphine from the canister (second) can be determined as follows: The red line symbolizes the measured concentration in the container. The point crossing the black line can than be used to draw lines in horizontal direction. Where the light blue line crosses the secondary x-axis, the required volume of air can be read off, while the green line crossing primary x-axis ascertains the volume of phosphine to be taken from the canister.

The endpoint to be determined shall be “walking” or not walking”. After the species specific time, the test can be terminated. To record the testing, the kit includes pre-printed forms, which are a useful overview, whether or not suspicious insects occur and to follow up on consequent fumigations (see table 2).

Tab. 1 Dilution scheme for desired syringe concentration of 3,000 ppm (testing concentration)

concentration in the canister (ppm)	take out from canister (mL)	volume air (mL)
3,000	100.0	0
3,250	92.3	7.7
3,500	85.7	14.3
3,750	80.0	20.0
4,000	75.0	25.0
4,250	70.6	29.4
4,500	66.7	33.3
4,750	63.2	36.8
5,000	60.0	40.0
5,250	57.1	42.9
5,500	54.5	45.5

3. Results

Study data from a monitoring project to be published shows that immobilization of 100 % of all species is not a feasible endpoint from the biological point of view. Therefore, the immobilization of 19 out of 20 individuals during the species specific exposure time is enough to proof normal susceptibility.

After finishing the observation time (max. 90 min, or after the species specific determination time), the outcome has to be evaluated in a very simple way. If the test indicates a strongly tolerant strain, the key parameters for the scheduled fumigation need to be reconsidered and adjusted to the circumstances.

4. Discussion and Outlook

The Detia Degesch Tolerance Test Kit has been proven to be useful in various occasions as a small and simple tool to evaluate insects´ susceptibility status by any user. It can be seen as the basis for a proper and situation-based fumigation of the infested commodity or storage system.

To extend the possibilities, the tool will include a scientific protocol to be used by institutions in laboratories as well. Here, it has become more and more important to evaluate a factor scientifically known as delayed mortality. This has been in discussion to give a more detailed picture about phosphine induced mortality and will be part of a new research project. Furthermore, the simplicity of the kit is very handy for laboratories and institutions with high security status, as the small container enables a safe and clean use of the gas without demanding cylinder stored gas or others.

Acknowledgement

Detia Freyberg GmbH would like to thank the University of Thessaly for their engagement in the projects with and behind this testing method.

We also highly appreciate the cooperation with Control Union and AgroSpeCom for supporting the sampling of insects all over Europe.

Likewise, thank you to all participating pest protection companies, laboratories and end users for supplying the project with insect samples.

Abstract

Hydrogen phosphide (PH_3) is the most commonly used gas for insect control in durable stored products. One of the quick diagnostic tests that are currently in use is the Detia Degesch Phosphine Tolerance Test Kit (DDPTTK), which has been developed by Detia Degesch GmbH (Laudenbach, Germany). DDPTTK provides a rapid evaluation tool for phosphine resistance, where insects are exposed in syringes that contain a high concentration of gas (e.g. 3000 ppm), while this gas is produced on site by adding tablets into a canister. We used DDPTTK to evaluate resistance of the red flour beetle, *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae) to phosphine. For this purpose, we followed a specific succession of observations on the exposed adults of this species, in an effort to set the scene for designing a rapid diagnostic tool for phosphine resistance, based upon quick bioassays. Two *T. castaneum* strains were used, one susceptible and one resistant to phosphine. Twenty adults of each of the populations (separate sets of adults each time) were placed in syringe of 100 ml under 1000 or 3000 ppm of phosphine. The insects inside the syringe were monitored at 15-min intervals, for a total period of 90 min, and classified as active, under narcosis and immobilized. After this period, all insects were removed from the syringe and placed in plastic petri dishes with a small quantity of wheat flour. The insects were classified again at the three categories above, after 2 h, 1 d, 2 d, 3 d and 7 d. Regarding the exposure period, at 1000 ppm, all adults of the susceptible strain were immobilized after 60 min of exposure, and remained at this condition until the end of the observation period. At the same concentration, the majority of adults of the resistant strain remained active until the end of the observation period. At 3000 ppm, for the susceptible strain, all adults became immobilized after 90 min observation. For the same concentration, the percentage of the adults of the resistant strain that were active was notably reduced in comparison with 1000 ppm. For the post-exposure period, at 1000 or 3000 ppm, for the susceptible strain, the number of adults that were immobilized reached 95 % after 7 d. At the same phosphine concentration, almost all of the adults of the resistant strain were active even at the 2 h post-exposure period, and practically remain at this condition until the end of the observation period. Our findings indicate that time-to-narcosis / immobilization is inversely proportional to time-to-recovery of the same individuals, and this characteristic can be also considered as an indicator for resistance.

Keywords: phosphine, narcosis, mortality, *Tribolium castaneum*, resistance, diagnostic tool

Diagnosis and indicators

Evaluation of resistance to phosphine and its diagnosis has been performed in many places of the globe, using different diagnostic tools. The most common diagnostic method is the Food and Agriculture Organization (FAO) protocol, which is based on the exposure of the insects for 20 h at concentrations that are generally fixed as "discrimination concentrations" per target species and usually fall within the range of 30 to 50 ppm (FAO 1975). Other tools include bioassays that last for longer, e.g. 3 d, and are carried out at higher concentrations, in order to quantify resistance, in contrast with the FAO method that is used to indicate the presence or absence of resistance (Nayak and Collins 2008, Kaur and Nayak 2014, Holloway et al. 2016, Collins et al. 2017, Koneman et al. 2017). In these bioassays, apart from the initial mortality, which is the mortality that is recorded after the exposure, delayed mortality is also estimated, given that surviving insects are likely to be affected at a later post-exposure stage, which usually is determined at 7 or 14 d after the exposure. This last indicator is generally considered more reliable than the initial mortality.

There is also one more indicator that is taken into account as a means of quantifying resistance: insect immobilization. Theoretically, insects that are susceptible to phosphine are immobilized faster than those that are resistant. This is a generally accepted rule, despite the fact that there are different theories suggesting that immobilization is not concentration-depended and that quick immobilization is not always reliable as an indicator of resistance. In this regard, additional experimental work is needed to underline the potentials of using immobilization as an indicator towards this direction.

Recovery after exposure

While there are many papers that are focused on the evaluation of immobilization or mortality after exposure to phosphine, there are disproportionally few works that examine recovery as an indicator of resistance. Quick recovery may suggest that the insects are resistant to phosphine; nevertheless, the "speed of recovery" here is crucial, and cannot be estimated in one observation interval alone. Recovery may be expressed more vigorously in the case of quick diagnostic tools, such as the Detia Degesch Phosphine Tolerance Test Kit (DDPTTK) (Steuerwald et al. 2006, Aulicky et al. 2015). In DDPTTK, the insects are exposed at high concentrations (usually 3000 ppm) for some minutes that are usually less than 15 and immobilization is used to indicate if the exposed insects are susceptible to phosphine. This method is very easy in its use, and practically this is the only method so far that can be used by fumigators, flour millers etc. on site, without the need to go to a specialized laboratory. In the current work, we used different populations of the red flour beetle, *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae), to illustrate immobilization and recovery patterns after short exposures to DDPTTK (data have been submitted for publication to a scientific journal and briefly described in the abstract above). In this effort, there is indeed a big difference regarding the "speed to immobilization" and the "speed to recovery" between strains that have different levels of susceptibility to phosphine. Hence, based on the current data, the theory "fast immobilization=slow recovery" may be true for the tested strains, and can be used further to understand resistance to phosphine and its diagnosis.

Abstract

We evaluated the susceptibility to phosphine in different populations originated from 14 European countries, by following different diagnostic protocols. In total, more than 200 populations were screened during these tests, classified to 9 beetle species: *Tribolium confusum* Jacquelin du Val (Coleoptera: Tenebrionidae), *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae), *Oryzaephilus surinamensis* (L.) (Coleoptera: Silvanidae), *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae), *Sitophilus granarius* (L.) (Coleoptera: Curculionidae), *Sitophilus zeamais* Motschulsky (Coleoptera: Curculionidae), *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Laemophloeidae), *Rhyzopertha dominica* (F.) (Coleoptera: Bostrychidae) and *Lasioderma serricorne* (F.) (Coleoprtera: Anobiidae). The different bioassay-related diagnostic protocols that were followed were based on different exposure intervals and phosphine concentrations, ranging between 90 min and 4 d, and between 30 and 3000 ppm, respectively. Our results indicated that one of the populations that had been sampled from Europe was strongly resistant to phosphine. Moreover, the different protocols provide comparable results, which means that a standardized diagnostic can be further designed and adopted. Moreover, molecular assays indicated that the mutations P49S in *R. dominica* and P45S in *T. castaneum* are common among different populations, regardless of the degree of resistance to phosphine. Our results suggest that there are reliable quick tools for the evaluation of resistance to phosphine and that insect sampling in target areas should be conducted on a regular basis.

Keywords: Phosphine resistance, tolerance, fumigation, stored product beetles, protocols

1. Introduction

Phosphine fumigation is the primary fumigation tool to control stored product insects. Nevertheless, although phosphine has been proved effective against most major stored product insect and mite pests, its extensive use meets with several drawbacks (Benhalima et al., 2014). The main disadvantage on the use of phosphine is the development of tolerance/resistance by several stored product insect species. Actually, many species, such as the lesser grain borer, *Rhyzopertha dominica* (F.) (Coleoptera: Bostrychidae) (Opit et al.; 2012), the rusty grain beetle, *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Laemophloeidae) (Konemann et al., 2017), the red flour beetle, *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae) (Ridley et al., 2012), the rice weevil, *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae) (Daglish et al., 2014) and the cigarette beetle, *Lasioderma serricorne* (F.) (Coleoptera: Anobiidae) (Saglam et al., 2015) have developed a

considerable level of resistance, and there are specific strains of these species that can survive concentrations that are considerably higher than the recommended application rates. Currently, resistance to phosphine is found in several parts of the world, such as Brazil (Lorini et al., 2007), USA (Gautam et al., 2016), Australia (Nayak et al., 2017), India (Kaur et al., 2015) while, for the majority of the species tested, eggs and pupae are considered the most tolerant life stages (Price and Mills, 1987; Rajendran et al., 2001; Ridley et al., 2012). However, there is still inadequate information on the evaluation of the level of tolerance to phosphine in Europe, despite the fact that phosphine is widely used in Europe.

There are different diagnostic tests have been widely used for the evaluation of phosphine resistance. The most widely accepted protocol for the evaluation of phosphine resistance is the Food and Agriculture Organization (FAO) method number 16 (Food and Agriculture Organization, 1975). This method uses a discriminating dose with a concentration based on the $LD_{99.9}$ for different stored product insects. In this concentration, the insects are exposed for 20h and after this interval, the exposed individuals are removed and mortality is recorded usually after a 14-d post-exposure period. Hence, survival after this interval is an indication of resistance in this test. A modification of FAO protocol is the Dose Response Protocol, known also as Dose Bioassay. This protocol is based on a different exposure period (3 days) in a range of concentrations. Another protocol is the one that has been developed by the Cooperation Centre for Scientific Research Relative to Tobacco (CORESTA) for tobacco pests, were the insects are exposed to 200-700 ppm for 4-10 days (CORESTA, 2013). Moreover, a quick test has been developed by Detia Degesch (Steuerwald et al., 2006) which is based on the evaluation of the mobility of the insects after short exposures (usually 15 min or less) to high concentrations (e.g. 3000 ppm).

Apart from the "classic" protocols for the evaluation of phosphine resistance, molecular/genetic methods have been designed, with the use of PCR and molecular markers (Chen et al., 2015; Nguyen et al., 2016). According to literature, there are two major loci, *rph1* and *rph2*, that are responsible for strong resistance. When *rph1* and *rph2* loci are individually homozygous they confer weak resistance, but when they are both homozygous they confer strong resistance (Schlipalius et al., 2002; Jagadeesan et al., 2012; Nyugen et al., 2015; Nguyen et al., 2016). The stored product insects that have been genetically characterized with this method are *R. dominica* (Schlipalius et al., 2008), *T. castaneum* (Chen et al., 2015), *S. oryzae* (Nguyen et al., 2016) and *C. ferrugineus* (Tang et al., 2017).

The present study aims in investigating the tolerance/resistance of different populations of stored product insects in Europe with different evaluation methods. Preliminary investigations were also carried out to detect the genes that are responsible for phosphine resistance in some of these populations. Knowledge of phosphine resistance in different countries in Europe will provide the inferences necessary for improving fumigations and stored product protection measures in general.

2. Materials and Methods

2.1 Populations tested

A total of 500 samples of different commodities (e.g. rice, wheat, barley, chocolate) were collected during 2016-2018 from storage and processing facilities from 14 different European countries. The insects of each sample were identified isolated and transferred to 1L glass jars with commodity to initiate rearing. All rearings have been carried out at the Laboratory of Entomology and Agricultural Zoology, Department of Agriculture, Crop Production and Rural Environment, University of Thessaly at 25° C, 65 % r.h., and continuous darkness. In this study, we present the results of 18 different populations of stored product insects, corresponding to nine different species: the maize weevil, *Sitophilus zeamais* Motschulsky (Coleoptera: Curculionidae), the saw-toothed grain beetle, *Oryzaephilus surinamensis* (L.) (Coleoptera: Silvanidae), *S. oryzae*, *S. granarius*, *L. serricorne*, *T. castaneum* , *T. confusum*, *R. dominica* and *C. ferrugineus*. Only adults were used in the tests.

2.2 Methods for the evaluation of phosphine resistance

Resistance was tested using four different protocols. a) the FAO protocol, based on screening by exposure of the tested insects to 30 ppm for 20 hours, b) the Dose Response protocol, based on the exposure of the tested insects to phosphine to 50, 100, 200, 500, 700 and 1000 ppm for 3 days, c) the CORESTA protocol, based on the exposure of the tested insects to phosphine to 200ppm for 4 days, and d) the Detia Degesch Phosphine Tolerance Test Kit (DDPTTK), based on the exposure of insects at 3000 ppm for 90 minutes. For all protocols, after the termination of the exposure interval, the insects were classified as active, under narcosis or immobilized. Then, the exposed insects were transferred to a clear petri dish for additional 7 days, and then classification was made again. The whole procedure was repeated 9 times (three replicates of three sub-replicates).

2.2.1 FAO Protocol

Twenty (20) adults of the test species were placed in a 1.5 lt glass jar and exposed to phosphine concentrations of 30 ppm for 20 hours. After the termination of the exposure interval, active, under narcosis and immobilized insects were recorded and were transferred to a clean petri dish with food for 7 days. Then, delayed mortality or recovery were recorded.

2.2.2 Dose Response Protocol

The procedure was similar to that for the FAO protocol (including delayed mortality), while the tested adults were exposed for 3 d at 50, 100, 200, 500, 700 and 1000 ppm.

2.2.3 CORESTA

This protocol was based on the CORESTA guidelines, where 20 insects of the test species/population were placed in a 1.5 lt glass jar and exposed to 200 ppm concentration of phosphine for 4 days. After the exposure, active, immobilized and under narcosis insects were recorded, while if there were active insects, then the protocol was repeated with exposure of insects at 700 ppm for 10 days with new individuals (Guide 2 CORESTA).

2.2.4 Detia Degesch Phosphine Tolerance Test Kit (DDPTTK)

Twenty insects were placed in a syringe of 100ml and exposed to a concentration of 3000 ppm of phosphine for 5, 10, 15, 20, 25, 30, 45, 60 and 90 minutes. For strains that active insects were recorded until 90 minutes, the exposure time was extended to 270 minutes (recorded every 30 min). After each exposure interval, active, under narcosis and immobilized insects were recorded, and after the last exposure intervals, insects were transferred to clean petri dishes with food for seven days, to record the delayed mortality or recovery, as above.

2.3 Determination of the mutations that are related to phosphine resistance in *rph2* locus

For the molecular study, two populations of *T. castaneum* and three populations of *R. dominica* were used, based on earlier indications for their susceptibility to phosphine. Specific primers were designed for *T. castaneum* and *R. dominica*. A single band at ~1500-1600 bp was obtained for all the three insect species. PCR products were purified and sent for sequencing in Macrogen sequencing facility (Amsterdam, The Netherlands).

3. Results

Some levels of reduced susceptibility to phosphine, as compared with the laboratory populations, were recorded for many of the populations tested (Table 1). One hundred percent of active individuals were recorded in the population of *T. castaneum* and *C. ferrugineus*. After the exposure of 50ppm for 3 days, for one population of *C. ferrugineus* all (100 %) individuals were recorded as active. Moreover, some populations of *T. castaneum* and *R. dominica* had resistant individuals that could survive at 500 and 200ppm, respectively. Nevertheless, at the highest concentrations (700 -

1000 ppm) there was no survival for any of the populations tested. Moreover, active individuals were recorded after exposure to CORESTA protocol for only one population of *L. serricorne*. Finally, there were certain populations of different species (*S. oryzae* 3Tusc, *S. zeamais* Mach, *L. serricorne* E1, *T. castaneum* BTS and 3SP.18.1, *T. confusum* D1 and *C. ferrugineus* B1) that showed considerable percentages of active individuals after the exposure to DDPTTK.

The P45S allele of *rph2*, which is responsible for strong resistance, was detected from *T. castaneum* populations tested while P49S was detected in the case of R. *dominica*. All populations of *T. castaneum* and *R. dominica* tested are homozygous for the mutant allele, including the lab/susceptible ones, which the exception of *R. dominica* Inj which was found to be heterozygous.

Table 1: Percentage (% ± SE) of active adults of laboratory and field populations of different beetle species after the termination of a 7-d post-exposure period, following the exposure to phosphine under different protocols.

	Sample Code	Concentration of phosphine (ppm)/ exposure time (hours or days or minutes)

* these populations had been sampled from counties outside of Europe

4. Discussion

The results presented here indicate that there are some certain survival patterns in some of the populations tested after exposure to phosphine, but very few indications of possible strong resistance (i.e. populations that had survived after 3 d at 500 ppm). In a similar screening from Morocco, Benhalima et al. (2004) noted that all samples tested were phosphine resistant according to the FAO protocol. In the current work, there were some field populations that were susceptible to phosphine, e.g. *O. surinamensis* 1W and *S. oryzae* 3T. Bell et al. (1977) underlined that FAO protocol is a successful method of identifying resistant strains, while at higher doses of phosphine for 20h, the results from that study showed also resistance to some populations. In general, the FAO protocol could be used with success as a quick diagnostic tool to indicate possible resistance, but Dose Response at higher exposures can be performed to cross-check and quantify resistance. By using a similar approach, Konemman et al. (2017) reported that phosphine resistance in *C. ferrugineus* is common in Oklahoma. Specifically, at the discriminating dose of 56.2 ppm all field populations were resistant to phosphine with frequency that ranged between 6 and 100%. Nayak et al. (2013) also reported extremely high levels of resistance for populations of *C. ferrugineus* from Australia. In our study, one *C. ferrugineus* population was able to survive at 500ppm at the Dose Response test. The

current data set indicate that some of the populations that had been sampled from non-European areas, were much less susceptible to phosphine than the ones that had been collected from Europe.

Our study initially identified the presence of the P45S and P49S mutations that are related with phosphine resistance to *T. castaneum* and *R. dominica*, respectively. Genetic studies of phosphine resistance are focused especially to four major species: *T. castaneum*, *R. dominica, S. oryzae and C. ferrugineus*, and are based on the presence of two loci, *rph1* and *rph2* that are responsible for weak and strong resistance. Most studies were focus on *rph2* locus (Schlipalius et al., 2008; Kaur et al. 2013; Chen et al. 2015). More recently, Schlipalius et al. (2018) identified *rph1* locus for *R. dominica*, *S. oryzae*, *C. ferrugineus* and *T. castaneum*. They found one orthologous gene, a cytochrome b5 fatty acid desaturase (Cyt-b5-r), to be associated with the *rph1* locus in all four species. A more thorough research on these indicators will reveal the genetic basis for the resistance of different populations, in terms of frequency patterns in Europe and elsewhere.

In this work we performed a surveillance on the presence of resistance in populations that had been sampled from Europe and some comparable populations sampled from other areas. Our results showed no evidence of strong resistance in the European populations tested, whereas the common mutations that are related for phosphine resistance were identified for *T. castaneum* and *R. dominica*. Finally, we found that different protocols for the evaluation of resistance to phosphine, although they often provide dissimilar results, are comparable and could be revisited on the basis of designing a novel standardized protocol, which can be adopted further in laboratory trials and "real world" applications.

Abstract

Phosphine resistance monitoring typically involves bioassays of beetles from population samples collected from grain storage facilities. Insects are classified into susceptible or resistant phenotypes based on mortality or survival at one or more discriminating doses. Although valuable, phenotype testing has several drawbacks. First, phenotype testing needs live insects, and considerable effort is required to collect and maintain them before testing. Second, population samples may contain multiple genotypes expressing different levels of resistance that may not be distinguishable using discriminating dose bioassays. Third, collections are likely to be focussed around grain storages to maximise sampling success. Recent research shows that several key pests are actively dispersing through flight. The availability of commercial pheromone lures and recent advances in molecular screening provide an opportunity to provide information on resistance gene frequencies more broadly across the landscape. This approach is proving to be a valuable adjunct to traditional resistance testing in Australia.

Keywords: pheromones, DNA markers, traps**,** phosphine resistance, allele frequency

1. Introduction

The development of resistance in stored grain beetles threatens the efficacy of phosphine fumigation (e.g. Daglish et al., 2002; Lorini et al., 2007; Kaur and Nayak, 2015). Generally, monitoring for resistance involves bioassays of beetles from population samples collected from grain storage facilities, and insects are classified into different susceptible or resistant phenotypes based on mortality or survival at one or more discriminating doses (e.g. Benhalima et al., 2004; Daglish et al., 2014; Cato et al., 2017; Konemann et al., 2017). This approach, also known as phenotype testing, is valuable but has several drawbacks. The first drawback is that live insects are needed for testing, and considerable effort is required to collect and maintain them before testing. Another drawback is that population samples may contain multiple genotypes (including heterozygotes), expressing different levels of resistance, that may not be distinguishable using discriminating dose bioassays. Finally, collections are likely to be focussed around grain storages to maximise sampling success. Recent research shows that several key pests are actively dispersing through flight. The availability of commercial pheromone lures and recent advances in molecular screening provide an opportunity to provide information on resistance gene frequencies more broadly across the landscape. We demonstrate this using results from eastern Australia on the lesser grain borer, *Rhyzopertha dominica* (F.).

Phosphine resistance in *R. dominica* is conferred by two major genes (*rph1* and *rph2*) and there could be up to nine genotypes to be present in sampled populations (Schlipalius et al., 2002). Beetles that are homozygous for resistance at *rph1* alone are widespread in eastern Australia and exhibit weak resistance. Beetles that are homozygous for both *rph1* and *rph2* are much less common and exhibit strong resistance. While the FAO discriminating dose is useful for discriminating between susceptible and resistant beetles, using a discriminating dose to distinguish between weak (*rph1*) and strong resistance (*rph1* + *rph2*) is more difficult because of the overlap of the dose-response curves of beetles with weak resistance and those with strong resistance (Lorini et al., 2007). The dose-response curves of many of the other seven genotypes is not known, and further prediction of their responses is complicated by the semi-recessive nature of phosphine resistance.

The development of the capacity to screen with a molecular resistance marker for *rph2* means that individual beetles (including heterozygotes) can be tested for the presence of absence of *rph2* alleles (Kaur et al., 2013). Because resistance at *rph1* is already widespread, the presence of the resistance marker at *rph2* provides a strong indication that strong resistance is already posing a pest control problem or that it will soon emerge in insects at the site where it was found. An advantage of molecular testing over phenotype testing is that it does not need live insects, provided the DNA of the dead insects has been preserved. Traps baited with commercial aggregation pheromone lures for *R. dominica* have been used in Australian and North America to show that flying adults can be caught not only near grain storages but also many kilometres away (Edde et al, 2006; Mahroof et al., 2010; Ridley et al., 2016; Daglish et al., 2017). Also, such trapping has provided *R. dominica* specimens with intact DNA suitable for gene flow analysis (Ridley et al., 2016). A trapping program using aggregation pheromone lures is under way in southern Queensland, Australia, providing information on infestation pressure from flying *R. dominica*, and specimens for molecular resistance screening. This approach is proving to be a valuable adjunct to traditional resistance testing.

2. Materials and Methods

Trapping

A trapping program is under way around two large storage depots in southeast Queensland, Australia, hereafter referred to as Depot 1 and Depot 2, respectively. The two depots are about 25 km apart. Ten Lindgren four-funnel traps (Contech Inc, Delta, BC, Canada) were set up at each site, 50-100 m from the silos and sheds. Each trap is baited with an aggregation pheromone lure for *R. dominica* (Trécé Inc, Adair, OK, USA) and lures for two other species not covered here. A small

amount of propylene glycol in the trap collection containers serves as a preservative. A sub-set of trapped *R. dominica* is used for molecular screening (see below).

Genomic DNA extraction

Genomic DNA (gDNA) was extracted from individual insects using a modified Hotshot DNA extraction method described by Montero-Pau et al. (2008). Individual insects were placed in 96 well PCR plates and single insect was lysed in 75 µL Alkaline lysis buffer (25 mM NaOH and 0.2 mM EDTA) (pH = 12) at 95°C for 30 min, cooled down at 4°C for 10 min; then solution was neutralized by 75 µL of 40 mM Tris–HCl (pH = 5). Samples were centrifuged and the supernatant gDNA from individual insects were stored at -20°C. Susceptible (QRD14) and resistant (QRD569) laboratory strains were also included in each 96 well PCR plate in gDNA extraction for resistance marker visualisation and valid interpretation.

Resistance marker visualisation

The *rph2* marker used a previously designed QRD569_*rph2* PCR marker, which visualises a K142E substitution in dihydrolipoamide dehydrogenase (DLD) first observed in the strongly resistant laboratory strain QRD569, originally collected from Millmerran, Queensland (Schlipalius et al., 2002; Kaur et al., 2013). The PCR amplification was performed using a Terra™ PCR polymerase kit (Clontech Laboratories, Inc.) in a reaction volume of 50 µL containing 25 µL of 2×Terra™ PCR buffer, 1.5 µL of 10 µM forward (5_-CGTGACTTCCGATCCAGT-3_) and reverse (5_-ACACAGTGGTGAATTAGCGG-3_) primers, 1.0 µL of Terra™ PCR polymerase and 4.0 µL of gDNA stock. PCR conditions were: denaturation for 2min at 98°C, followed by 35 cycles of 98°C for 10 s, 60°C for 15 s and 68°C for 1 min and a final extension at 68°C for 1 min. Amplified 327 bp product was digested with 1 U of *Hpy*188III at 37°C for 2 h in a reaction volume of 10 µL containing 5 µL of PCR product, 1.5 µL of 10× buffer and 0.15 µL of 100× BSA. Digested product was visualised in 2% agarose gel electrophoresis. The susceptible allele in the PCR product showed two fragments, 135 bp and 192 bp fragments after digestion with *Hpy*188III, while the resistant allele showed no cleavage.

Total number of susceptible and resistant alleles in *R. dominica* populations from Depots 1 and 2 were scored and allelic frequency was calculated.

3. Results and Discussion

As an example, the trapping and screening results for *R. dominica* trapped between January and February 2018 are shown in Tab. 1. Pheromone trapping is proving to be an effective means of obtaining *R. dominica* adults for molecular screening in southern Queensland. This is expected based on similar trapping studies in Queensland using the same types of trap and pheromone lure (Ridley et al., 2016; Daglish et al., 2017). The number of beetles caught varied greatly between traps (8-34 at Depot 1 and 2-241 at Depot 2), showing that multiple traps should be deployed at sites to ensure sufficient beetles are available for screening and analysis. The trapping reported here occurred during summer so it is possible that trapping during colder months would yield fewer beetles (Ridley et al., 2016; Daglish et al., 2017). Lindgren funnel traps baited with aggregation pheromone lures have also been effective at trapping *R. dominica* in the USA (Edde et al, 2006; Mahroof et al., 2010) showing the potential for using trapping in other countries to obtain beetles for molecular screening.

Screening of *R. dominica* for the QRD569_*rph2* marker confirmed the presence of this resistance allele in beetles caught between January and February 2018 (Tab. 1). Despite being only 25 k apart there were large differences between the two depots. Allele frequency at Depots 1 and 2 were 6.0 and 13.4%, respectively. In comparison, Kaur et al. (2013) reported QRD569_*rph2* allele frequencies of 3-26% in populations of *R. dominica* collected from grain on farms in southern Queensland in

2011. Most of the beetles that were carrying the QRD569_*rph2* allele were heterozygotes, and it is unlikely that these would have been detected in phenotype tests because of the semi-recessive nature of phosphine resistance. Our screening results provide no information on resistance *per se*, but they do provide information on the frequency of one of the two alleles required for expression of strong resistance to phosphine. Changes in the frequency of resistance alleles shown through regular or periodic trapping and screening are likely to be correlated with changes in phenotypic resistance frequencies.

Beetles from a reference susceptible and strongly phosphine resistant strains were screened for the QRD569_*rph2* allele as well. DNA was extracted from 12 susceptible beetles and 12 strongly resistant beetles. PCR amplification was successful in all reference beetles. All susceptible beetles were homozygous susceptible for this allele while all resistant beetles were homozygous resistant for this allele, providing confidence in the screening. Although PCR amplification was successful in the reference beetles, this was not the case with many of the trapped beetles (Tab. 1). This shows the need to optimise methods to ensure that every trapped beetle can be genotyped.

Our results show that trapping with aggregation pheromone lures, followed by molecular screening for resistance alleles is providing information on resistance gene frequencies, and is proving to be a valuable adjunct to traditional resistance testing in Australia. The beetles caught in the traps could have been beetles flying away from the depots, beetles flying towards the depots, or a combination of both types of beetles. Thus, trapped beetles cannot be directly attributed to a storage site, unlike beetles collected by sampling directly from infested grain. Nevertheless, screening of trapped beetles can provide valuable information on background frequencies of resistance alleles. There are multiple resistance allele variants (Schlipalius et al., 2012), and the current results are for only one of these. The capacity to screen beetles for more of these variants would increase the information value of this approach.

Tab. 1 Screening for *rph2* phosphine resistance allele in *Rhyzopertha dominica* caught in southeast Queensland using traps baited with aggregation pheromone lures.

In this study, the status and prevalence of phosphine resistance in *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae) populations collected from Mersin and Konya Province in Turkey were investigated by conducting the discrimination concentration tests and the concentration–mortality bioassays. Discriminating concentration tests showed that 89.9 and 83.3 % populations of tested total *S. oryzae* populations collected from Mersin and Konya province respectively were resistance to phosphine, which reveals high prevalence of phosphine resistance in the insect sampling locations of both provinces. Moreover, discrimination low concentration (0.04 mg/l) tests indicated that 62.5 and 33.3% of total *S. oryzae* populations collected from Mersin and Konya province respectively had 90% or above survival rate, which showed that the frequency of high phosphine resistance in *S. oryzae* populations collected from Mersin province was higher than that in *S. oryzae* populations collected from Konya province. The concentration–mortality bioassays indicated that there were significant differences in resistance levels of *S. oryzae* populations collected from different provinces. Based on the resistance factors (RF) calculated by LC_{50} values *S. oryzae* populations from Mersin and Konya province were 102- to 104-fold and 38- and 81-fold resistance to phosphine compared with susceptible *S. oryzae* population, respectively. The highest level of phosphine resistance was determined in *S. oryzae* populations from Mersin province, followed by those from Konya provinces, respectively. These results indicated that *S. oryzae* populations from Mersin province had higher phosphine resistance than those from Konya Province. In conclusion, this study showed that high levels of phosphine resistance in *S. oryzae* populations collected from different grain storages in Mersin and Konya province of Turkey were prevalent.

Key Words: Phosphine resistance, *Sitophilus oryzae*, populations, discrimination concentration, Turkey

Introduction

Total global grain production is around 2.569 billion tons in 2015-2016 (FAO 2016). Turkey's total grain production is nearly 33.2 million tons in 2015-2016 (FAO 2016), presenting 1.29% of total global grain production. During storage, grains are attacked by a numerous pests, particularly insect species, which cause very serious quantitative losses and qualitative degradations. Pest control in any storage system depends on fumigation with either methyl bromide or phosphine. Phosphine is the primary fumigant used to protect the majority of grain and a variety of other stored commodities from insect pests (Chaudhry 2000; Wang et al. 2006). Attributes that contribute to wide- spread use of phosphine are that it is relatively inexpensive, easy to apply, leaves minimal residues and can be used in a wide range of storage types and commodities (Nayak and Collins 2008).

The lack of ideal airtight conditions for fumigation in leaky structures increases the frequency of control failures and thus increases the frequency of phosphine fumigation (Pacheco et al. 1990; Chaudhry 2000; Benhalima et al. 2004; Lorini et al. 2007). Phosphine fumigation is a long established effective method to control stored product insects, but its continuous and discriminate use has resulted in the evolution of resistant populations (Chaudhry 2000; Collins et al. 2005; Lorini et al. 2007; Pimentel et al. 2007). Repeated application of phosphine in poorly sealed warehouse resulting in under closing have been cited as the cause of the development of strong resistance (Friendship et al. 1986; Zeng 1999). Strong phosphine resistance in all key species of stored grains has been reported in a number of countries (Lorini et al. 2007; Pimentel et al. 2010; Opit et al. 2012; Daglish et al. 2014). The resistance of stored grain insect pests to phosphine was reported following a worldwide survey carried out by the Food and Agriculture Organization (FAO) of the United Nations in 1972-73 (Champ and Dyte, 1976) which detected resistance in 33 out of the 82 countries they surveyed involving 82 of the 849 population tested.

Strong resistance to phosphine was first recorded in *S. oryzae* in China in a 1995–1997 survey (Zeng 1999). In this survey, a resistance level 337 times that of a fully susceptible strain was observed. The resistance level of this species in India was reported in 1998 to have increased to 425 times that of a susceptible reference strain (Rajendran 1999). Weakly resistant *S. oryzae* is found at a high frequency in most regions of Australia, with strong resistance occurring sporadically in field collected strains (Emery et al. 2003). To date, there is only one study on the status of phosphine resistance in stored grain insect pests in Turkey, published by Koçak et al. (2015). In this study, four Turkish population of *T. castaneum* were tested through bioassays for determining phosphine resistance phenotypes and all population exhibited high level of phosphine resistance. There is very limited information on the status of PH_3 resistance in stored grain insect pests in Turkey. The objective of present study to determine resistance frequencies and the levels of phosphine resistance in *S. oryzae* adults collected from grain storage facilities in South and South-eastern region of Turkey.

Material and Methods

Test insects and insect collection

Sitophilus oryzae adults collected from two provinces of Turkey were used in the bioassays and were cultured in the laboratory on whole wheat at 26 ± 1ºC and 65 ± 5 % relative humidity (RH). Insect populations were taken in Mersin and Konya provinces of Turkey, which are located in Central Anatolian and South-eastern regions. For Mersin and Konya province, 18 and 6 *S. oryzae* populations were collected respectively. Wheat grains were taken in bulk with a spiral grain probe from ten different wheat storages per each province. Cylindrical plastic probe traps (STORGARD WB Probe II trap, TREECE, USA) were also used to detect adult stage of *S. oryzae* in bulk stored-grain. From June, 2016 up to November 2016, the probe traps were checked for adult beetles every month.

Phosphine fumigation procedures

One hundred fifty ml fumigation glass vials with the insects and 40 gr wheat, which are closed with aluminum cap with septa by using the crimper. Phosphine gas cylindrical tube (volume; %1 PH_3 + % 99 N_2 and latex rubber ball for gas sampling. Collecting phosphine gas from gas sampling ball by the syringe. Injection of phosphine gas into the fumigation glass vials for dosing. A GC with FPD detector for measuring phosphine concentration. Taking phosphine gas concentration in each vial and injection to GC sampling port. Fumigation jars held for 20 hours at 25 ± 1°C. Insects held for 14 d at 25 ± 1°C and 65 ± 5% RH

Phosphine resistance tests

Discrimination concentration tests

Discrimination concentration tests was used to determine whether the samples had detectable resistance and the frequency of resistance (presence of resistance) by FAO Protocol #16 FAO Protocol: *S. oryzae* adults exposed to low discrimination dose (0.04 mg/l-29 pm) phosphine for 20 h, at 25°C and 65% RH. Mortality determined after 2 wk. In order to classification resistance population weak or strong, high discrimination dose (0.20 mg/l-1436 ppm) for 20 h by method of modification of Daglish and Collins (1998) (Table 1). Mortality determined after 2 weeks. FAO Protocol recommends 3 replications for each treatment and each replicate 40 mixed sex adults.

Table 1. Interpretation of discrimination concentration test results

Low dose 0.04 mg/l*	High dose 0.20 mg/l**	Resistance classification
No survivors	No survivors	Susceptible
Survivors	No survivors	Weak resistance
Survivors	Survivors	Strong resistance

*FAO (1975) **Modification of Daglish and Collins(1998)

Concentration-mortality tests

In order to determine the levels of phosphine resistance in *S. oryzae* adults collected from grain storage facilities in Mersin and Konya provinces of Turkey, two populations for each province, which had the highest resistance frequency and one of phosphine-susceptible population were used for concentration-mortality tests. For concentration-mortality tests, each selected population was exposed to at least 6 to 8 different concentrations of phosphine for 20 h at 25°C and 65% RH. Mortality assessments were conducted at 14 day after phosphine fumigation. Bioassay procedures were similar to discrimination concentration tests.

Data processing and analysis

In all biological tests, numbers of dead and live insect obtained on the 14th day after the fumigations were counted and the survival rates were calculated. Analysis of variance (ANOVA) was used to analyze percentage survival data after arcsine transformation to normalize the data. Percentage survival was also adjusted for natural survival in controls using Abbott formula before analysis and was then analyzed using two-way analysis of variance (factors; application concentration and insect population). Differences between the means were determined using the Duncan's Multiple Range Test at the 5% significance level. In order to calculate the lethal concentration values (LC_{50} and LC_{99}) of the phosphine-resistant *S. oryzae* populations, the concentration-mortality data obtained were subjected to probit analysis using the POLO-PC (LeOra Software, 1994) program. The resistance factor (RF_{50}) for each phosphine-resistant population was obtained by dividing the LC_{50} value estimated for each insect population by the LC_{50} value of the phosphine susceptible population.

Results and Discussion

Discriminating concentration tests showed that 89.9 and 83.3 % populations of tested total *S. oryzae* populations collected from Mersin and Konya province respectively were resistance to phosphine, which reveals high prevalence of phosphine resistance in the insect sampling locations of both provinces. Moreover, discrimination low concentration (0.04 mg/l) tests indicated that 62.5 and 33.3% of total *S. oryzae* populations collected from Mersin and Konya province respectively had 90% or above survival rate, which showed that the frequency of high phosphine resistance in *S. oryzae* populations collected from Mersin province was higher than that in *S. oryzae* populations collected from Konya province.

The concentration–mortality bioassays indicated that there were significant differences in resistance levels of *S. oryzae* populations collected from different provinces. Based on the resistance factors (RF) calculated by LC_{50} values *S. oryzae* populations from Mersin and Konya province were 102- to 104-fold and 38- and 81-fold resistance to phosphine compared with susceptible *S. oryzae* population, respectively. The highest level of phosphine resistance was determined in *S. oryzae* populations from Mersin province, followed by those from Konya provinces, respectively. These results indicated that *S. oryzae* populations from Mersin province had higher phosphine resistance than those from Konya Province.

Conclusion

This study showed that high levels of phosphine resistance in *S. oryzae* populations collected from different grain storages in Mersin and Konya province of Turkey were prevalent.

Abstract

Populations of rusty grain beetle, *Cryptolestes ferrugineus*, have developed a very high level of resistance (1300×) to the fumigant phosphine (PH_3) in Australia. Resistant insects triggered control failures, threatening the country's annual grain market worth AU$8 billion. Although PH_3 protocols were amended to manage this new resistance, fumigation requires lengthy exposure periods which has practical difficulties. While there is no suitable replacement for PH_3, the current study explores potential approaches to enhance the efficacy of this fumigant. One possibility is co-fumigation of PH_3 with another complementary fumigant, sulfuryl fluoride (SO_2F_2 or SF), with the dual goals: enhanced efficacy and minimise use of both fumigants. A cohort of mixed age eggs and adults of PH_3-resistant *C. ferrugineus* was fumigated with PH_3 and SF individually, as well as in combination inside desiccators at 25°C and 60%RH for 168 h. Two doses below the maximal registered rates for SF (8.9 mg L^{-1}, equivalent to 1500 g hm^{-3}) and PH_3 (1.0 mg L^{-1}) were tested. Co-fumigation was performed simultaneously for 168 h. Our results revealed that, the mixture of 1.1 mg L^{-1} or 2.2 mg L^{-1} of SF and 0.5 mg L^{-1} of PH_3 over 168 h achieved complete control against resistant *C. ferrugineus* eggs and adults, whereas each of the tested doses failed individually. Our study confirms that SF and PH_3 enhance the efficacy of each other when used in combination, which holds great potential for managing resistant *C. ferrugineus*.

Key words: stored grain, phosphine resistance, sulfuryl fluoride, co-fumigants, resistance management

1. Introduction

Phosphine (PH_3), an effective fumigant is commonly used to disinfest stored grains and processed products from insect pests. However genetic resistance to this fumigant in insect pests is widespread and increasing (Schlipalius et al., 2012). For example, in Australia, populations of rusty grain beetles, *Cryptolestes ferrugineus* (Stephens), have developed a high level of resistance (1300×) to PH_3 and resistant insects require high concentrations (1 mg L^{-1}) and long exposure periods up to 14 days (Nayak et al., 2013). Thus, resistant insects of this species are a threat to grain industry as live insects of this species can jeopardy the country's access to international grain export markets worth of AU$ 8 billion annually. Although, new PH_3 protocols were developed (Kaur and Nayak, 2015) with higher PH_3 rates, there is an urgent need to find alternative pest control strategies that can enhance the efficacy of PH_3, specifically to shorten the fumigation period. One of such approaches is co-

fumigating PH_3 with another fumigant. Sulfuryl fluoride (SO_2F_2 or SF) is an ideal choice for co-fumigation as it exhibits complementary properties to PH_3.

Like PH_3, SF is a broad spectrum fumigant, that is currently being used as an alternative to PH_3, specifically to eliminate PH_3-resistant insects (Nayak et al., 2016). However, SF is a greenhouse gas (Tsai, 2010) and leaves fluoride residues on the treated materials (Sriranjini and Rajendran, 2008). It is also relatively expensive compared to PH_3. Therefore industry is receptive to strategies to minimise use of this fumigant on commodities. In this context, co-fumigation of PH_3 with SF would be of considerable interest for the grain industry as this approach aims to use low dose rates of both the fumigants over relatively short exposure periods. Such an approach may help industry not only to overcome PH_3-resistant insects but also minimise the usage of SF on treated commodities. Additional benefits from this approach may include, shorter fumigation periods, less treatment cost, and reduced selection pressure in insects to both fumigants.

Preliminary research on the efficacy of the PH_3 + SF mixture have indicated that both the fumigants at reasonably low concentrations, have enhanced the efficacy of each other (Misumi et al., 2010; Naito et al., 2006) against grain pests, including PH_3-resistant phenotypes (Jagadeesan et al., 2016b). However, these studies were conducted over short exposure periods (16-48 h) aiming to reveal the type of toxicity relationship between PH_3 and SF in the mixture and so no prior information is available in relation to developing co-fumigation protocols. Thus the present study was conducted to assess the efficacy of co-fumigation of PH_3 with SF against eggs and adults of PH_3-resistant *C. ferrugineus*. We have evaluated concentrations similar to field application rates in both the fumigants, over an exposure period of 168 h (7 days), towards developing a joint fumigation protocol, as a part of integrated pest and resistance management strategy.

2. Materials and Methods

2.1 Insect strain and life stages

A PH_3-resistant strain, QCF122 collected from Edgeroi, south east Queensland, was used in this study (Nayak et al., 2013). A cohort of 100 adult beetles of mixed age and sex, were released into 100 ml glass jar containing 50g of recommended dietary media (barley flour + 5% yeast) (Jagadeesan et al., 2016a) and allowed to lay eggs in the media for 3 days. Thereafter, the experimental jars containing parental adults and 0-3 day old eggs along with the dietary media were fumigated with selected PH_3, SF and the PH_3 + SF concentrations (Tab 1).

2.2 Fumigation bioassay

For both SF and PH_3, the derivation of the source gas, initial concentration measurement using gas chromatograph, and estimating the required volume of gas for achieving desired concentrations within the air-tight desiccators for bioassays were explained in detail previously (Jagadeesan and Nayak, 2017). The experimental jars containing eggs and adults were placed inside the desiccators and fumigated using gas-tight syringes. Two concentrations for each fumigant were selected based on their field application rates. This includes, 0.5 and 1.0 mg L^{-1} for PH_3, and 1.1 mg L^{-1} (187.5 g hm^{-3}) and 2.2 mg L^{-1} (375 g hm^{-3}) for SF. These concentrations were tested individually and in combinations as per the treatment structure explained in Table 1. The fumigation for individual treatments (PH_3 alone or SF alone), was performed independently over 168 h at 25°C and 60% RH, whereas co-fumigation by injecting required volume of PH_3 and SF into the air-tight desiccators simultaneously (at the same time) and the fumigation continued for 168 h. After the fumigations, the treated jars were aerated and shifted to controlled environment room for recovery at 25°C and 60% RH. The entire experiment was replicated twice and each treatment contained two technical replicates. The mortality of adults was recorded 48 h after the fumigation bioassay, whereas for eggs, mortality was recorded after 6 weeks by estimating per cent reduction in the emergence of F_1 adults in treated jars in comparison to the control.

3. Results and Discussion

As anticipated both of the tested concentrations of PH_3 failed individually to achieve complete control against eggs and adults of PH_3-resistant *C. ferrugineus* over 168 h at 25°C. A significant proportion of eggs (57 and 84.6%) and adults (2 and 47.6%) survived at 0.5 and 1 mg L^{-1} PH_3, respectively (Table. 1). In the case SF, although complete mortality in adults was achieved at both the selected doses (1.1 and 2.2 mg L^{-1}) individually, substantial proportion of eggs survived at these concentrations. For example, the egg mortalities were 83.6 and 98.8%, for 1.1 mg L^{-1} and 2.2 mg L^{-1}, respectively, confirming that these concentrations of SF failed to achieve complete control, individually (Table 1). Comparison of our results across SF alone and PH_3 alone treatments, clearly indicates that SF is effective against PH_3-resistant insect pests irrespective of the insect life stages and re-affirm our recent conclusion that PH_3 resistance does not confer cross resistance to SF in PH_3-resistant grain insect pests, including *C. ferrugineus* (Jagadeesan and Nayak, 2017).

Table. 1 Efficacy of co-fumigation of phosphine (PH_3) with sulfuryl fluoride (SF) against eggs and adults of rusty grain beetle, *Cryptolestes ferrugineus* at 25°C and 60% RH over 168 h (7 days)

Individual treatments (168 h)			**Mortality (mean ± SD) (%)**	
PH_3 alone (mg L^{-1})			Adults	Eggs
0.5			2.0 ± 1.3	57.0 ± 9.3
1.0			47.6 ± 13.3	84.6 ± 15.7
Control			0.0 ± 0.0	0.0 ± 0.0
SF alone (mg L^{-1})			Adults	Eggs
1.1			100 ± 0.0	83.6 ± 5.5
2.2			100 ± 0.0	98.8 ± 0.07
Control			0.0 ± 0.0	0.0 ± 0.0
Simultaneous co-fumigation (168 h)			**Mortality (mean ± SD) (%)**	
PH_3 (mg L^{-1})	+	SF (mg L^{-1})	Adults	Eggs
0.5	+	1.1	100 ± 0.0	98.9 ± 0.15
0.5	+	2.2	100 ± 0.0	100 ± 0.0
1.0	+	1.1	100 ± 0.0	100 ± 0.0
1.0	+	2.2	100 ± 0.0	100 ± 0.0
Control	+	Control	0.0 ± 0.0	0.0 ± 0.0

Examination of combination treatments, clearly showed that co-fumigation of PH_3 at 0.5 mg L^{-1} along with 2.2 mg L^{-1} of SF over 168 h was sufficient to achieve complete control against eggs and adults of strongly PH_3-resistant *C. ferrugineus* (Table 1). This is an important finding indicating that PH_3-resistant insects can effectively be managed by adopting a combination regime containing half of the maximal registered rate of phosphine with one fourth of maximal registered rate of SF over a standard exposure period of 7 days at 25°C. Similar enhancement in toxicity of the PH_3 + SF mixture was also observed against different life stages of maize weevil *Sitophilus zeamais* (Motschulsky) (Misumi et al., 2010; Naito et al., 2006) and granary weevil, *S. granarius* (L.) (Naito et al., 2006) over 48 hr at 15˚C, supporting the results of the present study. Currently, we are testing series of PH_3 and SF co-fumigation regimes, including the effective regime identified in this study on sequential pattern. In this, co-fumigation was achieved in two separate fumigations with SF first for 78 h followed by PH_3 for 78 h with a break period of 12 h for aeration. Preliminary results of this experiment suggest that both simultaneous and sequential co-fumigations are equally effective in enhancing the efficacy of PH_3 and SF. Overall, our study has confirmed that co-fumigation of PH_3 with SF, either simultaneously or sequentially enhances the efficacy of each other, and holds great potentials for managing PH_3-resistant grain insect pests.

Abstract

Present investigation was carried out to elucidate the extracts of botanicals i.e., *Cichorium intybus, Glycyrrhiza glabra, Trachyspermum ammi* and *Terminalia chebula*, for their possible toxic effect against *C. chinensis* population. The results revealed that mortality was highest (94.649%) in case of *T. ammi* treatment, followed by *T. chebula* with mortality value 56.929%. Mortality was 52.363% where application of *C. intybus* was carried out. Minimum mortality (34.500%) was observed in *G. glabra* treated grains. A natural ecto-parasitoid, *Anisopteromalus calandrae* was used to manage *C. chinensis* population. *A. calandrae* male and female adults (5, 10 and 15 pairs) were released to analyze the parasitism efficiency. *A. calandrae* was reared in the laboratory on *C. chinensis* larvae. Honey was offered as a suitable food to parasitoid. The parasitism data was recorded after the adult emergence of brunchid beetles. The experiment conducted under Completely Randomized Design and results statistically evaluated using statistical software at 5% level of significance. *A. calandrae* parasitized both larval and pupal stages of *C. chinensis* and preferred 4th instar larvae of *C. chinensis*. Large amount of *A. calandrae* may efficiently control the *C. chinensis* population. As compared to control (1558.7 host adult), the minimum host emergence (699.00 host adult) was observed with high population density of *A. calandrae*. It was also

obvious from the results, that mortality was increased with the increase in concentration so, a direct dose-mortality response was observed.

Key words: Callosobruchus chinensis, Plant Extracts, Anisopteromalus calandrae, Mortality,

1. Introduction

Mungbean is highly infested by particularly three species included *Callososbruchus chinensis* (L.), *C. maculatus* (F.) and *C. analis* (F.); caused significant losses during storage (Angus, 2010). *C. chinensis* is a well known insect pest of stored mung bean, chickpea and other pulses. Use of synthetic pesticides is the main method to control the insect pest due to their high cost, environmental pollution and development of resistance in insects, alternative approaches have been developed to manage insect pest problems. To control the insects in this sense, essential oils are the best alternative (Perez *et al*., 2010).

Trachyspermum ammi is traditionally widespread used medicinal plant to treat various illnesses. The essential oil of this plant has antimicrobial activity (Kaur and Arora, 2009). Due to the insecticidal activities of *T. ammi*, its essential oil has been used against *C. chinensis* (Chaubey, 2011). *Glycyrrhiza glabra* has antifungal and antimicrobial efficiency. It has small cellular toxicity, anti-tumor and anti-virus (Wang *et al*., 2003). *Terminalia chebula* has antibacterial and anti-pathogenic potential (Malekzadeh *et al.,* 2001). The roots of *Saussurea lappa* have distinct antimicrobial and anti-inflammatory potential and used as a traditional drug for the treatment of several ailments (Pandey *et al*., 2006). *Cichorium intybus* is a popular folk medicinal plant used in curing the urinary tract inflammation, gallstones and liver disorders. It helps in maintaining healthy gastrointestinal tract and metabolism (Roberfroid and Slavin, 2000).

Anisopteromalus calandrae has a wide host range including *Sitophilus granarius* (Ghani, and Sweetman, 1955)*, Sitophilus oryzae* (Lucas and Riudavets, 2002), *Lasioderma serricorne* (Ahmed and Khatun, 1988) and *Rhyzopertha dominica* (Menon *et al.,* 2002). *Anisopteromalus calandrae* gave effective control for *C. maculatus* in Cameroon. It was used as an adult parasitoid and gave efficient results (Ngamo *et al.,* 2007). *Anisopteromalus calandre* ecological and biological investigation were made under laboratory condition and showed that it preferred 4th larval instars over pupa and then 2nd instars for parasitism (Kazemi *et al*., 2004).

In the light of above discussion the present study was carried out with the objective to develop environmentally friendly IPM, to check the biological activity of some plants including *Trachyspermum ammi, Glycyrrbiza glabra, Terminalia chebula* and *Cichorium intybus* and to evaluate the efficiency of an ectoparasitoid *A. calandre* to manage *C. chinensis* populations.

2. Materials and Methods

Collection and Rearing of Insects

Callosbruchus chinensis population was collected from grain market in Faisalabad. Insect population was reared on mung bean in sterilized jars which kept in the incubator at temperature 30±2ºC, 70±5% relative humidity and 12:12 L:D photoperiod to get the homogeneous population. Thirty insects were released in each jar which contains 500 g of mung bean. The jars were covered with muslin cloth so that to avoid insects escape. After five days adults were separated from the mung bean and the grains containing eggs were kept again in the incubator to get another generation. The grains containing adults were also kept in the jar to get homogenous population.

Preparation of Plant Extracts

Plant materials including *Trachyspermum ammi* (Ajowin), *Terminalia chebula* (Hararr), *Glycyrrhiza glabra* (Mulathi) and *Cichorium intybus* (Kasni) were purchased from a medicinal plant shop, Faisalabad. The material was cleaned to avoid contamination. The materials were grinded to get powder. The extraction of plant extracts was accomplished using rotary shaker by dipping 50 grams

of powder in 250 ml acetone. The extracts which were obtained were placed in clean bottles and stored in refrigerator.

Mortality Bioassay

The experiment was carried out in 60 small jars. Different concentrations of plant extracts were applied on the inner side of jar and allowed to get dry. Twenty adults of test insects were released in each jar and then the jars were covered with muslin cloth. Mortality of the adults was recorded three times after equal intervals of 24 hours.

Parasitism Bioassay

Anisopteromalus calandrae was reared on the adults and pupae of *C. chinensis*. The trial contained 36 jars with 20 g of mungbean grain. Thirty adult females of *C. chinensis* were released in each jar for egg laying. After one week the adults were removed and the eggs were placed in jars with grains till emergence. With the start of emergence, the parasitoids were introduced on cowpeas infested by *C. chinensis*. This allowed the synchronisation of the life cycles of the parasitoid and its host. The jars were placed in an incubator and the adult emergence of *C. chinensis* was checked after 27-42 days to record the parasitism data.

Statistical analysis

After the completion of the experiment the recorded data was analyzed using statistical software and the corrected mortality was measured using Abbott's formula. The data was analyzed using Completely Randomized Design and suitable statistic software.

3. Results

Effect of plant extracts against adult mortality of *Callosobruchus chinensis*

Results showed that impact of plants and duration of insects to plant extracts has a highly significant effect on mortality of *C. chinensis*. Interaction of plants and time and interaction of plants and concentrations also have significant impact on mortality. But concentrations, interaction of time and concentrations and interaction of plants, time and concentrations have no significant impact on mortality of test insect. Figure 1 shows the mean comparison of percent mortality of *C. chinensis* of various plant extracts. The results showed that maximum mortality (93.65%) was recorded of *T. ammi* extract and it was statistically different to *C. intybus, T. chebula* and *G. glabra* with percent mortality of 64.67, 63.67 and 44.42% was observed respectively. The results regarding mean comparison of percent mortality of *C. chinensis* at various time exposures revealed that maximum mortality (80.20 %) was recorded after 72 hours and it was statistically different to 48 and 24 hours with percent mortality of 69. 63 and 49.98% was observed respectively (Figure 2). Mean comparison of percent mortality of *C. chinensis* at various time exposures of plant extracts is given in Figure 3. The results showed that maximum mortality (69.33%) was observed at 5% concentration. It was statistically similar to 15 and 10% concentrations, where mortality was 65.46 and 65.01%, respectively.

The results regarding mean comparison of percent mortality of adults of *C. chinensis* of plant extracts and various time periods showed that the effect of interactions of plant extracts and various time exposures was significant (Figure 4). Similarly, the results in Figure 5 show that the effect of interactions of plant extracts and various concentrations was significant.

Maximum mortality (97.62%) was observed with *T. ammi* after 72 hours while minimum mortality (26.16%) was observed with *G. glabra* after 24 hours of exposure. In the interactions of plant extracts and concentrations, maximum mortality (98.21%) was observed with *T. ammi* at higher (15%) concentrations and minimum mortality (39.85%) was observed with *G. glabra* at 10% concentrations. With the interaction of exposure time and concentrations the maximum mortality

(83.92%) was recorded after 72 hours at 5% concentration. In plant, exposure time and concentrations interaction the maximum mortality was observed with *T. ammi* after 72 hours at 15% concentrations and minimum mortality (23.19%) with *G. glabra* after 24 hours at 15% concentration.

Effect of Anisopteromalus calandrae on parasitism (%) of Callosobruchus chinensis

With respect to biological control, the response of *A. calandrae* was also observed. *A. calandrae* was released in three different treatments with 5, 10 and 15 pairs of the parasitoids on *C. chinensis*, and observations were made after 15 and 45 days.

After 15 days of Host Emergence

Results showed that impact of treatments of host insects to parasitoid has a significant effect on adult emergence of *C. chinensis*. Results in Table 1 show the mean comparison of adult emergence of *C. chinensis* in the presence of parasitoid. The finding revealed that the effect of parasitoid on adult emergence differed significantly. Minimum percent adult emergence (699.00) was observed with the release of fifteen pairs of parasitoid and it was statistically different from the other treatments. Maximum of percent adult emergence (1558.7) was observed in control. The trend of adult emergence in respect of parasitoid was mentioned in order to Fifteen pairs < Ten pairs < five pairs < Control.

After 45 days of Host Emergence

Results regarding after 45 days of host emergence revealed that the effect of parasitoid on adult emergence differed significantly among treatments (Table 1). Minimum percent adult emergence (17536.00) was observed with the release of fifteen pairs of parasitoid and it was statistically different from others. Maximum of adult emergence (36754) was observed in control. The trend of adult emergence in respect of parasitoid was mentioned in order to Fifteen pairs < Ten pairs < five pairs < Control.

Tab. 1 Comparative effect of different treatments on parasitism (%) of adults of *C. chinensis* after 15 and 45 days of host emergence

Treatment	Parasitism (%) After 15 days	Parasitism (%) After 45 days
Control	1558.7 a	36754 a
5 pairs	1132.0 b	31893 b
10pairs	961.7 c	24165 c
15 pairs	699.0 d	17536 d

Discussion

Overall results revealed that maximum percent mortality 93.65% of adults of *C. chinensis* was recorded with *T. ammi* and minimum 44.42% was observed with *G. glabra.* These results are in line with the findings of Pereira *et al.* (2008) who reported that the oils of *Piper aduncum*, *Lippia grcillis* and *Cymbopogon martinii* gave 100% mortality against *Callosobruchus maculatus*. Moreover, similar results of several plant extracts have been observed by Shimizu and Hori (2009) against *Callosobruchus maculatus*, while other studies show good efficacy of certain plant extracts for the control of *Callosobruchus* spp. (Roberfroid and Slavin, 2000; Wang *et al.*, 2003; Pandey *et al*., 2007).

Results regarding parasitism effect showed that after 15 days of host emergence, minimum adult emergence (699.00) was observed with fifteen pairs of parasitoid and maximum adult emergence (1558.7) was observed in control. At the same time, after 45 days of host emergence, minimum adult emergence (17536) was observed with fifteen pairs of parasitoid and maximum adult emergence (36754) was observed in control. However, from these results it was concluded that maximum parasitism was achieved at highest number of pairs of *A. calandrae* and after highest time interval (45 days) while at lower number of pairs and time interval test insect percent mortality was not sufficient. Our findings are also related to Utida (1943) who conducted as series of experiments with the same host-parasitoid complex, and found that the species can coexist for 50 generations. He described that *A. calandrae* showed functional response of type III. Our results are also in accordance with the findings of Ngamo *et al.* (2007) who reported a significant reduction in progeny emergence of *C. chinensis* due to the presence of *A. calandrae.* Previous studies have also provided similar findings of the effect of *A. calandrae* against *Rhyzopertha dominica*, *Sitophilus oryzae*, *Lasioderma serricorne* and *Tribolium confusum* (Mahal *et al.*, 2005, Ghrimire and Phillips, 2007, Belda and Riudavets, 2010).

From these results it is concluded that the use of plant extracts and bio-control agents could be a better alternative to our conventional synthetic insecticides and could be an integral part of stored grain IPM programs.

Abstract

Insects, either adults or larvae, living inside grains are difficlut to detect but can cause enormous loss of grain. Therefore, we explored the use of low-field nuclear magnetic resonance (LF-NMR) techniques to detect *Sitophilus oryzae* hidden inside wheat. Significant difference in transverse relaxation times (T_2/ms) and the T_2 components proportion (P_2/%) was observed between wheat and *S. oryzae* at its four different growth stages (small larvae, large larve stage, pupal stage and adult stage). The transverse relaxation signals on the infested

wheat kernels varied with *S. oryzae* developmental stages. LF-NMR image of uninfested wheat were very different than infested wheat with the hidden insects at its four growth stages. Therefore, LF-NMR, as a novel non-destructive method, could be used to detect insects hidden in grains to take necessary management against pest damage to grains during storage.

Keywords Rice weevil (*Sitophilus oryzae*); Grain storage; Transverse relaxation signal; Infested wheat; Low field magnetic resonance imaging

1. Introduction

Insect infestation in stored grain is a worldwide problem. Insect pest infestations in grain are responsible for qualitative and quantitative losses of 5 - 10% grain losses in developed countries and 30 - 40% in some developing countries(Brader et al., 2002; Kumar and Kalita, 2017) ENREF_1. Insect detection is a prerequisite of Integrated Pest Management, a process often used to solve pest problems while minimizing risks to people and the environment. Many methods have been developed for the detection and monitoring insect infestations, including visual inspection, sampling & sieving, floating & cracking (Brader et al., 2002), trapping (Hagstrum et al., 1998), bioacoustic methods (Mankin et al., 2011), computer vision (Ridgway et al., 2002), near-infrared hyperspectral imaging (Kaliramesh et al., 2013; Singh et al., 2009), and soft X-rays (Karunakaran et al., 2003). Recently, some new techniques have emerged, such as microwave heating (Jian et al., 2015), zymography (Piasecka-Kwiatkowska et al., 2014), solid phase micro-extraction (Laopongsit et al., 2014), and biophotonic methods(Shi et al., 2016). However, most of these approaches cannot be commercialized due to various issue including throughput limits, unreliability, labour costs, time consuming and safety concerns. The most common used technique are sieving samples or the probe-and-trap methods. It is important to note that exceptions to the probe-and-trap include the United States, where visual images are used in combination with probes, and Canada, where the Berlese funnel method is mandated (Sabu et al., 2011). These time-consuming techniques have low accuracy, which detect adult insects and ignore larvae growing inside the kernels. Primary pests, such as the granary weevil, the rice weevil, the maize weevil, the lesser grain borer, and the Angoumois grain moth, cause most of the damage to grains in storage and transportation. The larvae of the primary insect pests live entirely inside the kernel and are hard to detect. Therefore, a rapid, simple, and accurate method for detecting internally feeding life-stages of insects in grains is highly desired by grain industry and inspection and quarantine branch.

Low-field nuclear magnetic resonance (LF-NMR) is a sensitive and non-destructive technique, and widely used to detect water characteristics in numerous systems (Greiff et al., 2014; Hills, 2006) ENREF_15. Typically it detects ingredients with high numbers of hydrogen protons after the food is processed or stored such as starch (Ritota et al., 2008), salted fish (Carneiro et al., 2016), blanching sweet corn (Shao and Li, 2012, 2013), ripening bananas (Raffo et al., 2005), and drying wheat (Ghosh et al., 2006). The difference in moisture is directly proportional to signal produced, which allows or the NMR to identify regions of higher moisture. Grain is typically stored at 12%-18% moisture, whereas the moisture content of insects about 65% (Shrestha and Baik, 2013), suggesting that NMR technology could be a promising approach to detect insects. The difference in moisture between insects and wheat kernels has been used to detect insects in the grain by electrical conductivity (Pearson and Brabec, 2007; Pearson et al., 2003) ENREF_23 ENREF_23. However, the sample must be milled before determination. It is a destructive method, whereas NMR require no sample destruction. Previously, only two studies using NMR were done on detecting insect infestations in grain (Chambers et al., 1984; Street, 1971). In those experiments, grain weevils (*Sitophilus granarius*) were detected at different stages of development inside of grain kernels by measuring chemical shifts using high-field NMR. Even though the technique showed promising results, research in using NMR for insect detection ceased, due to a lack of scientific expertise and high equipment costs. With the development of economical low-field NMR instrumentation, the use of low-field NMR for quality monitoring has recently become feasible in agri-food sciences. Therefore, we explore here the possibility with low-field proton NMR relaxation signal measurement

and magnetic resonance imaging (MRI) to detect hidden insect at different growth stages within wheat.

2. Material and methods

2.1. Insect sample preparation

Sitophilus oryzae was reared on whole wheat kernels in the National Engineering Laboratory of Grain Storage and Transportation, Nanjing, China. Approximately 500 adult *S. oryzae* were mixed with 1 kg of wheat (about 13.5%, w/w) in a wide-mouth glass bottle covered with a cotton cloth, and were maintained in a growth chamber at 29 ± 1°C and 65 ± 2% relative humidity. After 48 hours, all of the adults were removed from the bottle. *S. oryzae* at 4 different stages (small larvae, large larvae, pupae and adult as shown in Figure 1) were separated and collected from the infested wheat by a knife after 15, 20, 25 and 40 d, respectively. The samples were tested after collecting.

2.2. Infested wheat preparation

Approximately 400 adult *S. oryzae* were mixed with 20 g whole wheat for 48 h for infested wheat kernels. High population density of pests increases the probability of having infested kernels. Wheat kernels with single pest egg were collected under a microscope (Chongqing Guangdian Instrument Corporation Ltd., Chongqing, China). The infested kernels were divided into 2 g per jar, and cultured in a chamber at 29 ± 1°C and 65 ± 2% relative humidity. The samples were tested at 5, 10, 15, 20, 25 and 30 d. Some adults of *S. oryzae*, which emerged from the wheat, were removed before 30 d test.

2.3. Moisture content measurement

The moisture content of wheat kernels was determined using the whole-grain oven drying at 130 °C for 19 h (ASABE, 2009). About 1 g of *S. oryzae* at each growth stage was dried at 70 °C for 48 h to a constant weight, placed in a desiccator for 12 h, and then weighed (Singh and Sinha, 1977). Each sample was done in triplicate.

2.4. LF-NMR measurements

Transverse relaxation measurements were proceeded on NMI20 Benchtop Pulsed NMR Analyzer (Shanghai Niumag Corporation Ltd., Shanghai, China) operating at a resonance frequency for protons of 22.6 MHz. Spin–spin relaxation time (T_2) was measured using the Carr–Purcell–Meiboom–Gill (CPMG) sequence, a common and stable sequence for T_2 measurement (Carr and Purcell, 1954; Meiboom and Gill, 1958). Pests (0.2 g) or infested wheat (2 g) were placed in a 15-mm diameter glass test tube. The T_2 measurements were made with τ value (time between 90 and 180° pulses) of 100 μs. Data from 10,000 echoes were acquired as 32-scan repetitions at 32 °C. The repetition time between subsequent scans was 1.5 s. Relaxation data were calculated by MultiExp Inv Analysis software (Shanghai Niumag Corporation Ltd., Shanghai, China) and the CONTIN algorithm was used for the multi-exponential fitting analysis.

2.5. LF-NMR image measurements

Magnetic resonance imaging was done on NMI20 Benchtop Pulsed NMR Analyzer. For these measurements, the following specifications were used: equipment field of view = 80×80 mm; matrix size = 192×256; echo time = 5.9 ms; repetition time = 160.0 ms, number of scans = 256; and slice width = 10.0 mm. Using these setting, proton density images were measured.

2.6. Statistical analysis

Statistical analyses were done with SPSS software (Version 16.0, Inc., Chicago, IL) and graphical data were generated with Origin Pro 8.5. One-way analysis of variance (ANOVA) followed by Duncan's

multiple comparisons test (at 0.05) was carried out. Values of $p < 0.05$ were considered statistically significant.

3. Results and discussion

3.1. Moisture content of wheat and S. oryzae

Figure 2 shows the moisture content of wheat and *S. oryzae* at four growth stages. From the larval stage to adult stage, the moisture content decreased from 66 to 44%, and moisture content of the wheat kept at about 13.5%. Moisture content of *S. oryzae* at every growth stage was much higher than that of the wheat kernel. In storage, insects can obtain water through three ways, consuming food, absorbing from unsaturated air, and from metabolic activities, such as oxidation of carbohydrates and fats (Arlian, 1979; Devine, 1978; Yaowaluk et al., 2008). Since the moisture content of wheat was low, the insects must rely on water obtained from unsaturated air or through metabolic activity. It is the basis to get different signals from grains and insects according to their moisture differences in subsequent experiment.

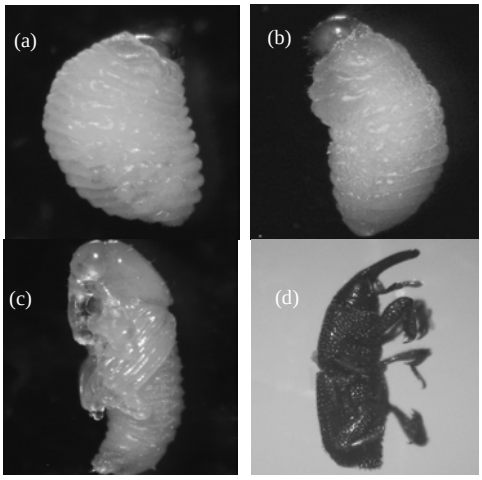

Figure 1 The life cycle of the *Sitophilus oryzae* (rice weevil): (a) small larva, (b) large pupa, (c) pupa, and (d) adult. Photographs are at about ×20 magnification.

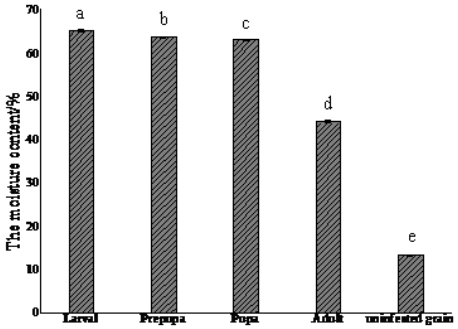

Figure 2 Moisture content of the four *Sitophilus oryzae* growth stages and uninfested grain.

3.2. Transverse relaxation signal analysis for wheat and S. oryzae

Figure 3 shows the distribution of transverse relaxation times T_2 for *S. oryzae* adults and wheat kernels. Two peaks were overlapping for a single wheat kernel (Figure 3a), whereas two separate peaks were observed for multiple wheat kernels (Figure 3b). Two separated peaks for multiple kernels was sharper and narrower than for single kernel. In Figure 3c, 1 peak was observed on single adult, but 3 peaks were obtained on about 90 adults. The peak height was directly related to the proton content and therefore low proton content in the sample reduced the detection accuracy. Accuracy of LF-NMR can be improved by amplifying the magnetic field, increasing the sampling time or by using a larger number of samples. However, amplification of magnetic field and increase sampling times, result in increased equipment costs and longer detection time. Therefore, a certain number of samples were used in the following experiment. As shown in Figure 4, the representative continuous distribution of transverse relaxation times for wheat and *S. oryzae* at the four growth stages. Two T_2 components were detected in both samples, but with different distributions for wheat kernels and insects. The intensity of the signal per unit mass of *S. oryzae* was higher than that of uninfested wheat as the higher moisture content of the insect (Figure 2). The position of the insect

peaks moved leftward as they grew up, indicating that molecular mobility in insect bodies decreases with maturity.

Table 1 shows transverse relaxation times (T_2) and percentages of water component (P_2) in four different growth stages and wheat. In wheat samples, T_{2b} was the short relaxation time at 0.76 ms that was associated with strong boundary water trapped within macromolecular structures, such as starch and protein (Bertram et al., 2001; Li et al., 2014; Shao et al., 2016a; Shao et al., 2016b). The long relaxation time was T_{22} at 96.02 ms that could be the superimposed signal from water and lipid molecules, although the lipid level was very low in wheat. For *S. oryzae*, the short relaxation time T_{21}, ranging from 1.6 to 2.8 ms, was related to the protons integrated with organized protein structures and associated with weakly bound water (Bertram et al., 2001; Li et al., 2014; Shao et al., 2016a; Shao et al., 2016b). The long relaxation time T_{22}, ranging from 37 to 58 ms, could be attributed to immobilized water or capillary water located in the intercellular space or capillaries, and was significantly lower in insects compared to wheat ($p < 0.05$). The P_{22} percentages for the insects at the 4 different insect growth stages ranged from 89.53 to 91.64%, implying that the main water component was immobilized water, irrespective of the *S. oryzae* growth stage. In contrast, the main water component in wheat was strong boundary water, accounting for about 90% water. Therefore, molecular mobility in insects when compared to that of wheat kernels was significantly different as water under low moisture conditions (i.e. in case of wheat) was less mobile. This observation was particularly useful in identifying insect infestations.

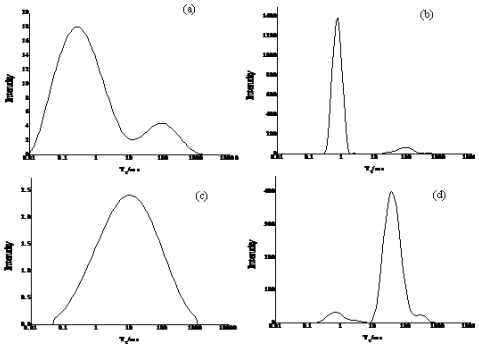

Figure 3 Typical distribution of T_2 relaxation times for *Sitophilus oryzae* adults and wheat kernels: (a) single uninfested wheat kernel; (b) multiple uninfested wheat kernels (Approx. number: 38); (c) single adult; (d) multiple adults (Approx. number: 91).

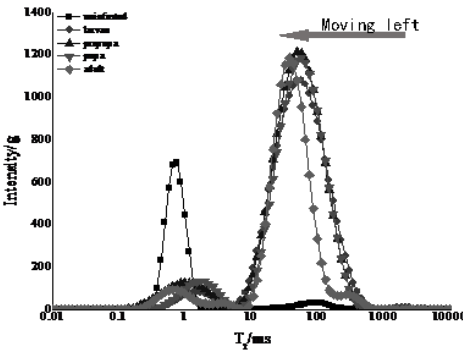

Figure 4 Typical distribution of T_2 relaxation times for *Sitophilus oryzae* at different growth stages and for uninfested grain.

Table 1. T_2 and percentages for each water component obtained by LF-NMR for *Sitophilus oryzae* at the four different growth stages and wheat

Growth stages	T_{2b}/ms	T_{21}/ms	T_{22}/ms	P_{2b} / %	P_{21} / %	P_{22} / %
Small larva	—	1.93 ± 0.47^{a}	57.22 ± 0.00^{b}	—	8.78 ± 0.58^{a}	90.75 ± 1.47^{a}
Large larva	—	1.60 ± 0.26^{a}	51.01 ± 2.78^{b}	—	7.76 ± 1.74^{a}	91.64 ± 1.62^{a}
Pupa	—	2.25 ± 0.42^{ab}	57.22 ± 0.00^{b}	—	7.58 ± 0.35^{a}	90.63 ± 1.06^{a}
Adult	—	2.77±0.75^{b}	37.65 ± 0.00^{a}	—	9.69 ± 0.72^{a}	89.53 ± 0.57^{a}
Wheat	0.76 ± 0.00	—	96.02 ± 12.33^{c}	90.97 ± 0.28	—	5.01 ± 1.28^{b}

Note: $^{a–c}$ means within a column with different letters are significantly different ($P < 0.05$).

Table 2. Moisture content of the infested wheat kernels varied with *S. oryzae* growing up.

Sitophilus oryzae growing days (d)	Moisture content (%)
0	13.44% ± 0.12[a]
5	13.94% ± 0.06[b]
10	14.95 ± 0.11[d]
15	15.19 ± 0.08[e]
20	19.24 ± 0.08[f]
25	20.04 ± 0.03[g]
30	19.09 ± 0.08[f]
Control group of wheat at 30 d	14.18 ± 0.02[c]

Note: [a-h] means within a column with different letters are significantly different ($p < 0.05$).

3.3. Transverse relaxation signal analysis for infested wheat with S. oryzae inside

Table 2 shows that there was a significant increase in the moisture content of infested wheat when insects were developing inside the kernels. This is obvious, as a living organism inside the kernel would add moisture to its microclimate due to respiration and metabolic activity. There was a sharp rise between 15 and 20 d, probably due to metabolic water produced by the insects increased to adapt to higher growth rates. Table 3 shows the transverse relaxation time values for insects that developed inside wheat. T_{2b} ranged from 0.76 to 1.52 ms over 30 d, indicating that the water mobility in wheat changed over time. This occurred because the macromolecular structures of wheat were destroyed by *S. oryzae* to free water from the macromolecular structures and new water component was accumulated in the pest body. It can be confirmed by that the water component P_{2b} decreased after 5 d and P_{22} increased after 10 d as shown in Figure 5. These results suggest that insect infestation not only affected the total moisture content of the stored grain, but also changed the mobility characteristics inside the kernel. However, there was a decrease in T_{22} (96.02 ms to 43.77 ms) as the insects grew up. This was similar to independently detecting *S. oryzae* at each growth stages, although the correlation of this data needs further investigation in future. Especially, T_{22} with 56.75 ms at 5 d was significant from that with 96.02 ms at 0 d ($p < 0.05$), suggesting that the early growth stages of the insect could be detected by LF-NMR. The changes between water component P_{2b} and P_{22} were the opposite of each other in Figure 5. The continued increase in P_{22} from 5 to 25 d showed that the intensity of the *S. oryzae* signal increased gradually, in agreement with the total water content in the infested wheat kernels in Table 2. This is probably due to developed larger insects that contain more water in their bodies. Unexpectedly, P_{2b} increased while P_{22} decreased at 30 d. The P_2 changed in non-monotonic way whereas T_2 values were monotonously changing (seen in Table 3), varied with *S. oryzae* growing up. Only at 30 d, we found that some adult *S. oryzae* climbed out and left empty grain. All indicated that transverse relaxation signal by LF-NMR could accurately measure the whole growth of rice weevil *S. oryzae* in kernels.

Table 3. T_2 values of the infested wheat kernels varied with *S. oryzae* growing up

Infested days (d)	0	5	10	15	20	25	30
T_{2b}/ms	0.76 ± 0[a]	0.89 ± 0.08[ab]	0.92 ± 0.06[b]	1.02 ± 0.05[c]	1.28 ± 0.07[d]	1.32 ± 0[d]	1.52 ± 0[e]
T_{22}/ms	96.02 ± 12.33[d]	56.75 ± 9.28[c]	59.99 ± 9.99[bc]	51.27 ± 7.37[abc]	52.33 ± 4.48[ab]	50.84 ± 2.61[ab]	43.77 ± 6.23[a]

Note: [a-e] means within a row with different letters are significantly different ($p < 0.05$).

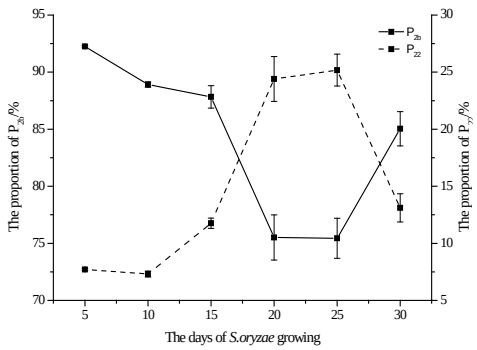

Figure 5 P_{2b} and P_{22} water component percentages of the infested wheat kernels varied with *S. oryzae* growing up.

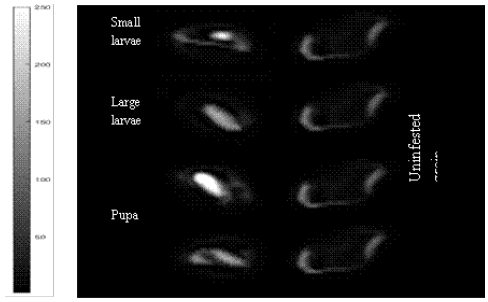

Figure 6 Low field NMR images of an infested wheat kernel at the four growth stages (left column) and for uninfested grain (right column). Sidebar stands for the grey-scale intensity of the images.

3.4. LF-NMR image analysis for infested wheat

Figure 6 shows the LF-NMR images of internally infested grain for the four growth stages and for the uninfested grain. The intensity of the signal is directly related to the sample's proton density (water or oil content); therefore, brighter zones contain larger amounts of water (Alessandra et al., 2010). Once an insect infested a wheat kernel, a bright spot appeared in the endosperm and this became enlarged as the insect grew up. This area was much brighter than the rest of the wheat kernel, suggesting that the moisture content of the insect was higher than that of wheat. This agreed with Figure 2. In addition, a bright tunnel could be seen at the adult stage because the adult had consumed the inside of the grain and was moving around freely within the grain. Therefore, LF-NMR image can visually detect insect infestation.

Conclusions

In summary, we measured and analysed LF-NMR transverse relaxation signal and image differences in wheat and wheat infested by *S. oryzae*. Our findings show that LF-NMR signal measurement or imaging could have potential to detect infested grain with hidden pests.

IPM guidelines as fundament for sustainability in plant protection: The case for stored product protection

Bernd Hommel*, Nadine Feuerbach

Extended Abstract

According the EU Framework Directive 2009/128/EC of Sustainable Use of Pesticides (EU, 2009), member states shall implement into practice, amongst others, crop or sector-specific guidelines for integrated pest management (IPM) on a voluntary basis. In this context, article 14 demands that *"member states shall take all necessary measures to promote low pesticide-input pest management, giving wherever possible priority to non-chemical methods"*. Furthermore *"Public authorities and/or organisations representing particular professional users may draw up such guidelines. Member states shall refer to those guidelines that they consider relevant and appropriate in their National Action Plans"*.

For these aims, the EU has defined eight general principles of IPM in Annex III.

These general principles comprise:

- Principle 1: Prevention and/or suppression of stored product pests where ever possible.
- Principle 2: Monitoring of pests with adequate methods and tools.
- Principle 3: Decision-making in collaboration with profesional advisors to apply appropiate plant protection measures.
- Principle 4: Practicable non-chemical measures should be preferred.
- Principle 5: Pest–specific chemical products with the lowest detectable side effects for humans, target-organisms and environment should be preferred.
- Principle 6: Where appropriate, all control measures but mainly the use of chemical products should be restricted to the minimum extent, e.g. by reducing authorized doses, and frequency of application or by partial application.
- Principle 7: Implementation of resistance strategies to maintain the efficacy of the chemical products.
- Principle 8: Documentation of all plant protection measures and evaluation of their success for future decisions.

Barzman et al. (2015) have reviewed in detail application of these eight general principles of IPM from the perspective of what their implementation means for research, advisory services and farmers. There is no doubt that practicable measures of "prevention and suppression" and "monitoring" are of utmost importance to restrict all kinds of direct interventions on a minimum and thus, to keep low risks for human health, the natural environment and groundwater. The sequence of these eight general principles can be considered as a repetitive decision-making tree where misjudgements can be adjusted in the next vegetation period(s). But, Barzman et al. (2015) conclude that there is a need for flexible, locally adapted and practical IPM strategies.

In Germany, the general principles of IPM became binding for farmers and advisors with the entry into force of the revised Plant Protection Act in February 2012. Thereby these general principles are part of the mandatory good plant protection practice. However, due to this practice and several action plans since 2003, high standards of plant protection have already been implemented in Germany for years (Hommel et al., 2013).

Because of the uncontrolled environment, plant protection in arable and horticulture farms is more in focus of critical public debates than stored product protection under controlled environments in stockkeeping or processing companies. These debates and – in many cases - farmers' green attitude have the potential to support development and implementation of innovations to improve plant protection strategies in the context of IPM. In contrast, stored product protection takes place in fully controlled environments (e.g. warehouses, silos, containers, packagings) that are clearly separated from the natural environment. Environmentally-based driving forces to change or improve things are therefore less influential. Only economically-based preconditions, e.g. declined availability of chemical products, storage losses, avoidable discounts in the trade chain, and hygienic reasons are responsible for investments in better trained workers, extension services or storage conditions. It has been shown that protection goals, public goods or dependencies of trading partners are extremely crucial to implement profitably IPM guidelines into practice.

The National Action Plan on Sustainable Use of Plant Protection Products (NAP), issued by the Federal Government in 2013 for 10 years, focuses on all these aspects to strengthen voluntary activities of farmers and all stakeholders to reduce risks to humans, animals and the environment as demanded by the directive 2009/128/EC (https://www.nap-pflanzenschutz.de/en/).

The first IPM guideline for the sector "stored product protection" in Germany was developed in co-operation of different stakeholders (led by the Julius Kühn-Institut, JKI), financially supported by the Federal Ministry of Food and Agriculture (BMEL) and submitted to the BMEL in 2017. After its assessment done by The Scientific Advisory Board of the NAP, it is expected that this guideline will be added to Annex 1 of the NAP in 2018.

The guideline contains a general part with explanations of the eight principles in the context of stored product protection.

This specification of the principles comprises:

Principle 1: Appropriate storage, discharge and conveying, adequate sanitation, sealed chambers or silos, facilities for cleaning, cooling, drying;
Principle 2: Intake control, monitoring, claim advice;
Principle 3: Decision-making for the current problem, solutions to prevent the problem in future, claim advice;
Principle 4: Relocation, cooling, thermic and biological measures;
Principle 5: Choose low-risk products, think about the need for resistance strategies;
Principle 6: Appropriate equipment, dose and frequency of application;
Principle 7: Change of active compounds or alternative measures, monitoring;
Principle 8: Documentation of measures and their success, adjustment of measures for future stored product protection.

In addition, a more detailed table of measures is given for grain and bulk storage in the IPM guideline. Other stored products will be added later. The table shows the sequence of measures to be considered for individual pest problems. There is a clear priority to preventive and non-chemical measures. All measures are evaluated according to their practicability. To this end, the criteria effective, economically viable and proven are considered individually.

The IPM guideline for the sector "stored product protection" will be evaluated regularly and an adoption of advances in IPM is possible. In Germany's NAP, the aim is that 50 % of stock keepers shall apply the guideline 5 years after its publication, i.e. in 2023. To achieve this ambitious goal, a network will start in 2018 under the acronym VSnet for IPM demonstration in on-farm and off-farm commercial grain storage facilities.

DOI 10.5073/jka.2018.463.227

Without precaution, insects may cause serious damage to museum collections. Quarantine of potentially infested objects can be logistically challenging. Anoxia under controlled nitrogen atmosphere is a most compatible but also time-consuming method to eradicate insect pests in all kinds of different materials. Treatment results are usually effected by duration, temperature, humidity and residual oxygen content. During a two-year research project, 34 relevant pest insect species of all developmental stages were tested in several different materials (wood, paper, wool) to monitor treatment success and to determine optimum treatment parameters. Duration of treatment ranged from one to three weeks at temperatures of 20 - 27 °C. As expected, results showed significant differences in mortality among tested species. Highest tolerance of hypoxic conditions was found in older larvae of *Hylotrupes bajulus*. However, this species is an unlikely museum pest. Anobiids and other wood boring beetles are more often an issue related to cultural heritage. Tested imbedding materials in general had no mortality lowering influence. A combination of three weeks exposure time at up to 0.5 % residual oxygen and at 24 °C and 50 % RH is recommended for infested artefacts.

Susceptibility of phosphine-resistant cigarette beetles to various insecticides

Abstract

Management of phosphine resistance in the cigarette beetle *Lasioderma serricorne* (F.) has become a topic of great interest to the tobacco industry in recent years. Effective use of contact insecticides with modes of action different from that of phosphine can be a key element in preventing or delaying the evolution of phosphine resistance. This study was conducted to ascertain whether five insecticides selected from three mode-of-action classes (fenitrothion, pirimiphos-methyl, permethrin, bifenthrin, and spinosad) can be incorporated into a phosphine-resistance management strategy. Specifically, we examined the contact efficacy of the insecticides to a phosphine-susceptible strain and six resistant strains (38–184-fold in resistance ratio based on LC_{50}). Susceptibility to organophosphates (fenitrothion, pirimiphos-methyl) and spinosad was not significantly different between phosphine-susceptible and phosphine-resistant strains (within 2.3-fold resistance ratio). The absence of the cross-resistance between these insecticides and phosphine makes them ideal for resistance-management programmes. However, high resistance to synthetic pyrethroids (>145-fold for permethrin and >1697-fold for bifenthrin) was found in three of six phosphine-resistant strains. Based on these results, synthetic pyrethroids cannot be recommended as insecticides of primary choice.

Keywords: *Lasioderma serricorne*, resistance management, contact insecticides, pyrethroid resistance

1. Introduction

The cigarette beetle, *Lasioderma serricorne* (F.) is the most important pest of stored tobacco. Fumigation by phosphine, the most important method for disinfestation of stored tobacco, has been used for post-harvest management of insect pests since the 1970s. Phosphine resistance in *L. serricorne*, although first recorded in India and the United States in the 1990s (Zettler, 1990;

RAJENDRAN AND NARASIMHAN, 1994; ZETTLER AND KEEVER, 1994), has spread globally along with international tobacco distribution (HORI AND KASAISHI, 2005; CORESTA, 2013). The tobacco industry had successfully managed the resistance problem by revising the industrial fumigation protocol (CORESTA, 2013). Nevertheless, highly resistant populations able to survive the present fumigation protocol, i.e., 6-d exposure with 600-ppm at 25°C, have emerged recently in the United States (SAĞLAM et al., 2015). The sustainable use of phosphine will be threatened if such high resistance becomes widespread. Therefore, countermeasures capable of preventing or delaying the elevation of resistance are eagerly sought. The emergence and spread of resistance are mainly attributed to heavy reliance on a single insecticide or single mode-of-action insecticides. Therefore, enforcement of an integrated approach incorporating as many different control measures as possible is a principle for successful management of phosphine resistance. The use of insecticides with different modes of action is one such measure. Various contact insecticides, including organophosphates and pyrethroids, have been used as space-spray or surface-spray applications in tobacco warehouses in practice (RYAN, 1999), although their efficacy against phosphine-resistant *L. serricorne* has not been ascertained. The present study assesses the effects of five contact insecticides selected from three mode-of-action classes (fenitrothion, pirimiphos-methyl, permethrin, bifenthrin, and spinosad) (IRAC, 2017), to phosphine-susceptible and phosphine-resistant *L. serricorne*.

2. Materials and Methods

a. Insects

Seven laboratory strains of *L. serricorne*, one phosphine-susceptible and six phosphine-resistant strains, were used for this study (Table 1). The phosphine-susceptible strain TSC has been maintained in the laboratory for decades without exposure to any insecticide. The other six strains (THR, C87, NGY, IWT, SKG, and MLY) were established from phosphine-reistant field populations collected from tobacco warehouses at different times and locations. They underwent laboratory selection with phosphine for at least 13 generations before the study so that uniformity of phosphine susceptibility in individuals in each strain was promoted. They had never exposed to insecticides, except for phosphine, since their collection from the field. All insects were maintained on cornmeal containing yeast (10% mass fraction) at 27°C and 60% r.h.

Table 1 *Lasioderma serricorne* strains used for the study

Strain	Initiation of culture	Origin	Phosphine-susceptibility, LC_{50}[a] (95% confidence interval), ppm	
TSC	Unknown	Unknown	6.6	(3.0–10.3)
THR	1999	Tobacco warehouse in Tokyo, Japan	250.4	(227.2–272.6)
C87	2011	Food and Environment Research Agency (York, UK)	284.5	(248.3–318.9)
NGY	1997	Tobacco warehouse in Aichi, Japan	298.1	(264.9–331.0)
IWT	1999	Tobacco warehouse in Shizuoka, Japan	340.2	(305.7–375.1)
SKG	2010	Tobacco warehouse in Fukushima, Japan	412.6	(333.1–474.1)
MLY	2012	Tobacco warehouse in Shah Alam, Malaysia	1215.5	(1051.3–1351.6)

a Phosphine concentrations required to achieve 50% lethality (LC_{50}) for eggs at 72-h exposure, 25°C, and 75% r.h.

b. Insecticides

The efficacy of five commercial formulations of insecticide from three mode-of-action classes (IRAC, 2017) was evaluated: fenitrothion (Sumithion EC; Sumitomo Chemical Co., Ltd., Tokyo, Japan) and pirimiphos-methyl (Actellic EC; Nihon Nohyaku Co., Ltd., Tokyo, Japan) belonging to IRAC group 1B (organophosphates: acetylcholinesterase inhibitors); permethrin (Adion EC; Sumitomo Chemical

Co., Ltd., Tokyo, Japan) and bifenthrin (Talstar FL; Ishihara Sangyo Kaisha, Ltd., Osaka, Japan) belonging to the group 3A (synthetic pyrethroids: sodium channel modulators); and spinosad (Spinoace SC; Dow AgroSciences Japan, Ltd., Tokyo, Japan) belonging to the group 5 (nicotinic acetylcholine receptor allosteric modulators), all of which belong to different classes from phosphine (group 24A: mitochondrial complex IV electron transport inhibitors).

c. Insecticide susceptibility testing

Insecticide susceptibility was evaluated using dipping method. Thirty adults (collected within 3 d of emergence) that had been anesthetized with CO_2 were put into a glass tube (⌀21 mm, height 25 mm); then both ends of the tube were closed with polyester gauze. The insects within the glass tube were dipped for 10 s in the insecticide solution, which had been adjusted to the appropriate concentration (up to 10000 ppm) with water containing Triton X-100 (Wako Pure Chemical Industries, Ltd., Osaka, Japan) at 0.02%. After removing free drops of the solution using filter paper, the insects were transferred into a polystyrene vial (⌀25 mm, 50 mm depth) and were maintained at 27°C and 60% r.h.

The mortality was detemined at 24 h after exposure for fentrothion, pirimiphos-methyl, bifenthrin, and spinosad or at 48 h for permethrin. The viability was assessed as a measure of locomotion (i.e., paralyzed adults were regarded as dead).

Data were subjected to a probit analysis using the PriProbit (ver. 1.63) computer program developed by SAKUMA (1998), which was downloaded from https://www.ars.usda.gov/pacific-west-area/parlier/sjvasc/cpq/docs/priprobit-download/. The concentrations to achieve 50% lethality (LC_{50}) and 99% lethality (LC_{99}) were determined.

3. Results

Organophosphates fenitrothion and pirimiphos-methyl exhibited excellent performance at lower concentrations (< 20 ppm in LC_{99}). The susceptibilities were almost equal between the strains, irrespective of phosphine resistance (within 2.2 fold in resistance ratios calculated based on LC_{50}) (Table 2). The spinosad effect was constant among strains, although it was inferior to the two organophosphates tested. However, results show great differences in susceptibility to the two pyrethroids among strains. Three strains C87, SKG, and MLY exhibited high resistance to both permethrin and bifenthrin: most insects survived exposure, even at the highest concentration tested: 10000 ppm. To the other strains, TSC, THR, NGY, and IWT, bifenthrin exhibited high efficacy (≤ 25 ppm in LC_{99}), although permethrin was less effective (235–384 ppm in LC_{99}).

Table 2 Insecticide concentrations necessary to achieve 50% lethality (LC_{50}) and 99% lethality (LC_{99}) and resistance ratios of adults of *Lasioderma serricorne* strains

Insecticide	Strain	LC_{50} (95% CI[a]), ppm	LC_{99} (95% CI[a]), ppm	Resistance ratio[b]
Fenitrothion	TSC	5.9 (5.4–6.3)	11.6 (10.1–14.3)	1

	SKG	>10000[c]		>10000[c]		>1696.5
	MLY	>10000[c]		>10000[c]		>1696.5
Spinosad	TSC	130.2	(111.4–152.6)	731.9	(511.6–1278.3)	1.9
	THR	152.8	(130.9–180.3)	856.2	(589.1–1543.6)	2.3
	C87	117.9	(101.4–136.8)	581.2	(421.4–952.5)	1.8
	NGY	115.3	(98.1–135.4)	682.1	(476.2–1190.9)	1.7
	IWT	100.8	(85.0–118.6)	722.6	(490.4–1322.4)	1.5
	SKG	125.2	(104.5–150.4)	1007.1	(646.1–2052.0)	1.9
	MLY	67.0	(50.7–83.4)	904.5	(532.3–2263.9)	1

[a] 95% confidence interval.

[b] Resistance ratios were calculated using the respective LC_{50} values relative to the strain which exhibited the smallest LC_{50} value for the respective insecticides.

[c] Probit analyses were not applied because most insects survived exposure even at the highest concentration: 10000 ppm.

4. Discussion

Higher contact toxicities of fenitrothion and pirimiphos-methyl against the same phosphine-susceptible *L. serricorne* strain as that examined in this experiment have been reported already (Orui, 2004). They have been used practically as space-sprays and surface-sprays in tobacco warehouses in the past, but the position as tobacco protectants of organophosphates has been replaced completely by pyrethroids. The absence of cross-resistance with phosphine, as shown in this experiment, makes them ideal for resistance-management. The time might come to review their usefulness against these pests.

Spinosad, derived by fermentation of soil actinomycete, has attracted attention as a grain protectant for its reduced risk properties (Hertlein et al., 2011). However, it has not been applied to tobacco in practice because it requires higher doses to achieve sufficient effects (Branc et al., 2004; Hertlein et al., 2011; Flingelli, 2014). Lower insecticidal activity against *L. serricorne* adults was found using a dipping method in this study (581–1007 ppm in LC_{99}). The cost of spinosad is higher than those of general synthetic insecticides at present. Therefore, it is not practical for the control of *L. serricorne* for economic reasons, although no cross-resistance with phosphine is apparent.

Synthetic pyrethroids are widely used today as surface-spray agents in tobacco warehouses around the world. This study revealed the existence of permethrin resistance and bifenthrin resistance in three of six phosphine-resistant strains which have mutually different origins. Coexistence of deltamethrin-resistance and phosphine-resistance in *L. serricorne* was found also in a population collected in a tobacco warehouse in Germany (Flingelli, 2014). Apart from tobacco pests, the widespread development of pyrethroid resistance has come to pose an immense practical difficulty in many parts of the world (Liu, 2012). These findings suggest that resistance to synthetic pyrethroids has developed in many field populations of *L. serricorne* through long-term use. Therefore, they cannot be recommended today as insecticides of primary choice for *L. serricorne*.

Abstract

The lesser grain borer, *Rhyzopertha dominica* is one of the serious cosmopolitan stored grain pests worldwide. High phosphine resistant *R. dominica* has been reported in several countries. The evolution of strong phosphine resistance is a major challenge for continuous application of the fumigant. Rapid detection of phosphine resistance level is a prime key to implement an appropriate strategy for control the stored-product pests. Dihydrolipoamide dehydrogenase (DLD) is a key metabolic enzyme mediating the phosphine resistance in population of *R. dominica*, *Tribolium castaneum* and *Caenorhabditis elegans*. Analysis of the DLD sequences deposited in GenBank revealed that the P45/49S mutation was the most common one in many PH3-resistant stored-product pest insects. This information now enables direct detection of resistance using molecular diagnosis in field populations. We herein propose a method for rapid detection of phosphine resistance in *R. dominica* according to P49S point mutation of the DLD gene. Our data provides evidence that the ARMS-PCR method can be used for early warning of phosphine resistance in *R. dominica i*n field conditions.

Tetra-primer amplification refractory mutation system polymerase chain reaction (ARMS-PCR) method, in which two pairs of specific primers are applied was carried out based on the single nucleotide mutation in dihydrolipoamide dehydrogenase (DLD) gene. An ARMS-PCR assay was designed for diagnosing CCT to TCT (=P49S in amino acid sequence) mutation in the DLD gene sequences of *R. dominica*. The method employs four primers to amplify a common band from DNA containing the SNP and amplification representing each of the two allelic forms. Primers were designed to amplify fragments of differing sizes for each allele band in order to resolve using agarose gel electrophoresis. Primers were designed using primer1 software (http://cedar.genetics.soton.ac.uk/public_html/primer1.html). To increase the specificity of the reaction, a mismatch is introduced at the 3'end of each of the two allele-specific primers. The results of Taqman@ MGB-probe real-time PCR showed that there were no false-positive results in ARMS-PCR. In addition, the Food and Agriculture Organization (FAO) standard discriminating dose phosphine bioassay for eight *R. dominica* populations collected from China validated that the tetra-primer ARMS-PCR method was an accurate and sensitive method to diagnose *R. dominica* phosphine resistance level. The phosphine concentrations of 20 ppm phosphine for identification of weak resistance in *R. dominica* and 300 ppm for strong resistance according to FAO method were used. The sequences of the DLD gene were isolated from eight geographic populations of *R. dominica* collected from China. Further analysis of the DNA sequences revealed that the single amino acid mutated from proline to serine at the position #49 in the DLD enzyme, which are corresponding to CCC and TCC in nucleotide sequences of laboratory susceptible strain and strong phosphine resistant population of *R. dominica,* respectively. Genomic DNA was extracted from sixteen individuals from each of resistant *R. dominica* population and used as templates for PCR to generate 283-bp common band, 208-bp resistance phenotype and/or 130-bp susceptible phenotype band respectively. The discriminating fragments were a 130-bp band for susceptible (codon CCC) allele and a 208-bp band for mutant (codon TCC) alleles respectively. Therefore, genotype scoring was made according to the basis of presence/absence of 130bp and 208bp fragments, when the individual beetle was either heterozygous for the resistance allele or homozygous susceptible or homozygous resistant. A TaqMan real-time reaction was performed in parallel for P49S allele. In each reaction, a substantial increase in HEX fluorescence indicated a homozygous susceptible genotype, a substantial increase in FAM fluorescence indicated a homozygous resistant genotype and an increase in both signals indicated a heterozygote. The observed and expected ARMS results were conducted from eight populations previously discriminated by the phosphine discrimination dose. DLD allele frequencies in eight *R. dominica* populations were examined by the ARMS-PCR method to test all individuals in susceptibility bioassay. Overall, P49S allele frequency ranged from 9% to 94% in populations collected in this study. Chi-square analysis was carried to determine whether the genotype ratios at each population deviated from Hardy–Weinberg equilibrium. Significant changes in the allele frequencies across genotype frequencies within populations were used to identify phosphine resistance associated with the P49S resistance mutation in *R. dominica*. The phosphine resistance frequency of different geographical populations of *R. dominica* were diagnosed by FAO recommended method with discrimination 20ppm for weak resistance and 300ppm for strong resistance. The phosphine resistance frequency of different geographical populations of *R. dominica* were diagnosed by FAO recommended method with discrimination 20ppm for weak resistance and 300ppm for strong resistance. The results indicated that ARMS-PCR assay was easy to use, more sensitive and specific to detect the P49S mutation in phosphine resistant samples of *R. dominica* than previously used bioassay methods. Previous techniques for gene mutation detection are based on the polymerase chain reaction; many of them require post-PCR manipulations, such as isotopes irradiation, restriction enzymes, are required to two PCRs rounds. For example, using the (RFLP) typing method involved restriction and endonuclease digestion of PCR products, while some mutation sites were hard to find by appropriate restriction enzyme. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) analysis (Campbell 2008), mass spectrometry (MALDI-TOF-MS) assays (Park et al. 2008) and direct DNA sequencing methods are a sensitive, accurate and elegant diagnostic method, but they require expensive equipment and

have complex processing. Fast and economical assays that can be performed with standard PCR instruments are highly desirable for diagnostic analyses and for scientific studies of large numbers of pests. Individual *R. dominica* from distinct geographic populations can be discriminated into resistant homozygote, resistant heterozygote and susceptible homozygote from electrophoretogram after ARMS-PCR assay. Our TaqMan@ MGB probe assay could discriminate P49S mutation in DLD gene according to fluorescence labeling intensity variation and confirmed ARMS-PCR result as well. Our results show that the rapid detection of phosphine resistance in *R. dominica* populations in China provides important information to grain industries for decision-making in pest management strategies. In addition, our results suggest that this method could be applied for the detection of phosphine resistance in other grain pests, such as *T. castaneum* and *Sitophilus oryzae*, whose DLD genes have been sequenced. Our methods could be conducted on dead insects or insect fragments. Indeed, we evaluated consumable, running and capital cost for each method. The ability to quickly diagnose the resistance of these strains would be of great benefit. Furthermore, ARMS-PCR method for identifying the resistance locus mutation provides an opportunity to valuate level of phosphine resistance in other key pest species such as *Cryptolestes ferrugineus*, *S. oryzae* and *Sitophilus zeamais*. In addition, this technology could be extended to solve other pesticides resistance. The development of ARMS-PCR does not require generation of phosphine gas in the laboratory; also does not need collection and culture of field populations. Furthermore, the results are easier to assess with naked eye.

DOI 10.5073/jka.2018.463.230

In this study, the effects of two different concentrations of ozone gas (16.7 and 33.3 mg / L) against *Blatella germanica* adults at different exposure times (10, 20, 30, 40 and 50 minutes) were investigated under laboratory conditions. It was determined that the ozone gas had a noticeable effect on mortality of *B. germanica* adults. In general, ozone gas caused higher paralyisis-mortality rates of *B. germanica* adults than mortality rates of *B.germanica* adults at both concentrations and all exposure times. A concentration of 33.3 mg / L of ozone gas with 40 and 50 minute exposure times killed all cockroach adults after 24 hours. On the other hand, 16.7 mg / L concentration of ozone gas with 50 minute exposure time killed 90% of the *B. germanica* adults after 24 hours. When ozone gas is evaluated in terms of exposure time to *B. germanica* adults, the concentration of 33.3 mg / L of ozone gas with 10-20 minute exposure times caused 65 % adult mortality, with 30 minute exposure time caused 90% adult mortality and with 50 minute exposure times caused 100 % adult mortality after 24 hours. At a concentration of 16.7 mg / L of ozone gas, as the exposure times increased, the adult mortalities gradually increased after 24 hours and the adult mortality reached 90% with 50 minute exposure times. All these results show that ozone gas (33.3 mg / L) with 40-50 minute exposure times can successfully control *B.germanica* adults.

Keywords: Ozone gas, *Blatella germanica*, mortality, biological efficacy.

1. Introduction

Cockroaches are insect species that have remained unchanged since ancient times (Appel, 1995). There are approximately 3,500 species of cockroach in the world (Atkinson et al, 1991). Most types of cockroaches are insect species that live in outdoor environments. However, a few cockroach species are found in the living areas of insects. One of the cockraoch species found in people's

habitats is the German cockroach, *Blatella germanica* (L.), which is one of the most common cockroach species all over the world. It is easily distributed when indoor and outdoor temperature and humidity are suitable for this species.

In addition to the psychological effects to humans, this species has a considerable medical importance, as it harbors bacteria, fungi, helminths, protozoa, viruses that can cause diseases in humans (Mullen et al., 2002). Cockroaches also cause asthma in many people with allergies (Roberts, 1996). The control of German cockroaches is traditionally made with inorganic and synthetic organic insecticides (Rust et al., 1993). Due to adverse effects of the use of intensive chemical insectides in control of the German cockroach, an alternative control method which is not harmful to the environment, humans and animals is needed.

Ozone is a form of three atomic oxygen (O3) molecule. Ozone is produced as a bluish or colorless gas characterized by fresh clean odor in the air following the thunder storm. Ozone is an unbalanced gas and quickly converts oxygen to temperatures above 35 ° C. Therefore, it must be produced during use and can not be stored after it is produced. There is a striking characteristic odor that many people in ozone can notice even at very low concentrations (0.02 ppm by volume) (Kim et al., 2003). Commercially, mostly ozone is produced with pure oxygen or airborne corona current generators (Kim et al., 2003). The control of insects with ozone gas has started with stored product pests. Isikber and Öztekin (2009) tested ozone gas on some stored product pests. These are the application of ozone gas to the insects with products and without product environment. The toxicity data obtained from studies with ozone gas in unfilled environment (empty volume) revealed significant differences between ozone gas sensitivities of developmental periods of *Ephestia cautella* and *Plodia interpunctella*. Ozone application in unfilled environment (empty volume) caused 100% death of *E. cautella* and *P. interpunctella* in all life stages, with the exception of the egg. The toxicity results obtained in study showed that *Tribolium confusum* is generally more resistant to ozone gas than *Ephestia kuehniella.*

To our knowledge, there are no studies on the effect of ozone against *B. germanica*. For this reason, in this study, we determine the optimum ozone concentration and ozonation duration by using the osmotic gas in the adult control of German cockroach.

2. Materials and Methods

Insect

Colonies of *B. germanica* were reared in plastic containers (60 liter) and maintained at room temperature. The cockroaches were provided with water in glass tubes with cotton stoppers and dry dog food. Each container was provided with paper egg cartons as shelter. The adult cockroaches (5-10 days old) were tested for each bioassays at 25 (± 2) ºC and 50 (±5) % relatıve humidity.

Ozone gas fumigation chamber

In empty volume applications, 3 liters of glass jars with a metal cover of 9 cm in diameter were used in all of the biological tests. These hatches have 2 entry pipes, 0.5 cm in diameter and 3 cm in length. A 5 cm long silicone hose is connected to the end of each record (one of the hoses is connected to the vacuum pump and the other to the ozone generator). One of the hoses was provided with ozone gas from the other hole while the air in the glass jar where the biological tests were conducted was discharged. Thus, the ozone gas was periodically circulated in the glass jar. The adjustment of the ozone gas concentration is adjusted according to the flow rate of the pure oxygen gas. The flow rate of the oxygen gas is controlled by the flowmeter placed between the oxygen tube and the ozone generator.

Biological tests and Empty volume applications

For empty volume applications, biological tests were carried out in 3 l metal-lined glass jars (fumigation chamber) at a temperature of 26 ± 1 and 65 ± 5% relative humidity. In all tests, *B. germanica* adults were used. The adults used in the biological tests were placed in 3 l jars where ozone fumigation was carried out and a small amount of food was added to the bottles. The solution was prepared by adding 10 ml of purified water to 100 g of MgNO2 (Magnesium Nitrate) to keep the media noodle in the jars constant at 65 ± 5%. This solution was soaked in a jar until wetted to a drying paper size of 5 x 2 cm. As the individuals exposed to ozone gas were placed in glass jars, the air in the jars used in the tests was evacuated to 760 mm Hg by low pressure pump (KNF, Germany). As the air in the jars is evacuated, the hoses on the covers of the jars are closed with the help of plastic clips to prevent gas in and out of the jars. After taking the air in the jars used in the biological tests, ozone gas is delivered to the ozone generator of the oxygen gas with the help of the flowmeter and ozone gas is produced. In order to produce ozone gas at different concentrations, the oxygen gas flow was set at 5 and 10 l / h and the flow rate was monitored from the flowmeter screen. When the desired flow rate is reached, the clips in the lids of the jars are opened and the produced ozone gas is directed to the fumigation chamber and the pressure inside the jar is filled with ozone gas until reaching normal pressure conditions. Since ozone gas is not a stable gas, it quickly transforms into oxygen form due to the effect of temperature and relative huminity. Therefore, ozone gas application has been completely applied to biological tests. In empty volume applications, application times were determined as 10, 20, 30, 40 and 50 minutes and the air in the jars where the tests were carried out once every 30 minutes in 40 and 50 minute applications was evacuated by vacuum pump and ozone gas was applied again. Experiments were carried out in 3 replicates of 10 individuals each time, leaving 3 controls for each trial. Upon completion of the application period, the ozone gas applied jars were ventilated and the insects were removed from the jars. The adults exposed to ozone gas were placed in 1 l glass jars and a small amount of food that was not exposed to ozone gas were added to the bottles. Dead and alive individuals were counted 1 hour, 6 hours and 24 hours after the termination of the experiments.

3. Conclusion

In this study, the toxicity of ozone gas against adults of *B. germanica* was demonstrated at two different application concentrations and different application times. In this study, as a result of the biological tests, ozone gas was generally observed in both the ozone gas concentration and the paralysis-mortality rate in all the application periods in the adults of *B. germanica*, was higher than the death rate. This has shown that ozone gas is a knockdown feature on this insect which leads to death. When the concentration of 33.3 mg / L of ozone gas was applied to adults of *B. germanica* with 40 and 50 minutes, respectively, it killed all cockroaches after 24 hours of application. On the other hand, when a concentration of 16.7 mg / L of ozone gas was applied to *B. germanica* adults for 50 minutes, it killed 90% of the adults of *B. germanica* after 24 hours of application. When the ozone gas is evaluated in terms of exposure time to *B. germanica* adults, the concentration of 33.3 mg / L of ozone gas with 10-20 minute exposure times caused 65 % adult mortality, with 30 minute exposure time caused 90% adult mortality and with 50 minute exposure times caused 100 % adult mortality after 24 hours. At a concentration of 16.7 mg / L of ozone gas, as the exposure times increased, the adult mortalities gradually increased after 24 hours and the adult mortality reached 90% with 50 minute exposure times. At a concentration of 16.7 mg / L of ozone gas, as the exposure times increased, the adult mortalities gradually increased after 24 hours and the adult mortality reached 90% with 50 minute exposure times. All these results have shown that ozone gas has potential for controlling *B. germanica* and may be an alternative to the synthetic chemicals used in the control of this insect. However, a comprehensive study of the ozone gas applicability in the natural habitat of the German cockroach and the determination of its effect on different factors when applied in natural conditions is necessary.

Does the lower concentration of anticoagulants affect the efficacy of rodenticide baits?

Extended abstract

Rodents belong to dominant synanthropic pests in agriculture environment, where cause wide range of damages by feeding on crops, gnawing of materials and faecal/urine contamination (Frankova et al. 2016, Stejskal et al. 2016). Rodents are predominatly controlled by anticoagulant-based rodenticides (AR) with the chronic mode of action (e.g. Frankova et al. 2017). Their delayed efficacy prevents rodents to connect the consumption of the bait with subsequent toxic effects and thus, favours them over other chemical rodenticides. On the other hand, application of ARs is permitted under strict regulation (Regulation (EU) No 528/2012) as ARs are considered as PBT (i.e. persistency, bioaccumulativity and toxicity) substances which pose environmental risks.

In addition, EU Commission recently adopted reclassification of ARs products (Commission Regulation (EU) 2016/1179; shall apply from 1 March 2018) - rodenticides with anticoagulant of 30 ppm or more must be labelled as "toxic to reproduction" and will be available to professional use only. Currently, it concerns seven of the eight approved anticoagulants, which contain 50 ppm of active substance. This Regulation leads manufacturer to produce rodenticide baits with a decreased concentration of anticoagulants to avoid a reclassification of products.

We focused on the testing efficacy of standard (50 ppm) and lower (25 ppm) concentration of anticoagulant in two brodifacoum-based baits in wild house mouse (Mus musculus). The laboratory no-choice feeding tests showed 100% mortality (mean survival time was 5.3 ± 2.1 days) for both concentrations. The consequent field experiments confirmed the previous laboratory results for the new baits with the lowered concentration (i.e. 25 ppm): during the three-week application period we found a significant decrease of both the tested bait and monitoring non-toxic bait consumption. Our study shows promising efficacy of products with the lowered concentration of brodifacoum. Nevertheless, there is a work ahead rodent scientists to illuminate the new baits efficacy in rodent populations with the decreased physiological sensitivity or increased resistance to anticoagulants.

Abstract

Sound biosecurity systems contribute to achieving sustainable agricultural and environmental systems, reducing the threat of introducing unwanted pests and supporting food safety and product integrity. Within Australia, the Grains Farm Biosecurity Program (GFBP) is a national initiative to assist in the development and implementation of improved biosecurity practice within its grain industry. Initiated in 2007, the extension focused program contributes to the industry's risk mitigation activities, supports continued market access and promotes a partnership approach involving governments, industry and community. The program is funded through grower levies in partnership with state government agencies and Plant Health Australia.

Using a variety of community engagement strategies, the GFBP has developed a wide range of tools to improve the management of and preparedness for, biosecurity risks in the Australian grains industry at the farm and industry level by highlighting risk pathways and activities throughout the supply chain and encouraging adoption of practices and strategies to mitigate risks. The GFPB also promotes and conducts surveillance for high priority pests especially in on-farm storage. Evaluations indicate an increased awareness of biosecurity risks, industry capacity and voluntary adoption of biosecurity best practices throughout the sector.

The GFBP focus on biosecurity best practice through industry engagement has seen it contribute to safeguarding and maintaining Australia's export reputation, with the program recently winning a national biosecurity award.

Keywords: Grains biosecurity, farm biosecurity, market access, Grains Farm Biosecurity Program, industry engagement

1. Introduction

The Grains Farm Biosecurity Program (GFBP), initiated in 2007, contributes to the Australian grains industry's risk mitigation activities, and promotes a shared responsibility involving governments, industry and community. The program aims to promote and improve the management of, and preparedness for, biosecurity risks in the grains industry at the farm and industry level.

Australia's geographical isolation and strong biosecurity system has ensured that many overseas pests of crop production and post-harvest storage are not present in Australia. Freedom from exotic plant pests provides both a yield advantage as well as market access benefits (especially in relation

to stored product pests such as khapra beetle) for Australian crop production industries such as grains.

Along with exotic pests, endemic pests can also impact upon production and market access. There is a nil tolerance for live insects in delivered grain in Australia, and with increasing on farm storage, prevention and control of stored grain pests is a critical function undertaken by growers. Management of stored grain pests is just one example of how farm biosecurity and hygiene practices are a key component of integrated pest management and form a vital role in minimising the establishment and contamination of pests in stored grain.

Importantly, national and state biosecurity systems are complemented and supported by measures carried out at the industry and regional level. As risks of new pests entering Australia can never be totally eliminated, industry biosecurity is regarded as a shared responsibility where all links in the production and supply chain engage and take responsibility for minimising biosecurity risks that are within their control. Growers implementing farm biosecurity practices, agronomists, researchers and other service providers including contractors can all play an important role in safeguarding the industry at a farm, regional and national level. An aware and trained grains industry has the capacity to minimise the risks posed by new and established pests, and respond effectively to any pest threats that would impact on the future sustainability and viability of the industry (Taylor-Hukins et al. 2015).

2. Materials and Methods

The GFBP has appointed specialised Grains Biosecurity Officers in five key grain growing states of Australia. The program is funded by Grain Producers Australia through grower levies in partnership with state government agencies, and is managed by Plant Health Australia (Bellati et al. 2015).

Yearly, over 100 activities are undertaken using a variety of community engagement strategies. The GFBP has developed a wide range of tools to improve the management of, and preparedness for, biosecurity risks in the Australian grains industry throughout the supply chain.

Core activities undertaken by the Grains Biosecurity Officers include:

- education and training to increase awareness of high priority exotic pests
- facilitating surveillance of high priority exotic pests for early detection and proof of absence
- development of practical resources and training materials
- demonstrating simple and effective methods for implementing farm biosecurity
- building collaborative networks and alliances across industry
- promotion of industry advocates
- emergency response and preparedness

3. Results and Discussion

Monitoring throughout the program indicates an increased awareness of biosecurity risks and voluntary adoption of biosecurity best practices throughout the sector. Table 1 provides a snapshot of results from surveys conducted by the Farm Biosecurity Program (initiative of Animal Health Australia and Plant Health Australia) between 2010 and 2017, measuring the percentage of respondents (grain producers) implementing suggested biosecurity practices. A general trend of uptake can be observed, with particular mention to monitoring stored products.

The national GFBP has aligned key awareness messages and education objectives to current grains industry extension programs, in order to deliver grains biosecurity training and education seamlessly. A critical element to the success of these strategic alliances is value adding to existing program content, where biosecurity messages and exotic pest identification information is embedded within industry training programs such as Pulse Australia best management practice accredited workshops (Bellati et al. 2010). This continues to be a strength of the program, with new linkages and alliances formed in particular for surveillance.

Tab. 1 An extract from surveys conducted by the Farm Biosecurity Program measuring practice change within the grains industry at the farm level

Practice	2010	2013	2017
Keep records	59%	82%	89%
Monitor stored products	52%	80%	93%
Clean machinery/equipment coming in property	57%	73%	81%
Control visitor movement on property	34%	47%	54%
Report anything unusual	31%	42%	49%

The latest initiative from the program is a pilot Sentinel Silo project, using both targeted and general surveiilance to monitor grain storages, 'ag pantries' and other risk sites and pathways for exotic stored product pests. The surveillance is aimed at strengthening evidence of absence, improving industry participation and knowledge of stored grain pests and surveillance and promoting best management practices.

4. Conclusion

The GFBP is Australia's flagship program for promoting farm biosecurity, with its success encouraging other industries to implement similar extension programs. The focus on biosecurity best practice through industry engagement has seen the GFBP contribute to the safeguarding of grains production and helping to maintain Australia's grain export reputation.

The GFBP is celebrating 10 years of success raising awareness of biosecurity among grain growers and helping the industry respond to serious pest incursions. In March 2018, the program was awarded an Australian Biosecurity Award for its ongoing contribution to Australia's biosecurity integrity.

A commercial method of controlling bedbugs (*Cimex lectularius*) using CO_2 in dwellings

Hagit Navarro, *#., Shlomo Navarro[1].

[1]. Green Storage Ltd., Argaman 5, Rishon Lezion, 7570905, Israel.

DOI 10.5073/jka.2018.463.233

Abstract

As a result of withdrawing residual insecticides such as organophosphates and carbamates throughout the world, infestation in *Cimex lectularius* has been dramatically increased in recent years. The ability of this pest to

starve for three months and its flattened shape of body enables it to hide in tiny holes/cracks or folds, making it difficult to control. Therefore, as a complementary action, fumigating products like textile products and furniture within the dwellings became a practice in Israel. After the conventional treatment of stripping the room, vacuuming, steaming the mattresses and then spraying with a Pyrethroid – a novel method was developed; instead of steaming the mattress and dry cleaning all textile clothes and products, fumigating all movable furniture and textile products with CO_2 inside the dwellings. Based on several scientific papers on the efficacy of CO_2 on the bedbugs, this method has been successfully implemented in Israel. All textile products are inserted into a sealed, low permeability fumigation cube for three days of exposure time at room temperature to reach a calculated concentration of 100% CO_2. Since textile products absorb some of the CO_2, the concentrations quickly drops to about 80%. During the summer of 2017, numerous treatments have been carried out with a 100% success and repeated treatments were not required. This treatment has proved to be a promising method of controlling *C. lectularius* with no need for evacuation of the residents and saving money and efforts in dry cleaning cloths and textile products. It is highly effective against all life stages of the pest.

Key words: *Cimex lectularius*, CO_2 fumigation, bedbug, Modified Atmospheres.

1. Introduction

From ancient history the Greeks and Romans times, to early Jewish and Christian writings bedbugs appear in the literature and folklore of many cultures and countries (Usinger, 1966). Although there are several species of blood-feeding bugs which belong to Hemiptera: Cimicidae which have been persistent pests of humans throughout recorded history, only two species are truly associated with humans. The common bed bug, *Cimex lectularius* L. and the tropical bed bug, *Cimex hemipterus* (Fabricius). Their biology is strikingly similar and most life history traits and behavioral aspects of their biology are overlapping. *C. lectularius* can be found in most parts of the world although is less abundant in tropical regions, while *C. hemipterus* is mostly found in tropical to sub-tropical areas mainly within the 30° latitudes (Usinger, 1966).

Bedbugs consume only blood, usually feeding on a mammal (e.g., human, bat) or bird. They need at least one blood meal of adequate volume in each active life stage (instar) to develop to the next stage and to reproduce. There are five nymph stages, and each one may feed multiple times if hosts are readily available. The nymph stage has to feed once to be able to molt into the next stage. The length of the life cycle decreases with temperature up to an optimum of 30°C where it takes 24.2 days to complete (Usinger, 1966). Bedbugs can survive long periods without food and this is also affected by temperature. At 10, 18, 27 and 37°C bedbugs can survive on average for 401.9, 175.6, 43.4 and 17.4 days respectively, if fed once (Usinger, 1966). At low temperature (<10°C) adult bedbugs can survive for a long time without a blood meal. First instars nymphs, when newly hatched, can live up to three months without blood (Usinger, 1966). A fed female lays on average one egg per day (Polanco et al., 2011). It is estimated that bedbugs, at least in theory and under optimal conditions, can lay up to 200 to 500 eggs in a life time (Usinger, 1966).

Adult bedbugs may feed every three to five days throughout their estimated six to 12 month life span. The act of biting a host can cause both physical and psychological discomfort, and can result in local allergic skin reactions to injected salivary proteins (Feingold et al., 1968). Yet, there is no solid evidence bedbugs are disease vectors (Goddard et al., 2009)

When bedbugs have completely engorged, they immediately seek a harborage to hide. They are concealed most of the time; they mate, molt and lay eggs in this cryptic location until they require a blood meal or are disturbed (Usinger, 1966). They prefer harborages that contain aggregation pheromones, which they detect with the pedicel of the antenna (Olson et al., 2009; Siljander et al., 2007), and they prefer the company of conspecifics within their refuges. This aggregation behavior protects the insect from detection by their host, increases the chance of mating and helps reduce the loss of water (Benoit et al., 2007). Their favorite sites are wooden frames in box-spring mattresses, behind skirting, wall sockets and cracks in the wall.

The insect prefers to be active at night time, when the host is most likely to be asleep (Romero et al., 2010) and the risk of detection is minimal, but they are also activated by host cues at daytime (Aak et al., 2014). A host seeking bedbug shows positive thermotaxis, the movement towards an up or

down gradient of temperature, but when engorged show negative thermotaxis (Reinhardt and Siva-Jothy, 2007; Reis and Miller, 2011). This results in the bedbugs spending as little time as possible close to their host where the risk of harm and detection is the greatest. Therefore, their biology and cryptic behavior make it difficult to control.

After World War II, widespread use of synthetic insecticides led to sharp declines in bed bug populations in most industrialized countries. By 1997, they were so scarce in the U.S., Canada and Europe that it was difficult to find fresh specimens to use in teaching college entomology classes (Snetsinger, 1997). Many contemporary Pest Management Professionals (PMPs) with years of experience have never seen an active bed bug infestation. During the past 18-20 years, a resurgence of bedbugs has been reported in the U.S., Canada and European countries, Australia and parts of Africa. Infestations have occurred in homes, hotels, hostels, cruise ships, trains, and long-term care facilities (Cooper and Harlan, 2004; Doggett et al., 2004; Hwang et al., 2005; Johnson, 2005).

The increase in trade, the change in pesticides use from residual and more violent once such as organophosphates and organo-clorides, development of resistance to pesticides, the use of second hand furniture and products and the lack of public awareness has led to re-establishment of the pest worldwide, especially in developed countries (Anders et al., 2010; Akhtar and Isman, 2013).

Each country takes its own measures of treating those bedbugs; in Greece, heat treatment for the whole dwelling is applied. Although heat treatment provides no residual effect, there is a potential physical distortion of structures or their contents, as well as flammability risks associated with some kinds of heat sources, may be a concern in particular situations (Usinger, 1966). Moreover, in order to reach the target temperature of more than 47°C, the residents must evacuate their dwellings since the treatment is a 24 h.

In Israel, the conventional treatment consists of several steps; stripping the room, vacuuming, steaming the mattresses and then spraying with a Pyrethroid. After the treatment all cloths, blankets and pillows are either dry cleaned or being washed at a temperature above 60°C. These actions of vacuuming and steaming textile products such as sofas and mattresses requires a lot of working hours which are not always successful. When applying steam treatments, this technique requires practice and care. If the tip is too far away, the steam may not be hot enough to kill all the bedbugs and eggs that it contacts. If the tip is too close, excess moisture may be injected into the treated material, which may lead to other problems (e.g., facilitating dust mite population survival and increase; growth of surface molds). Sometimes the strength of the steam causes the pest to be spread to other hiding places. This time consuming technique of steaming (10-30 seconds) causes mortality of only 84-94% of all stages, if applied properly (Puckett et al., 2013). Also, if the textile cloths are dried in a home dryer, temperatures in the center do not always reach the target temperature of 50°C. Within the army bases, cold treatment is applied. Yet, each of these measures has its own limitations and disadvantages. For example, exposure to low temperatures can kill bedbugs if they are kept cold enough long enough. Bedbugs can tolerate -15°C for short periods and, if acclimated, they can survive at or below 0°C continuously for several days (Usinger, 1966).

Therefore, as a complementary treatment, in order to eradicate the pest from dwellings, a novel method was developed; instead of steaming the mattress and dry cleaning all textile clothes and products, fumigation of all mobile furniture and textile products with CO_2 inside the dwellings is applied. This novel approach is described in this paper.

2. Materials and methods

During the summer of 2017 several commercial treatments were done in several dwellings in Israel.

All textile products were inserted into sealed flexible low permeability fumigation cubes for three days exposure time at room temperature to reach a calculated concentration of 100% CO_2. The surrounding temperatures were 25-30°C. One 13 m^3 and three 7.8 m^3 flexible fumigation cubes were used to reach, when shrinked, 8, 7.7 and two 5.5 m^3 in accordance. The volume of each flexible

fumigation cube was lowered by using a shrink tape around it. After placing the products inside the fumigation cubes a half life-time pressure decay test was applied by negative pressure to ensure gas-tightness of the cubes. Pressure was reduced from 6 mm H_2O to 3 mm H_2O column. Before connecting the pressure hose, an expansion space was left using a perforated plenum. After connecting the pressure hose to the CO_2 cylinder, the cylinder was placed on a scale to measure the amount of the calculated gas at a dosage of 2 kg CO_2/m^3. While introducing CO_2, at the top end of the opposite gas introduction side, approximately 30 cm diameter area was left open to enable air to exhaust. Measurements were taken from the top during the introduction of the gas.

3. Results

The results shown in Fig. 1 are measurements of CO_2 taken from the top end of the four flexible fumigation cubes each at a volume of 8, 7.7, 5.5 and 5.5 m^3. On average 33 min were needed for the gas purging phase. The amount of CO_2 correlates with its concentration; at the 7.7 m^3 fumigation cube 10.3 kg of CO_2 were purged and 85% CO_2 was obtained. The 5.5 m^3 fumigation cube which reached 85% CO_2 was flushed with 10.3 kg and the second 5.5 m^3 fumigation cube was flushed with 9.5 kg CO_2 to reach 75% CO_2 (Table 1). In the case of the 8 m^3 fumigation cube the cylinder was not placed on a scale.

Since the air is being flushed out, measurements were taken from the top end, indicating the weakest point of concentration. Some measurements were taken from the middle (data not shown) indicating an intermediate concentration.

Since all these fumigation cubes were of small volume, at the end of the treatment, after spraying the dwellings, measurements were taken once again, indicating an even distribution of CO_2.

After exposure time of 72 h, measurements were taken again from the top, middle and bottom (only at the 8 m3 cube) of the fumigation cubes (Table 1). Although calculated dosage was of 100% CO_2, it did not reach it due to sorption by the treated textile products.

Table 1: CO_2 concentration (%) in four flexible fumigation cubes at the beginning of exposure time and at the end, after 72 h, the amount of CO_2 (kg) and the time (min) of half life-time pressure decay test.

Volume of the fumigation cube		8 m^3			7.7 m^3		room # 1 5.5 m^3		room # 2 5.5 m^3	
Location of measurment		Bottom	Middle	Top	Middle	Top	Middle	Top	Middle	Top
[CO2] (%)	T_0	-	82	86	-	85	72	75		85
	T_{72}	82.7	73	75.5	84	81.5	80.9	81	81	77
CO2 (kg)					10.3		9.5		10.3

4. Discussion

Bedbugs (*C. lectularius* L. and *C. hemipterus* F.) are very difficult pests to manage, in part, because of their widespread resistance to insecticides and mostly because of their cryptic behavior (Romero et al., 2007; Zhu et al., 2010). Bedbugs are not limited to sleeping and resting areas such as beds and sofas, instead, literally, anything is susceptible to infestation; from air conditioners outlets, electronics, books, pictures in between sofas (Picture 1) and other household fabrics and equipment. Eliminating bedbugs safely and effectively from these types of items is often more challenging than eliminating bedbugs hiding in cracks and holes in furniture or the structure itself. Therefore either a gaseous treatment is required or physical methods such as heat or cold.

In preliminary laboratory tests by the German Federal Environmental Agency, all life stages of common bedbugs were reportedly killed by constant exposure to very high concentrations of carbon dioxide, at ambient atmospheric pressure, within 24 hours or less (Herrmann et al., 2001). According to Wang et al. (2012), CO_2 fumigation lasting 24-48 h was sufficient to kill all stages of bedbugs at room temperature, depending on the quantity of materials placed in each bag and whether CO_2 was introduced one or two times at the onset.

In these fumigations which were held inside dwellings, in order to ensure both successful treatment and residents' safety, the half life-time pressure decay test is a fundamental step. According to Navarro (1998), in his attempts to correlate gas loss to pressure decay tests, recommended a 5 minutes pressure decay time which were compared with daily CO_2 decay rates of >1% CO_2 daily to obtain successful insect controls (Navarro, 1998). In all of these fumigations, more than 5 minutes were obtained indicating appropriate gastightness for successful treatments (Table 1). Even though pressure tests are not capable of measuring the degree of gas losses through the flexible liner, it still serves as a good indicative measure to predict the degree of gas tightness of the chamber has and whether the fumigation would be successful. It can be understood from Table 1 the significance of this test; there was a decline in gas concentration of 10.5% at the 8 m^3 fumigation cube which obtaind only 6 minutes at the half time pressure decay test. Eventhough that, the results show successful treatment with an acceptable decline in gas concentration (Table 1).

The target concentration of 100 % CO_2 was not achieved due to sorption. Also Wang et al., (2012) could not achieve 100% CO_2 when CO_2 was applied from a cylinder and the bags were filled with fabric materials. In previous cases (data not shown) when purging the gas into the flexible fumigation cube, when the pathway was blocked with a textile products such as duvet it absorbed most of the gas and only after its adsorption target concentration was achieved. Therefore, an expansion space must be kept from the purging point of at least 40-50 cm long with a width of 40 cm. Nevertheless, when placing the shrink tape, it is important to wrap the fumigation cube from the very bottom of it to enable air to be flushed out easily (Picture 2). When placing it not from the very bottom, more gas is needed as it was obtained at the 5.5 m^3 fumigation cube where 10.3 kg of

CO_2 were needed to achieve concentration of 77% CO_2 at the end of exposure time instead of 81% CO_2 with only 9.5 kg of CO_2 (Table 1).

Compared with other insects studied, bedbugs are more sensitive to CO_2 fumigation than other urban insects such as oriental cockroach (*Blatta orientalis* L.) (Gannon et al., 2001), and stored product pests (Navarro, 2006). The relatively short exposure time (2 d) makes CO_2 fumigation a promising technique for eliminating bedbugs from infested household items. In commercial use, the recommended exposure time is of 72 h to ensure mortality. After the conventional treatment of stripping the house, vacuuming and spraying with a pyrethroid the residents may return home and stay at home with no risk.

5. Conclusions

CO_2 is an effective alternative of all life stages of bedbugs compared to conventional fumigants for eliminating bedbugs hiding in infested household items such as clothing, shoes, books, electronics, sofas, and other household items. The CO_2 fumigation may be peformed in one of the empty rooms of the house. There is no need to evacuate the residents from neither their dwellings nor the materials to other places in order to fumigate with poisonous fumigation products, to freezing or heating the chambers.

Abstract

Aflatoxins and fumonisins are fungi metabolites produced when climate conditions are favorable. They contaminate feed ingredients when storage conditions are unfavorable. Aflatoxins and fumonisins have a negative impact on animal health and productivity. Humans are indirectly exposed to mycotoxins when they consume contaminated animal source foods from livestock fed contaminated feeds. A total of 3328 feed samples were collected in all 30 district of Rwanda between March and October 2017. Four categories of participants participated in the study (dairy farmers, poultry farmers, feed processors/grain millers, and feed vendors). Feed samples were highly contaminated with aflatoxins but not fumonisins. Average aflatoxin levels were highest in dairy feeds (108.3 μg/kg) followed by poultry feed (103.81 μg/kg). Average aflatoxin levels were lowest in samples from feed vendors (88.64 μg/kg) compared to samples from feed processors (94.95 μg/kg). This study documents high levels of aflatoxin contamination in feed samples, and recommends year-round surveillance of feed ingredients and mixed feeds for mycotoxin presence. Additionally, more awareness through communication and education needs to be raised among stakeholders in the evolving feed value chain in Rwanda to mitigate the consequences of mycotoxin contamination on public health and animal produtivity.

Keywords: aflatoxins, fumonisins, ELISA, value chain

Introduction

Mycotoxins (e.g., aflatoxins and fumonisins) are secondary metabolites produced by fungi. Aflatoxins are produced by *Aspergillus flavus* and *A. parasiticus* while fumonisins are produced by *Fusarium verticillioides* and *F. proliferatum* in favorable conditions. They contaminate crops especially maize, peanuts and cottonseed throughout sub-Saharan Africa (Binder, Tan, Chin, Handl, & Richard, 2007; Perrone & Gallo, 2017; Richard, 2007). Aflatoxins and fumonisins have a negative impact on human and animal health. Human exposure to these mycotoxins is the result of ingestion of contaminated foods (e.g., maize flour, peanut butter), or indirectly from consumption of animal source foods (e.g., dairy products, eggs) derived from animals previously exposed to aflatoxins in feeds. Aflatoxins are classified as carcinogenic susbtances (IARC, 2002). Fumonisins are associated with neural tube defects, disrupt sphingolipid metabolism and folate transport (Marasas et al., 2004). Fumonisins are also associated with different animal diseases such as Equine Leukoencephalomalacia (ELEM) in horses and Porcine Pulmonary Edema (PPE) in pigs. They are

reported to be nephrotoxic, hepatotoxic and hepatocarcinogenic in a number of livestock and poultry species (Wan Norhas et al., 2009). Mycotoxin feed contamination has attracted worldwide concern due to losses in animal productivity and feed safety (Bryden, 2012; Placinta, D'Mello, & Macdonald, 1999). Different factors contribute to high risk of feed contamination in Africa. Environmental conditions with high relative humidities and temperatures favor fungal growth. Socio-economic status and food production system result in high contamination of feeds (Wagacha & Muthomi, 2008). Feed contamination will not only lead to reduction in animal productivity but will also contribute to milk contamination due to aflatoxin M1 which is the result of aflatoxin B1 metabolism and excreted in milk. A number of studies have reported feed contamination in different African countries (Kang'Ethe & Lang'A, 2009; Mohammed, Munissi, & Nyandoro, 2016; Nyangi et al., 2016). Thus, mycotoxins are a significant risk to animal productivity and food safety in East Africa (Atherstone, Grace, Lindahl, Kang'ethe, & Nelson, 2016). The main objective of this study was to assess the prevalence of aflatoxins and fumonisins in stored animal feeds and ingredients in Rwanda.

Materials and Methods

a. Sample collection

A countrywide survey in all 30 districts of Rwanda was carried out between March and October 2017 targetting four categories of participants: dairy farmers, poultry farmers, feed vendors and feed processors/grain millers. Samples were collected in six rounds by taking approximately 2 kg of feed from each participant who agreed to participate in the study.

b. Sample analysis

All collected feed samples were analyzed using competitive Enzyme-Linked Immunosorbent Assay (ELISA) technique (Catalog #941AFL01M-96 and Catalog #951FUMO01C-96 for Total Aflatoxin Assay and Fumonison ELISA Assay, respectively, Helica Biosystems, Santa Ana, CA, USA).

Results

Table 1. Aflatoxin and fumonisin levels in feed samples collected at different points in the feed value chain.

	Aflatoxins (µg/kg)			Fumonisins (mg/kg)		
	Mean	**SD**	**Median**	**Mean**	**SD**	**Median**
Dairy farmers	109	145	44	1.5	1.8	0.7
Poultry farmers	104	136	48	1.2	1.5	0.6
Feed Vendors	89	129	31	1.5	1.7	0.8
Feed Processors/ Grain Millers	95	103	71	1.0	1.3	0.5

Discussion

Rwanda, a tropical country, offers favorable conditions for mycotoxigenic fungi growth. At all points in the feed value chain high aflatoxin contamination and less fumonisin contamination was documented in samples collected. In this study, the averaged fumonisin contamination was well below the guidance level by the U.S. Food and Drug Administration (USFDA) of 5 mg/kg in maize and maize by-products intended for equids and rabbits.

However, more than 85% of dairy feed samples exceeded the aflatoxin standard of 5 µg/kg for aflatoxin B1 established by Rwanda Standards Board (RSB) standard for feed ingredients. It confirms the concern over aflatoxin contamination in a few feed samples collected from different vendors in Kigali (Rwanda) during a previous study (Nishimwe, Wanjuki, Karangwa, Darnell, & Harvey, 2017). Lack of knowledge and awareness about aflatoxin contamination in grain and feed samples remains a concern. Aflatoxin and fumonisin contamination in animal feeds were also reported in different East African countries (Kang'Ethe & Lang'A, 2009; Mohammed et al., 2016; Nyangi et al., 2016;

Senerwa, 2016). Year-round surveillance and creation of mycotoxin awareness through communication and education along the feed value chain are needed for mitigating mycotoxin contamination in feed value chain of Rwanda.

Development of sensitive polyclonal antibodies against dominant stored wheat grain fungus for its immunological detection

Ranjana Kumari*, Ananta K. Ghosh

Department of Biotechnology, Indian Institute of Technology Kharagpur, 721302, India
*Corresponding author : ranjana@iitkgp.ac.in
DOI 10.5073/jka.2018.463.235

Abstract

Fungal infestation causes deterioration of stored food grains. Most fungal species produce secondary metabolites like aflatoxins which are highly toxic to animals and humans. *Aspergillus flavus* has been found to be the predominant contaminant in stored wheat grains collected from the godowns of Food Corporation of India, West Bengal. The present study focuses on the development of sensitive polyclonal antibodies (PAbs) for molecular immunological detection of dominant toxigenic fungus. Pure *A. flavus* isolate was cultured on

coconut agar media and its spores were harvested and inactivated by 4% formaldehyde. The inactivated spores were injected into a rabbit along with Freund's complete/incomplete adjuvant for the development of PAbs. Specificity of the raised antibodies in rabbit serum was examined by enzyme-linked immunosorbent assay (ELISA) using spore proteins as antigen obtained by bead beating method. Out of several proteins (ranging from 10 to 200 kDa present in spore, only two prominent proteins of around 76 kDa and 100 kDa were detected by western blot analysis using raised polyclonal antiserum. The PAbs were purified with protein A column followed by spore proteins conjugated CNBr activated sepharose column for its use in the detection of fungal antigens. This highly purified raised antibody can be used for the development of rapid, sensitive, and accurate techniques (such as dot blot/ELISA) for the detection of toxigenic fungi present in stored wheat grains.

Keywords: Spore Protein, Polyclonal Antibody, Fungus Detection

Introduction

In India, wheat is the third most produced and consumed cereal grain. It has economic importance as a staple food all over the world. It is a seasonal crop and hence needs to be stored safely as buffer stock for year-round consumption. It is estimated that around 30% of the total grain produced in the country is supplied to government storage house like food corporation of India (FCI) for keeping as buffer stock. Sometimes improper storage and handling can cause huge economical loss. Estimated loss of staple food grains during storage due to different biotic and abiotic factors varies widely. It may account to 10% worldwide but can reach 50% in tropical regions (Magan et al., 2007). The biotic factors of storage loss mainly include fungal infestation. Fungal infestation may lead to loss of seed germination capacity, viability, decoloration, foul smell and change in nutritional value (Birck et al., 2006). The most common fungal species causing grain spoilage in storage are *Eurotium* and *Aspergillus* (Tournas et al., 2018). *Aspergillus* species like *A. flavus* are particularly important because they are able to colonise even at very low moisture content on a range of food matrices, resulting in spoilage, and produce varied group of mycotoxins which may lead to refusal of stored food grains (Sohbatzadeh et al., 2016; Aldars-García et al.,2018). *Aspergillus flavus* can also cause aspergillosis in immune-compromised individuals (Amaike and Keller, 2011). Therefore, determination of the mycological contamination of stored grains is a very important issue as it is destined to be used as food and animal feeds. During the last decade, several direct methods like dilution plating, measurement of volatile compounds, evaluation of ergosterol or chitin level and next gen sequencing (NGS), and indirect methods like randomly amplified polymorphic DNA (RAPD) analysis, amplified ribosomal DNA restriction analysis (ARDRA) and denaturing gradient gel electrophoresis (DGGE) have been developed for the detection of fungi. However, numerous disadvantages are associated with these techniques. The direct methods are time consuming, labor intensive, and require mycological expertise; and are not completely accurate (Gourama and Bullerman, 1995). In indirect methods: it is impossible to distinguish among species or to yield quantitative data (Darling and Blum, 2007). As a consequence, there is a clear and urgent need to develop a new reliable method that will be highly specific, relatively rapid, inexpensive, and replicative. Immunological and molecular techniques offer such an alternative. The immunological method is based on antigen and antibody (either monoclonal /MAb/ or polyclonal /PAb/) interaction. Different sources of fungal material like surface washes from the growth medium, mycelial homogenate and extracellular polysaccharide have been used as antigens for the production of antibody but no study has been done by directly using fungal spore. In current study, we have isolated *A. flavus* fungus from stored wheat grain, developed polyclonal antibodies by directly using inactivated *A. flavus* spore and specificity of antibodies was analysed using ELISA and western blot method.

Materials and Methods

Isolation and characterization of *A. flavus* fungus from stored wheat grain

Stored wheat grains were collected from Food Corporation of India (FCI) godown of West Bengal. The grains were plated on aspergillus differentiation agar (AFPA) media for isolation of *A. flavus*. The fungal isolate was identified by analysing morphological characteristic of colony and sequencing

internal transcribed spacer (ITS) region of ribosomal DNA gene. The ITS region was amplified using universal (ITS1 and ITS4) primer set by PCR, then cloned in pTZ57R/T vector (Fermentas Life Sciences, EU) and sequenced in DNA sequencer (ABI 3500, USA). Homology search of nucleotide sequence was performed against the Genbank database for identication of fungal species.

Spores collection and inactivation

The identified *A. flavus* isolate was cultured on coconut agar media [100ml coconut milk and 2% agar] for 7 days at 28°C. The spores were collected in 1xPBS containing 0.1% tween 80. It was then inactivated by keeping in 4% formaldehyde solution, for 5 days at 4°C and followed by several wash with PBS. The inactivated spores were cultured on PDA media for 7 days at 28°C for analysis of inactivation efficiency. The spore density was calculated on haemocytometer under microscope.

Generation of polycolonal antiserum against inactivated spore

Polyclonal antiserum against inactivated *A. flavus* spore proteins was raised by immunization of rabbit (New Zealand) using the standard 6-month antibody production protocol. 10^8 spore per injection in Freund's complete adjuvant was subcutaneously injected for the first time and then in Freund's incomplete adjuvant for subsequent injections (at an interval of four weeks). Blood was collected 10 days after every injection. Sera were harvested by centrifugation at 3000 g for 15 minutes after allowing blood to clot for one hour at 37°C. Sera were stored at −20°C till use. Immunization and blood harvest protocols were followed as per IAEC guideline approval.

Preparation of immunoglobulin fraction from rabbit serum

Sera were first subjected to overnight precipitation at 4°C with ammonium sulphate at 50% saturation and then centrifugation at 5000g for 30 minutes at 4°C. The pellet was resuspended in appropriate volume in binding buffer (0.1 M Tris-Cl pH 8.0) and dialysed using 10 kDa cut off membrane against 1 L of binding buffer for 16 hours at 4°C to remove ammonium sulphate.

Protein-A affinity chromatography

Immunoglobulin rich fraction obtained after dialysis with binding buffer was loaded into a column containing protein A sepharose. Non-specifically bound contaminants were removed by washing with 5 column volumes of binding buffer and then bound IgG were eluted in 1 mL fractions with elution buffer (0.1 M Tris-glycine pH 2.4) into 1.5 mL tubes containing 200 µL of 1 M Tris-Cl pH 9.0 for neutralization. Fractions containing the IgG were checked by measuring OD at 280 nm, then pooled together and concentrated by using centicon YM-50.

Extraction of *A. flavus* spore protein

Spores proteins were extracted by bead beating method (Jenkinson et al., 1981). In brief, about 10^{10} spores were homogenised in 1 mL of extraction buffer [20 mM Tris-Cl (pH 8.0), 1 mM EDTA (pH 8.0) and 2% SDS] with 0.3 mg of glass bead (300 nm size), and then lysed in bead beater for 5 min and then incubated for 5 min in boiling water. Spores debris was pelleted by centrifugation, and the supernatant were analysed in 10% SDS PAGE.

Purification of anti spore protein specific immunoglobulin

Aspergillus flavus spore protein lysate was coupled to cyanogen bromide (CNBr) activated sepharose 4B (GE healthcare) as per manufacturer's protocol. In brief, CNBr activated sepharose CL 4B freeze dried powder (0.5 g) was suspended and subsequently washed with 150 mL of 1 mM HCl. The isolated spore proteins were dialyed in buffer (0.1 M $NaHCO_3$, pH 8.3 with 0.5 M NaCl). 5 mL of dialyed proteins (10 mg/mL) was coupled to activate CNBr sepharose beads by keeping on rotor for overnight at 4°C. The entire material was then transferred to a small glass column, washed and remaining active sites on the beads were blocked by suspending beads in 0.1 M Tris-Cl buffer (pH

8.3) for 2 h at room temperature. The loosely bound antigen was removed by washing with three cycles of alternating pH; each cycle consisting of a wash with acetate buffer (0.1 M, pH 4.0) containing 0.5 M NaCl, followed by wash with Tris-Cl buffer (0.1 M, pH 8.0) containing 0.5 M NaCl. The cupling of antigen in the bead was checked by analyzing an aliquot of antigen coupled beads on 10% SDS-PAGE. Prior to affinity purification, the column was equilibrated with binding buffer (0.1 M Tris-Cl, pH 8.0). Protein A purified immunoglobulin fraction was loaded into the column and unbound antibodies were allowed to pass through and the column was washed with binding buffer until the A 280 of the flow through became negligible. The specific antibody boundto column was eluted with 0.1 M glycine, pH 2.4 and fractions (1ml) were collected in microfuge tubes containing 200 µL of 1 M Tris-Cl pH 9.0 for neutralization. The fractions with A 280 greater than 0.2 (measured using Nanodrop) were pooled together and concentrated by passing through centricon YM- 50 (Millipore) and was checked by 10% SDS PAGE.

Western blot analysis

Western blot analysis was carried out based on protocol suggested by Mahmood and Yang, (2012). *Aspergillus flavus* spore protein lysate was run on 10% SDS PAGE. The proteins were blotted onto nitrocellulose membrane using Mini Trans-Blot ® Cell (Biorad) operated at 20 V for 14 h at room temperature. After the transfer, membrane was blocked with blocking buffer (1XPBS containing 0.05% Tween-20 (PBST) and 3% BSA) for 3 h at room temperature. Membrane was then washed three times using PBST and treated with anti *A. flavus* spore proteins specific affinity purified antibody 1 µg/mL (1:500 dilution) in PBST containing 1% BSA for 3 h at room temperature. Following three times wash with wash buffer; secondary reagent (Protein-A HRP conjugate, GE lifesciences) was added at 1:3000 dilutions in PBST containing 1% BSA and incubated for 2 h at room temperature. After three times wash with wash buffer; colour was developed using Opti-4CN substrate (Biorad) until signal with sufficient intensity was obtained. Reaction was stopped by rinsing the membrane thoroughly with deionised water and then photographed.

Enzyme linked immunosorbent assay (ELISA)

Wells of 96 well ELISA plates (Tarsons, U bottom well) were coated with 100 µL/mL of antigen (spore protein lysate) suspended in coating buffer (0.1 M bicarbonate buffer pH 9.6) for overnight at 4°C. Wells were washed thrice with PBST to remove unbound antigen. Wells were then blocked with 200 µL of blocking buffer (PBST with 3% BSA) for 3 h at room temperature. Wells were washed thrice with washing buffer and 100 µl of 1 µg/mL anti *A. flavus* spore proteins specific affinity purified antibody (1:500 dilutions) in PBST containing 1% BSA was added and incubated at room temperature for 2 h. Following three times wash with wash buffer, 100 µL each of secondary reagents (Protein-A HRP conjugate, GE lifesciences) was added at 1:1000 dilutions and incubated at room temperature for 2 h. Following washing, colour was developed using 100 µL of ABTS substrate (Sigma) along with 1 µL of 30% H_2O_2. Absorbance of the wells was read at 415 nm using microplate ELISA reader (Multiskan spectrum, Thermoscientific).

Results

Identification *A. flavus* fungus

Aspergillus differentiation agar (AFPA) media is a selective media for the enumeration and identification of *A. flavus* and *A. parasiticus* fungus *(*Pitt et al., 1983). The morphological analysis of *A. flavus* showed orange-yellow reverse colony pigmentation on *AFPA* media, colony appeared with globose to sub-globose vesicles and spore showed biseriate seriations, which is a characteristic colony features of *A. flavus* species as described by Klich (2002) (Fig.1). Further, ITS sequence analysis showed 100% query coverage and identity with the repoted ITS sequence for *A. flavus* and confirming its correct identification.

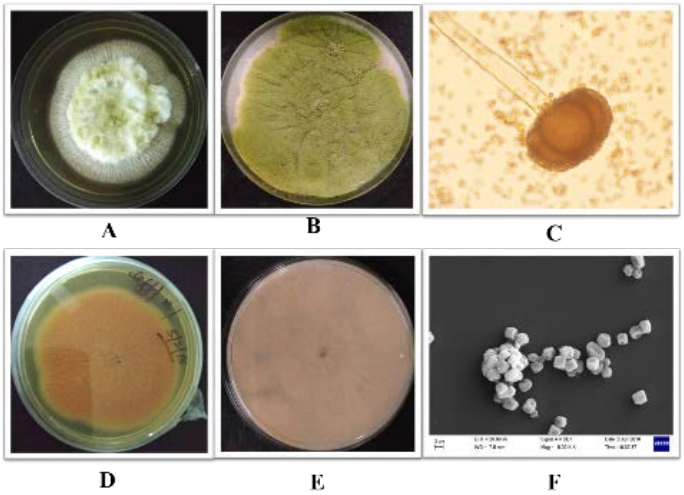

Fig.1. Analysis of *A. flavus* colony characteristics on culture media. A & D' front and reverse view on AFPA. B & E, front and reverse view on coconut media. C, microscopic characteristics of conidial ornamentation on hyphae. F, Spore morphology analysis in SEM.

Purification of anti spore protein Immunoglobulin

SDS PAGE analysis of Immunoglobulin protein fractions obtain after purification through protein A affinity column and through antigen affinity (spore protein) conjugated CNBr column also showed two sharp bands at 50 kDa and 25 kDa corresponding to the heavy and light chains of Immunoglobulin respectively indicating the successful purification of anti spore protein immunolo antibodies (Fig.2). The crude serum protein percipited using 50% ammonium sulphate solution. It showed smear of protein band through out the lane which indicated precipitation of several other proteins along with immunoglobulin. Futher purification through potein A column discarded other proteins and allowed purification of immunoglobulin proteins. The eluted immunoglobulin fraction was passed though the antigen conjugated CNBr activated sepharose column and purification of anti spore proteins antibodies was done.

Analysis of anti spore specific antibody for detection of A. *flavus*

The lysate of spore proteins run on 10% SDS PAGE showed several protein bands ranging from 10 kDa to 200 kDa (Fig.3A). The same amount of proteins was run in 10% SDS PAGE and trans bloted on nitrocellulose membrane. The blot showed two prominent proteins bands of around 76 kDa and 100 kDa (Fig.3B.).

Detection of *A. flavus* fungus by ELISA

The sensitivity of antibody for detection of spore protein was determined by indirect ELISA method. The protein concentration ranging form 10 µg /mL to 200 µg /mL in carbonte buffer were used for detection of sensitivity of antibody. The minimal detectable concentration of antigen was 20 µg /mL.

Discussion

India falls in tropical region, where fungal infestation is widely prevelent in pre and post harvested crops. It is estimated that approximately 25–50% of harvested food and feed gets contaminated with mycotoxins (Abdin et al., 2010). In present study, *A. flavus* species was isolated from stored wheat grains, and characterized by morphological and molecular method. Zulkifli and Zakaria, (2017) have suggested that to identify a fungus at species level, both morphological and molecular identification should be applied because for some species, morphological characteristics may be similar. Internal transcribed spacer (ITS) region of ribosomal gene is a universal barcode for molecular identification of fungal species (Pryce et al., 2003). Combination of morphological identification and sequencing of ITS can reliably identify Aspergillus isolates to species level.

Aspergillus flavus can produce aflatoxins, which is a toxic and carcinogenic secondary metabolite, and their contamination in food grains can adversly affect its quality and usability (Sun et al., 2016). Fungus produces sexual/asexual spores, in order to survive for long term in adverse physiological and environmental conditions. It is a key attribute for fungal reproduction, persistence, and dispersal. Therefore, spore would be a suitable antigen for immunological detection of fungal contaminants in stored grains. Polyclonal antibodies were raised against whole inactivated *A. flavus* spore in rabbit and purified through protein-A column followed by antigen affinity chromatography. Resulting antibody showed high specificity against *A. flavus* fungus as seen from the results of western blot where strong positive reaction of antibodies against two spore proteins were visualized. Further, these antibodies were again tested for sensitive ELISA for detection of *A. flavus*. These polyclonal antibodies can be used for the development of a specific and sensitive technique like dot blot ELISA for monitoring fungal contamination level in stored grains.

Smallholder farmers' perceptions of aflatoxins in maize in kamuli district, Uganda

Rachael Barnes, Thomas Brumm, Dirk E. Maier, Shweta Chopra

Department of Agricultural and Biological Systems Engineering, Iowa State University, Ames, IA USA

DOI 10.5073/jka.2018.463.236

Extended Abstract

Keywords: postharvest, harmful effects, mold, outreach, education

Aflatoxins are a family of highly toxic and carcinogenic compounds produced by fungi commonly found on maize. Aflatoxins have been estimated to be widespread in maize in Africa (Wagacha and Muthomi, 2008). Consumption of aflatoxins in foods is associated with liver cancer in adults and stunted growth and development in children. Studies have shown that over 50% of maize in Ugandan markets contain over 10 ppb aflatoxins, the safety limit set by Uganda National Bureau of Standards. Present in maize fields, these fungi (molds) continue to grow on maize when it is insufficiently dried and then stored, thereby increasing aflatoxin levels. Maize is an important staple crop for smallholder farmers. They often have difficulty properly drying and storing maize and thus face the risk of aflatoxin consumption. Previous published studies revealed that many smallholder farmers do not know what aflatoxin is nor the risks they face from it (e.g., Magembe et al., 2016).

Iowa State University Uganda Program (ISU-UP) works in smallholder farmer communities in the Kamuli district of Uganda to improve peoples' health, nutrition and rural livelihoods (www.csrl.cals.iastate.edu). It operates eight Nutrition Education Centers (NECs) where pregnant women and mothers of nutritionally challenged children within their first 1000 days of life can

receive nutritious meals. Mothers are instructed about nutrition and health issues and how to grow and serve nutritious food to their families. Once their children are no longer at nutritional risk, they "graduate" from the program and no longer receive assistance. Nearly all these women or their spouses/partners are smallholder farmers. Additionally, ISU-UP works with other smallholder farmers in the community to improve their livelihood through livestock and improved agricultural practices. ISU-UP will be starting outreach programs in postharvest techniques and practices, providing education in how to reduce postharvest losses and protect themselves against spoilage and the risk of aflatoxin.

This study sought to understand the perceptions and knowledge of smallholder farmers in the Kamuli District of Uganda about their postharvest practices and specifically about aflatoxin to establish a baseline for evaluating future postharvest outreach programs.

During the summer of 2017, 109 face-to-face interviews were conducted with smallholder farmers in the Kamuli District of Uganda with the use of an interpreter. Interviewees were chosen by stratified sampling methods and interviewees shared the characteristic of growing maize. 60 smallholder farmers were chosen at random and 49 were members of an ISU-UP Nutrition Education Center. At least ten farmers were interviewed in each of seven parishes in the Butansi and Namasagali sub-counties. 102 interviews resulted in complete data for analyses. The demographic distribution of the interviewees is shown in Table 1.

Interviewees were asked 37 open-ended questions that took an average of 30 minutes. Responses were transcribed into English. Transcripts were analyzed using grounded theory methodology to identify emergent themes in farmer perception and knowledge of aflatoxins, maize drying, and maize storage practices. Statistical analysis of associations between demographic characteristics and response frequencies used the chi-square test of independence with statistical significance declared at $p < 0.05$.

Table 1. Number of study interviewees by category (n = 102)

Gender	**Female**	**Male**		
	83	19		
Age Group	**18 to 29**	**30 to 39**	**40 to 49**	**50 and over**
	29	30	18	25
Education	**None**	**Primary School**	**Secondary School**	
	23	56	23	
NEC Membership	**Current**	**Graduate**	**None**	
	31	14	57	

Table 2 summarizes the results of the survey relevant to interviewees knowledge of aflatoxin. There were no significant differences in responses due to gender, age, education, or NEC membership for the questions "have you heard of the word aflatoxin," and "are you aware of aflatoxin contamination in crops." Nearly all participants had heard of aflatoxin before, which is different than previous published studies that showed smallholder farmers generally unaware of aflatoxin. When asked if they were "aware of harmful effects of aflatoxin in humans" there was a significant difference between male and female responses – all males said they were aware and only 71% of the females said they were aware. There were no differences in responses due to age, education of NEC membership.

Table 2. Interviewees awareness of aflatoxin

Question	**Female (n=83)**	**Male (n=19)**
Have you heard of the word aflatoxin?	Yes: 92%	Yes: 100%
Are you aware of harmful effects of aflatoxin in humans?	Yes: 71%	Yes: 100%

When asked what the harmful effects on humans were, it was difficult for farmers to correctly articulate those effects (Table 3). There were several misperceptions about the effect of mycotoxins

on human health. While 36% correctly identified "disease," they could not describe the kind of disease. Only 1% identified cancer.

Table 3. Harmful effects perceived by those aware of harmful effects in humans (n=78).

Disease	Stomach Ache	Don't Know	Diarrhea	Bad Smell	Malaria	Loss of Taste	Cancer
36%	25%	8%	6%	4%	3%	2%	1%

The farmers in this study were also asked about postharvest practices that might affect their exposure to aflatoxin. Although the visual presence or absence of mold does not determine the presence or absence of aflatoxin, moldy maize has a higher probability of the presence of aflatoxin. When asked if they "check for moldy maize before feeding to your family," 79% indicated yes and 21% indicated no, with no significant difference between gender, age, education or NEC membership. When asked what they do with moldy maize, a variety of responses were obtained (Table 4). Many of these actions do not reduce the risk of exposure of people or animals to aflatoxin.

Table 4. What interviewees that check for moldy maize do with it when they find it (n=96)

Discard	Animal Feed	Human Food	Mill it	Sell it	Dry Before Use	Blend w/ non-moldy maize
44%	18%	15%	9%	7%	5%	2%

92 % of the farmers indicated that they try to avoid moldy maize. These farmers were asked what they do to avoid moldy maize (Table 5). Most farmers said they repeatedly dried the maize.

Table 5. Practices used to avoid mold in maize (n=94)

Repeat Drying	Nothing	Avoid long-term storage	Dry before storage	Add Red Pepper
71%	11%	10%	2%	1%

From these results, it is clear that there were numerous misunderstandings about aflatoxin, its effect on humans and practices that could be adopted to limit the risk of exposure to aflatoxin. Women smallholder farmers were significantly less aware (only 71%) that aflatoxin had harmful effects on humans, yet they are often the ones that are feeding their families. There exists a clear and important need to educate smallholder farmers in the Kamuli District of Uganda about the dangers of aflatoxin and the postharvest measures that could be taken to prevent exposure. These results provide further impetus for ISU-UP to implement outreach education programs. The Nutrition Education Centers are a good first place to start. Future surveys will follow up with these interviewees to determine the effectiveness of these programs.

The mycoflora of bulk stored cocoa

Daniela Bartels

DOI 10.5073/jka.2018.463.237

In modern times, agricultural commodities are handled in ever-growing volumes. Nowadays not only cereals but further soft commodities like raw coffee and cocoa are transported as bulk cargo in containers or directly stowed into a ship's hold and stored in silos or bulk stores. This change of environmental conditions impacts upon the development of stored product pests. A typically encountered implication is the incidental occurence en masse of fungivorous beetle species, which becomes especially conspiciuous when the lot is moved. At that point, the initial area of infestation is hardly traceable.

The mycoflora of bulk stored cocoa in the Port of Hamburg was investigated from winter 2013/2014 till late autumn 2014. The survey was conducted as part of a research project, which aimed at developing a integrated concept for protection of bulk stored commodities and was funded by the State Ministry of Economic Affairs, Transport and Innovation of the City of Hamburg. It was shown that growth of mycotoxin producing Aspergilli and other spoilage causing fungal species is not only a problem of storage in the producing countries. The specific characteristics of bulk stored commodities can form a variety of different microhabitats within a lot. Furthermore, frequently found species like Aspergillus ruber can act as a door opener for more fastidious fungi and insects.

Borderline Cases between Biocidal Products Regulation and Plant Protection Products Regulation

Carsten Dogs

Detia Freyberg GmbH Head of Regulatory Affairs, Dr.-Werner-Freyberg-Str. 11, D-69514 Laudenbach, Germany,
E-Mail: carsten_dogs@detia-degesch.de

Extended abstract

Keywords: borderline cases, biocidal products, plant protection products

Introduction - background

Legislation on the Single Market for goods aims to ensure that products placed on the EU market meet high health, safety and environmental requirements and that products allowed to be sold in the EU can circulate without barriers to trade, and with a minimum of administrative burden.

Plant protection products and biocidal products are used by professionals and non-professionals on harmful organisms, to destroy, deter or render them harmless. Before they can be placed on the market, the authorities are responsible among others for assessing the effectiveness of these products and the risks associated with their use.

Plant protection products are 'pesticides' that protect crops or desirable or useful plants. They will primarily be used in the agricultural sector but also in forestry, horticulture, amenity areas and in home gardens. Relevant function from a fumigation company point of view: protect plants or plant products against pests after harvest.

Regulation (EC) No 1107/2009 is the legislation concerning the placing of plant protection products (PPPs) on the market in the European Union.

Biocidal products used to control unwanted organisms that are harmful to human or animal health, or that cause damage to materials (e.g. dams and dikes). These harmful organisms include pests (e.g. insects, rats or mice) and microorganisms (e.g. moulds or bacteria).

Regulation (EC) No 528/2012 lays down the rules and procedures for authorization of biocidal products.

Both plant protection products and biocidal products contain at least one active substance. Before an active substance can be used within these kind of product in the European Union it must be officially approved.

Borderline cases

The determination of clear borderlines between the Plant Protection Products Regulation (EC) 1107/2009 and the Biocidal Products Regulation (EU) No 528/2012 is determined as a crucial issue for a proper implementation of both legislations. Sometimes difficulties may arise to decide which Directive applies to a given product and use.

The following criteria could be help to examine regarding the area of application:

- The intended purpose of the product.

- The target organism
  - If it is harmful to plant products, then the product wil be considered as a plant protection product.
  - If it is harmful to humans or material (e.g. dams and dikes), then the product can be considered as a biocidal product.
- The place where the product will be applied to achieve the principal intended action.
  - Example: Products applied to the soil before sowing or planting of plants, are intended to destroy plant pests, and should considered as plant protection products (e.g. soil fumigants).
  - In cases where products will be used for a general hygiene purpose (health protection), it is agreed, to consider these products as biocidal products (e.g. fumigants used in storage rooms for food).

Several documents to provide guidance to Member States on borderline cases are available. On the other hand, they are not legally binding since only the Court of Justice can give an authoritative interpretation of existing Community law. For instance, under the biocides legislation where the scope of the application is unclear, issues will be discussed at EU level.

In former times, when the EU Commission finalised decisions on scope issues, these were included in the Biocidal Manual of Decisions. Numerous borderline situations were settled in this document. Since 2015, this guidance provided in the Manual of Decision is obsolete. Now all information with regard to the submission process can be found on the European Chemicals Agency (ECHA) website (responsible for biocides).

Nevertheless, the Manual of Decision is still always a helpful tool for the industry to identify the correct regulatory scope. Again, this guidance is not law: it is not binding.

Practical example

Recently we had a question regarding the regulatory differentiation of the treatment of tobacco (storage protection, fumigation with phosphine-based products).

Status

In the beforehand mentioned biocidal Manual of Decision it was mentioned under 2.1.1.2.:

"According to the Guidance Document 2 on the borderline between biocides and plant protection products, products in the unprocessed state or having undergone only simple preparation such as milling, drying or pressing, derived from plants, but excluding plants themselves are plant products in the meaning of the Plant Protection Products Directive.

If the target organism is detrimental to plant or plant products then the product used is considered as a plant protection product either if applied directly on plants or plants products or applied indirectly on empty structures to control pests of plant or plants products exclusively."

Reversal conclusion would mean that in case further processing steps are required it falls under the scope of the Biocides Regulation (EC) No 528/2012.

Tobacco

All tobacco are different, especially when it comes to curing the leaves. At first harvesting tobacco must be dried and cured. For instance, Virginia tobacco will dried by `flue-curing` where the leaves are hung for four to seven days in a drying barn and cured with warm air from a system of pipes. This drying process fixes the characteristic orange-yellow colour.

After tobacco cured, it will moved from the curing barn into a storage area for processing (e.g. involving several weeks of fermentation). The curing and fermentation processes establish the quality differences between tobaccos. While `drying` may seem like a basic process, the end result is open to infinite variety, reflecting the weather and nutrients in the soil during growing, individual skill and expertise, as well as the type of drying process used.

Conclusions

Due to the fact there are definitely several steps within this treatment needed, it should fall into the above-mentioned Biocide Regulation. For fumigation purposes, only biocide products for product type 18 should be used, which have an approval.

Official feedback given by the German Authority BAuA (Federal Institute for Occupational Safety and Health):

"The storage protection of processed tobacco and tobacco products falls into the regulatory scope of the Regulation (EC) No 528/2012 and it needs a biocide approval. "Processed tobacco" correlates to tobacco after the pass of fermentation, which is in our opinion no simple pass."

ECHA confirmed this opinion too:

"The German competent authority has the possibility to consult with the other national competent authorities and/or to raise formally the issue to the European Commission by requesting a decision according to Article 3 (3) of the Biocidal Products Regulation. The fact that the German competent authority has not made a request for an Article 3 (3) decision indicate that they are confident in the validity of the answer they have provided you with."

Future prospects

However, a same product can be used in several situations and fall under both legislations. Dual authorizations would mean two dossiers, two contacts with different rapporteur Member States respectively evaluating Competent Authorities and two fees. Objective should be a better coordination at EU level and experience sharing between the Member States within the European Union.

A distinct answer by the legislator is required, under which regulatory scope the registration process should be started.

We need a pragmatic solution for the fumigation industry to reduce regulatory workload and costs.

To avoid any confusion the industry would welcome a solution again, consisting of a document or database compiling all the answers relating to possible borderline cases. We need clear regulatory guidance.

Customer complaints about insect contaminated ready meals

Lidia Limonta*, Sara Savoldelli, Daria P. Locatelli

DeFENS, Department of Food, Environmental and Nutritional Sciences, Università degli Studi di Milano, Via Celoria 2, 20133 Milan, Italy,
*Corresponding author: lidia.limonta@unimi.it
DOI 10.5073/jka.2018.463.239

Abstract

More than one-hundred food complaints about ready meals, coming from mass catering, were analyzed from 2003 to 2017. Even if insects in meals have an enormous negative impact on customers, the percentage relevance, considering the long period and the number of meals served, is negligible. Coleoptera (34%) was the most represented order, followed by Lepidoptera (27%), and Diptera (23%). Coleoptera insects were mainly field

pests, found in salads and spinach, moths were represented by species infesting vegetables (58%) and by stored product pests (42%). Species of hygienic concern were found in Diptera. Few cases of cockroach contamination were reported on different food, but it is important to underline their presence in the meal, as it indicates a heavy environmental infestation and a high hygienic risk.

Keywords: mass catering, food serving, canteen, stored product pests, field pests.

1. Introduction

In Italy, mass catering is worth 6.6 billion euros and each day more than 5 million citizens lunch in schools, hospitals, and companies canteens (Anonymous, 2016). In 2016, Italian mass catering companies amount to 3117 (FIPE, 2017) and provide lunch formed by one portion of pasta or rice, one portion of meat, eggs or fish with vegetables, a piece of bread and fruit.

Complaints about ready meals from customers concern sanitary and hygienic aspects, including insects (Balzaretti and Locatelli, 1993). Insects that contaminate processed food can originate in crops, food industries, and stores (Trematerra and Fleurat-Lessard, 2015). The presence of insect in food repulses consumers and moreover, pests can cause hygienic problems, e.g. cockroaches, domestic flies, and rodents can contaminate food with pathogens (Gorham, 1991). Furthermore, the detection of pests in meals served to children in school canteens is often reported on TV and local press.

Complaints about insects in ready meals served in companies and school canteens, and delivered to Department of Food, Environmental and Nutritional Sciences, Università degli Studi di Milano over the last years, were analyzed.

2. Materials and Methods

Contaminated ready meals, coming from mass catering, were analyzed in the entomological laboratory of University of Milan from 2003 to 2017. Samples delivered by companies following customer complaints amount to 107. The insects were cooked with the food and most of the times the specimens were damaged and lacked features important for identification to species.

3. Results

The insects present in the contaminated samples were mainly Coleoptera (33.6%), followed by Lepidoptera (27.1%), and Diptera (23.4%). Coleoptera were principally field pests, found in salads and spinach, moths were represented by species infesting vegetables (57.7%) and by stored product pests (42.3%).

In table 1, complaints are grouped according to the environment infested. Almost half complaints concern field pests, stored product pests correspond to 23.4%. Occasional pests are predators or parasitoid insects, that are not directly linked to the food. In sanitary concern insects, flies and cockroaches are grouped. In one school canteen, a student found a head-louse in one serving of pasta. Evidently, it came not from the kitchen, where workers wear caps, but from a student's head, as in the primary schools, head-louse problems are seasonally common.

Tab. 1 Percentage of insects detected in ready meals, grouped according to the colonized environment (n=107).

Origin of the insect	Percentage (%)
Field	49.5
Stored product	23.4
Occasional	7.5
Sanitary concern	19.6
Total	100

All food courses were contaminated by insects, but vegetables constitute 40.2% complaints (table 2). Coleoptera adults and moth larvae were detected in salad and spinach, as they can hide among the leaves. Larva of *Tuta absoluta* (Meyrick) (Lepidoptera: Gelechiidae) was recorded in a tomato

salad. In pasta and rice, *Plodia interpunctella* (Hübner) (Lepidoptera: Pyralidae) larvae were mainly found; in a few cases, adults of *Sitophilus oryzae* (L.) (Coleoptera: Dryophthoridae), *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae) and *Lasioderma serricorne* (F.) (Coleoptera: Anobiidae) were detected.

Tab. 2 Percentage of courses were insects were detected (n=107).

Food type	Percentage (%)
Bread	10.3
Pasta or rice	28.0
Meat, fish	19.6
Vegetables	40.2
Fruit	1.9
Total	100

In pasta with vegetables, field pests were recorded, e.g. wireworm and noctuids larvae. One adult of *Fannia canicularis* (L.) (Diptera: Faniidae) contaminated one serving of pasta with tomato.

In portions of cooked meat or fish, the main contaminants are flesh-flies or blowflies adults. Only in two cases, field pests were found, coming from the vegetables used in the recipe. An adult of *L. serricorne* was detected in one serving of meat cooked with spices. Larvae of *Piophila casei* (L.) (Diptera: Piophilidae) were present in ham plates.

Contaminants of bread belong to different categories. Only three contaminants are flour pests, in three cases insects are of hygienic concern, that is, adults of *Blatta orientalis* L. (Dictyoptera: Blattidae) and *F. canicularis*. Hymenoptera also were recorded, e.g. a parasitoid, an ant and one head of *Polistes* sp. (Hymenoptera: Apocrita: Vespidae).

Only in two cases complaints concerned fruit serving: an adult fruit fly in a fruit salad and one *Periplaneta americana* (L.) (Dictyoptera: Blattidae) adult found by the consumer picking the fruit from a crate.

4. Discussion

Even if the detection of extraneous materials in food rarely happens, this fact causes significant loss of revenue and image to the companies involved. Among foreign matter reported in food, insects are considered one of the most important problems (Lewis, 1993; Edwards and Stringer, 2007). In the cases we reported, insects were detected only in one portion, not in the daily production, and the number of samples, considering the long period of time is negligible.

Insects that contaminate processed food can originate in crops, food industries, and stores (Trematerra and Fleurat-Lessard, 2015, Limonta et al., 2016). The presence of insect in food repulses consumers and moreover, the presence of pests can cause hygienic problems, e.g. cockroaches, domestic flies, and rodents can contaminate food with pathogens (Macovei et al., 2008; Sulaiman et al., 2011; Pava-Ripoll et al., 2012; Wasala et al., 2013). Insects of hygienic concern in this work are mainly represented by Diptera, but also few cases of cockroach contamination were reported on different food. It is important to underline their presence in the meal, as it indicates a heavy environmental infestation and the possibility that good sanitation practices were not strictly followed.

The presence of field insects in vegetables, in particular, if the insect hides inside or in folded leaves, can easily go undected if there is only one specimen. The matter is different when all the servings are contaminated, as it means that the crop wasn't correctly managed and the kitchen assistants didn't properly control and wash the vegetables.

Staff training is essential, as a careful examination of ingredients and of meals by kitchen assistants that serve food will greatly limit the risk of contamination. The adoption of good practices and regular monitoring is mandatory to guarantee safe meals.

Abstract

Loss in quality and quantities of rice during storage is an important issue to focus on. Moulds contaminating rice were investigated and their injuries on rice during storage were evaluated. Local and imported rice samples sold in markets and mills were stored for 3 months under laboratory conditions. The contaminated grains were counted and analyzed to characterize storage moulds.

All rice samples evaluated were contaminated by moulds, right from sampling date. The quantity of mouldy grains varied from 1.1% for the rice sample from UNVDA to 4.2% rice brand 'Main dans la Main'. The highest mould infestation in terms of quality and quantity, was recorded on imported rice samples of world rice and 'Main dans la Main' 22.3 and 25.3% respectively; meanwhile 'Tox 3145 parboiled', Uncle Benz and Neima presented 7.5, 8.9 and8.9% respectively.

In general, imported rice samples contained the highest fungal load with a proportion of 65.9% compared to 34.3% for local samples. Among the 67 isolated strains, the genus *Aspergillus* dominated, followed by *Penicillium, Mucor* and *Circinella* with 13.4, 8.9, and 4.4% respectively. Therefore in Cameroon, some locally produced, but mostly some imported rice contain moulds from different genera, which damage rice at different proportions. It is urgent to develop methods to inhibit the growth of potential storage moulds and preserve the quality of rice consumed.

Keys words: Rice, contamination, storage, loss, quality.

1. Introduction

Rice (*Oryza*spp) is the third most widely cultivated cereal in the world after maize and wheat and with an estimate production of 430, 865 and 695mt respectively (FAOSTAT, 2012). Rice constitutes a staple food for half of the world's population. Today, rice is a commodity of strategic significance across many African countries (Hegde and Hegde, 2013), driven by changing food preference in the urban and rural areas and compounded by increased urbanization (Khalil *et al.,* 2009).

About 90% of world's rice is produced in Asia (Food and Agricultural Organization [FAO], 2015. To satisfy their increasing demand with a low production, African countries, particularly west and central Africa import large quantities of rice from Asia (Seck*et al*., 2010; Otsuka and Kijima 2010).

The physical quality of rice is determined by biophysical factors such as the agro-ecological zone of production and production system and by the production practices (Mapiemfu-Lamare 2017). Rice storage problems are very often caused by inadequacies during prior phases, particularly inadequate harvesting and drying (Saunders *et al*., 1978; Barnabas *et al*., 2008; Bala*et al*., 2010). Also, poor rice parboiling can lead to loss at storage (Diop*et al*., 1997; Fofana*et al*., 2011; Ogunbiyi, 2011; Ndindeng *et al*., 2014; 2015). Improper rice storage can lead to both quantitative and qualitative losses caused by pests, insects, rodents, sprouting, discoloration or contamination of grains with unwanted materials or substances. A large amount of rice is lost during storage, 1 - 100% of the total harvest (Hall, 1970; Schulten, 1975; Hopf*et al.,* 1976; Adams and Harman, 1977; De Padua, 1977; FAO and UNECA, 1977; Green, 1977; Harris and Lindblad, 1977; Mushi, 1978; Ren-Yong *et al*., 1990; IRRI, 1997; Appiah *et al*., 2011).

Hermetic storage in airtight bags significantly improves storage by protecting rice from rodents, insects and fungal infestation, but are not currently used in local mills or markets (Jones *et al*., 2011; Gitonga*et al*., 2013).

Grain losses may occur in storage due to moisture losses, rodents, insect infestation and fungal growth and subsequent price discounts for damaged grain (Kaminski and Christiaensen 2014; Kadjo*et al*., 2015; Kadjo*et al*., 2016). In addition, rice sold in markets or mills being it imported or locally produced are usually packaged in jute or plastic bags of 5, 10, 25 or 50 kg stored in inappropriate conditions; open to insects and rodents, high humidity etc. leading to the development of moulds.

This work studies moulds in order to estimate loss of the quality of rice grains locally produced and imported, during storage.

2. Material and Methods

2.1 Rice Samples

Plant material was rice grains: paddy grains or milled rice. Rice samples were collected from mills in Ndop rice development hub (RDH) in Cameroon and in the Mokolo market in Yaounde (a major urban consumption zone and the political capital of Cameroon). RDHs are zones (rice ecologies) where rice research outputs will be integrated across the rice value-chain to achieve the desired development outcomes and impact (Africa Rice, 2011). These samples were paddy and milled rice, imported from Thailand or locally produced and sold in Ndop hub (Table 1).

Rice samples were stored at room temperatures at the Institute of Agricultural Research for Development (IRAD) Yaoundé for 10 weeks. Data on physical quality were evaluated as follows.

The moisture content of rice grains was determined using a Satake Rice Moisture meter (Satake Co. Ltd., Tokyo, Japan) according to manufacturer's instructions and expressed as a percentage. The determination was done in triplicates.

Discolored rice grains were evaluated using a sample of 100 g of rice. Rice grains presenting any yellow, black or purple color, visualized under magnifying glass were manually selected from the normal grains and weighed. The evaluation was done every two weeks till the 10th week of storage

to observe the evolution of discolored rice grains. Discolored rice grains were expressed as a percentage. The rice was held at an average relative humidity and temperature of 80% and 26°C respectively for 10 weeks, and samples taken weekly.

Table 1. Rice samples with respect to their origin and type

Rice variety or brand name	Origin	Type of rice
Main dans la Main (Mm)	Thailand	Milled w hite
Word rice (Wr)	Thailand	Milled w hite
Neima (Ne)	Thailand	Milled w hite
Uncle benz (Ub)	Thailand	Milled parboiled

Bamunka (Ba)	Ndop hub-Cameroon	Milled w hite
Jéhovah (Jé)	Ndop hub-Cameroon	Milled w hite
UNVDA (UN)	Ndop hub-Cameroon	Milled w hite
Ndop rice (Nd)	Ndop hub-Cameroon	Milled w hite

2.2. Characterization of Moulds

To isolate and obtain pure strains, PotatoDextrose Agar and Malt Extract Agar media were used as most of strains grow on semi-solid media.

The Ulster method which is direct and more indicative for the analysis of mould on food was used to detect, isolate and analyze mould present on the rice samples. In the Petri dishes containing moistened filter paper, 20 particles (discolored grains of rice) suspected to be contaminated were placed. The Petri dishes are then placed in a hermetically sealed plastic container in the dark and ventilated for 12 hours. The observation of the strains was carried out only after 5 to 7 days of incubation.

The transfer of strains was done under the laminar flow hood and consisted of aseptically transferring the isolated strain into new PDA and MEA culture media to perform the pure culture. Three (3) repetitions were performed for each strain. From the Petri dish containing the isolated strain, 0.6 cm of mycelium disk is transferred into new dishes containing the culture media. This operation is performed several times in order to obtain pure cultures. The sampling was preferably performed at the growth end of colonies. The Petri dishes were then placed at laboratory temperature (24-28 ° C).

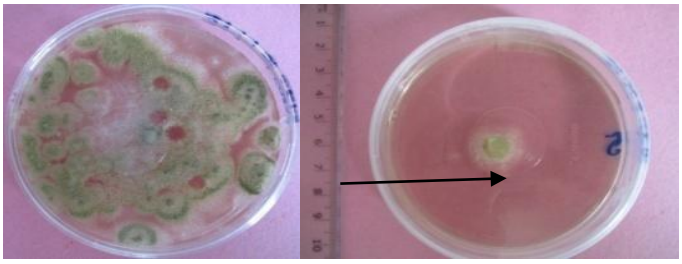

Fig. 1. Obtaining pure strain: a = isolated strain; b = pure strain (Douksouna photos, 2014)

The growth radius of mycelium was evaluated daily (48 hours after incubation) at the same hour. Each diameter is respectively measured on one of the two straight lines forming a right angle passing through the center of the explant (Fig. 2). The following formula was used to calculate the average growth radius.

$$D = \frac{d1 + d2}{2} - d0 \qquad \text{(Singh et } \textit{al.}\text{, 1993)}$$

Where d0 is the diameter of the initial explant; d1 and d2 are the diameters of culture measured in both perpendicular directions.

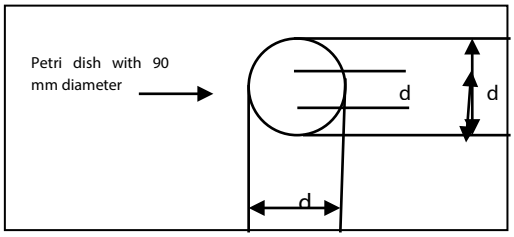

Fig. 2. Principle of measuring the radius growth of mycelium in Petri dish.
d0= diameter of the explant (0.7cm); d1and
d2=diameter perpendicular to pathogens.

The identification of many fungal species that can colonize food and alter the quality or even produce mycotoxins is an essential step in the evaluation of mycotoxic risk. A morphological identification was made based on the macroscopic characters (color, colony aspect, colony relief and the back of the boxes). The observation of the color and texture of the colony on the culture media as well as the microscopic structures made it possible to characterize the genera.

For all cultures obtained after 7 days, an identification key « Toxic Fungi in Food » allowed the characterization of moulds based on the technique of Pitt *et al*., (1997) according to the following characteristics:

- diameters of macroscopic colonies, measured in centimeter on the bottom of the box to evaluate growth;
- characters of colony, the appearance of the colony was observed by the naked eye under day light and in the presence or absence of a diffuse pigment to determine the colors of colonies.

Fungi were examined under the microscope as wet smears. To prepare a wet smear, a needle or an inoculation loop were used to collect a small portion of the colony with conidiogenous structures. The inoculum was taken from the edge of the colony because the fertile structures are young and the number of spores are acceptable. In addition, the structures that can enclose the spores have been taken near the center of the colony where the probability of finding mature spores is greatest.

The sample cut on a slide was first "wet" with a drop of ethanol 70% and a coverslip was laid, the excess liquid was blotted and followed by examination under microscope which is the microscopic study of the nature of differentiated organs. The observation was made at the objective 10 x and 20 x.

2.3. Data Analysis

The data obtained for all the parameters studied, were automated with the Excel software and the analysis were carried out by SPSS version 16.0. The different averages were compared at 5% significance level using Duncan's Multiple Range test.

3. Results and Discussion

3.1. Variation of Moisture Content of Rice Grains

There was a variation in moisture content among rice samples. In general, the level of moisture content was above 13% and could reach 15.6% at sampling. Moisture content (MC) is the weight of water contained in rice expressed in percentage. Moisture content is usually referred to the wet basis, meaning the total weight of grain including the water (IRRI, 2012). Results revealed a high moisture content at sampling date for imported milled rice samples sold at the Mokolo market: Uncle benz, Neima, World rice and Main dans la Main (Fig. 3); suggesting that these rice brands may

be poorly imported and stored by rice traders. Ten weeks after storage at room temperature, the moisture content of all rice samples (except for Tox 3145 whose moisture content was 15.6% at sampling date and remained the same after storage) showed a linear increase; suggesting that storing rice grains at room temperature allows them to re-absorb moisture. On the other hand, moisture content increased only around one unit or even less for rice samples Nerica L56, Tox 3145, Main dans la Main (Fig. 3). These rice samples already had high moisture content at sampling date, around 14%, suggesting that once the moisture content of rice has dropped upon drying, it can increase by some units, but cannot easily increase above 17%. The rice grain is hygroscopic and responds dynamically and physically to moisture and temperature changes in the environment. A dry grain surface re-absorb moisture in a humid environment, while a wet surface desorbs moisture in a relatively dry environment. Moisture adsorption is associated with water reentering the grain. This occurs when the vapor pressure at the surface of a grain is lower than the vapor pressure in the surrounding air (Lan and Kunze, 1996).

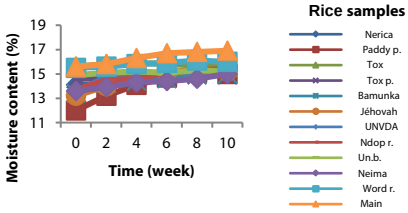

Fig. 3. Variation of moisture content of rice samples as a function of time

3.2. Discolored Rice Grains

Results revealed the presence of discolored rice grains in all the rice samples at the beginning of the experiment. The number of these discolored rice grains increased with time ($p < 0.05$), although at different frequencies within the different rice samples evaluated (Table 2).

All the four imported rice brands showed high number of discolored grains as compared with locally produced rice. Neima, Uncle benz, world rice and Main dans la Main which are the milled rice brands largely found in local markets in Cameroon like the Mokolo market where the sampling was done appeared to have highest number of discolored grains. This suggests that if these rice brands are stored at room temperature and humidity, there will be a large number of discolored grains, which are likely mouldy grain. These imported rice samples showed an increase of their moisture content during storage, meaning that when exposed to the ambient temperature and humidity, rice grains re-absorb moisture, creating favorable conditions for mould development, leading to discolored grains.

The rice brand which had the highest number of discolored grains was Main dans la Main at the beginning of the experimentand after 10 weeks storage. From my personal observations, this rice brand has a poorer appearance in the market and furthermore, its price is always lower than other imported rice brands sold in the market.

Table 2. Evolution of discolored rice grains in imported and local rice with respect to time

Time (week)	Rice brand											
	Nerica L56	Parboiled paddy	Tox 3145	Tox 3145 parboiled	Bamunka	Jéhovah	UNVDA	Ndop rice	Uncle benz	Neima	World rice	Main dans la Main
0	21a	25a	29a	36a	09a	11a	11a	17a	29a	19a	75a	117a
2	30a	49a	44a	107b	14a	14a	17a	25a	60a	46a	146b	170b
4	41a	53a	53a	163c	41ab	41ab	41a	31a	151b	57ab	203c	231c
6	53ab	63ab	59a	167c	45ab	43ab	43ab	38a	225c	68ab	235d	372d
8	57ab	67ab	63ab	173c	46ab	49ab	46ab	42a	231c	74ab	243d	385d
10	61ab	78ab	81ab	178c	49ab	57ab	49ab	53ab	237c	87ab	257d	389d

Means in a column with the same letter are not significantly different at $p < 0.05$ (Duncan's Multiple Range test).

The evaluation of discolored grains in terms of percentage showed that the mean total percentage of discolored rice grains 10 weeks after storage was high in imported rice brand and inTox 3145 parboiled (Fig. 4). The level of discolored rice was equal or higher than 3% in these rice samples, meaning that theycannot be graded premium or grade 1 rice, according to the Quality Standard for milled rice in the Philippines for instance.

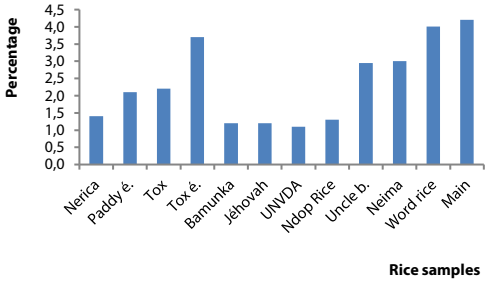

Fig. 4. Percentage of discolored rice grains in per rice brand or samples 10 weeks after storage

Percentages with the same letter are not significantly different at $p < 0.05$ (Duncan's Multiple Range test).

3.3. Characterization of moulds

3.3.1. Description of the isolated strains

The analysis of rice mycoflora revealed several genera distinguished by their morphological characters (Pitt et al., 1997).

The genus *Aspergillus* with seven species isolated: *Aspergillus niger*, *Aspergillus flavus, Apergillus ochraceus, Aspergillus fumigatus, Aspergillus oryzae, Aspergillus japonicas, Aspergillus parasiticus*. The genus *Penicillium,* the genus *Mucor* and the genus *Circinella.*

3.3.2. Characterization of moulds

Isolated colonies were keyed to species using Pitt *et al*., (1997). Results showed different ($p < 0.05$) growth of fungi according to their virulence. The radius growth of all the fungi increased with time from the second day to the fifth day, this at different growth rate (Table 3). The most virulent fungus was *Mucor* sp, whose growth radius was rapid and reached 7.4 cm at day five, followed by *Circinella* sp, *Aspergillus parasiticus* and *A. orchraceus* whose growth was comparable. The slowest growth radius was observed with *A. niger* (Table 3).

Table 3. Radius growth (cm) rate of fungi

Figures on a line with the same letter are not significantly different at $p < 0.05$; figures in bold and italic represent the comparison in column (Duncan's Multiple Range test).

3.4. Virulence of strains on rice samples

Mycological analysis showed that imported rice samples of world rice and Main dans la Main presented the highest fungal load (Table 4). No strain was isolated on Nerica L56. On world rice and

Main dans la Main rice samples, were isolated respectively eight and five different strains. This result corroborates previous ones obtained in the course of this study, where the rice brands world rice and Main dans la Main presented high moisture content and discolored grains; suggesting that rice grains with high moisture content and discolored grains probably possessed a high fungi load.

Table 4. Identified fungi per rice sample

In terms of percentage, the genus *Aspergillus* dominates with a total of 63.8% as compared to the other strains. The genus *Penicillium*, *Mucor*and *Circinella* presented respectively 13.4, 8.9 and 4.4% (Fig. 15).

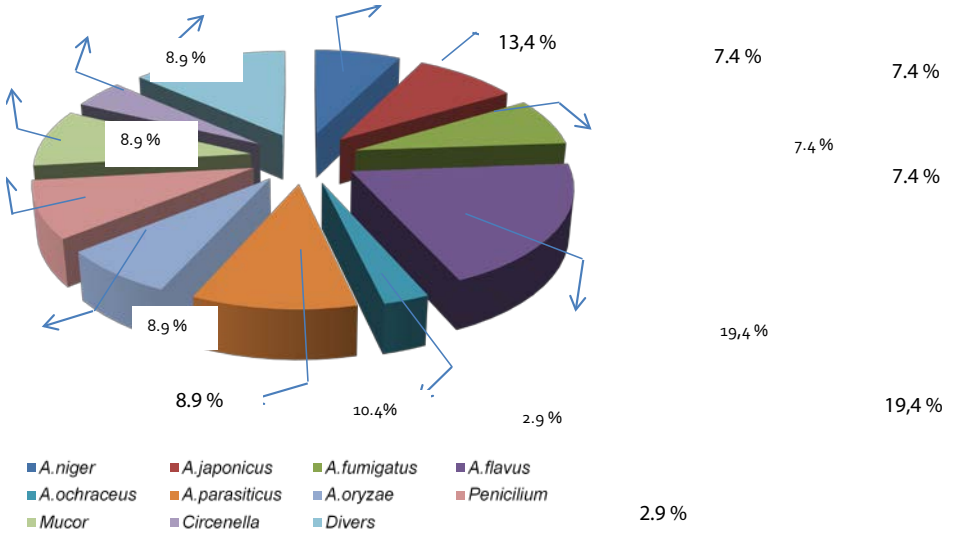

Fig. 5. Proportion (in percentage) of isolated strains infecting rice samples in Cameroon

4. Conclusions

This study evaluated some rice samples in Yaounde (Mokolo market) and Ndop rice development hub, which are respectively the main market of the political capital of Cameroon (Yaounde) and a rice-production division. There were imported milled rice brands sold at the Mokolo market and paddy or milled rice brands produced in Ndop.

It was found that the different rice samples were contaminated by moulds; certainly because of their high level of moisture content. The fungal charge was high in imported rice sample brands as compared to locally produced rice, suggesting that these rice samples may be imported or stored and sold in poor conditions, leading to the development of moulds.

In addition, isolated mycoflora was diverse. Four genera were found: *Aspergillus*, *Penicillium, Mucor*and *Circinella. Aspergillus* species dominate followed by *Penicillium* and *Mucor*.

Further studies can take into consideration all imported rice brands and rice samples produced locally and sold in local markets in Cameroon and assess the presence of toxin like aflatoxin in the rice grains.

Abstract

The present work brings together different rice varieties (black, brown and white) evaluated for their differences/ susceptibilities/resistance to ozone (O3) gas treatment for safer storage (mycological and toxicological contamination control). The three rice varieties were separated into two Groups –Control (GC) andtreated Groups (GT) which had O3 gas applied (5 L/min, 40 ppm and 60 min for gas flow). Samples were collected during the storage period to check for the O3 gas effect on fungi reduction (total count and fungi genera identification) and so for the humidity parameters of moisture content (mc) and water activity (aw). It was possible to verify the effectiveness of the O3 application in the samples when compared to Control. It was observed that even at the shortest time of gas exposure, O3 application caused changes to fungi (both growth speed & toxin formation). The grains did not change their organoleptic, physical and biochemical characteristics after O3 application. Recent studies from our Labmico Group indicated that the O3 application in addition to prevention of the biological contaminants, as reported in the current work, also reduces an insecticide (deltamethrin) residues. As O3 treated grain has reduced fungi contamination and toxicity of rice grains in all the varieties studied, it can be considered a potential agent to control fungi spoilage and so for toxigenic strains. Considering that there is a growing concern on the use of agrochemicals and their harmful effects on human health and the environment, O3 application can be a promising to implement decontaminationof highly consumed grains worldwide, such as rice.

Keywords: rice, fungi, storage, ozone, mycotoxins.

1. Introduction

Rice (*Oryza sativa* L.) is one of the most consumed cereals in the world, with 90% of its production coming from Asian countries. Outside of Asia, Brazil is the greatest producer of rice. Asian countries' rice consumption varies from 100 to150 kg/person/year (Sosbai, 2014). There are varieties that express different nutritional characteristics having impacts on the human health. Several consumers around the world prefer rice with translucent appearance, with intact and uniform grains (Castro, et al, 1999). In relation to the grain type, the market indicates a rice consumption migration from type 2 to 1 and parboiled rice in Brazil (Botelho et al, 2010). However, new trends in the food market favor the consumption of other varieties, since the increasingly consumer demand for food-health integration (Aziz et al, 2002).

Due to the demand for quality, it is important toemphasizethe post-harvestinsect protection management control and what they carry during storage: toxigenic fungi (Hoeltz, 2005; Soares et al, 2018). The presence and action of fungi affect the grains physical structures, compromising their quality & safety with deterioration, loss of nutrients and toxins production (Kreibich et al, 2016). Mycotoxins are secondary metabolites, whichare toxic substances able to affect humans and animals, and may be mutagenic, teratogenic or carcinogenic effects (Hoeltz, 2009).

Food contamination can pose risks to consumer health. Grains, such as rice are affected greatly by the presence of fungi and mycotoxins (Hining, 2011). In the field, contamination is influenced by environmental conditions such as air humidity, incomplete drying, product humidity, rainfall at harvest time, insects, soil fungus loads, air and plant health (Fonseca, 2008). The constant movement of insects within an ecosystem contributes to the dispersion of fungal spores, which are carried on the body surface (Bidochka 1997; Saint, 1984; Soares et al, 2018). Water (coming from inside the food or even from the external environment), is the medium that favors microorganisms growth (Pitt, 2009). The main pests present in the grains during storage are beetles and moths. Among the beetles are *Rhyzopertha dominica* F. and *Sitophilus oryzae* L. are some of the most damaging species in rice. Regarding moths, the main ones are *Sitotroga cerealella* and *Ephestia kuehniella* (Lorini, 2010).

Under favorable conditions, fungi develop rapidly during the cultivation, harvesting, transport and storage processes. However, the storage corresponds the main stage in which the grain is susceptible to those types of contamination. (Scussel, 2018). Among the mycotoxins that most affect rice cultivars are aflatoxins, ochratoxin A, zearalenone, citrinin and fumonisins and their main toxigenic fungi are the *Aspergillus, Penicillium* and *Fusarium* species, and the same fungus can produce several different toxins (Aziz and Moussa, 2002).

There are several methods of storage to prevent/control the fungi proliferation, among them temperature reduction and also technologies known as green methods, such as the application of ozone (O_3) gas (Kim and Dave, 1999).O_3 is a colorless gas with a pungentodor, unstable and partly water-soluble, and has high oxidizing power. Within 15 min in contact with the air, it ends up oxidizing and turning O_2. It does not generate residues and is a strong disinfectant agent with action on a great variety of pathogenic organisms, including bacteria, viruses and protozoa. (Botelho da Silva, et al, 2011; Savi et al, 2015). In addition, it is internationally recognized as a GRAS - generally recognized as insurance (Piacentini, 2015; Christ et. al, 2016, 2017).

This work evaluated the susceptibility of three rice varieties to fungi and mycotoxins decontamination byO_3 gas.

2. Materials and Methods

2.1 Materials

Samples: Three rice varieties of (a.1) black, (a.2) brown and (a.3) white with initial mc: 14.41, 13.86 and 13.61%, and aw: 0.060, 0.580 and 0.520, respectively).

Culture media and reagents: Potato dextrose agar (PDA) from Himedia (Curitiba, Parana, Brazil) and chloramphenicol were obtained from Vetec (Duque de Caxias, RJ, Brazil).

Equipment: autoclave, Phoenix (Araraquara, SP, Brazil); microwave oven, Philco (Sao Paulo, SP, Brazil); tweezers, Prolab (São Paulo, SP, Brazil);caliper, Digimatic (Mitutoyo, Tokyo, Japan); drying oven, Olidef-cz (Ribeirao Preto, SP, Brazil); aw meter, Aqua- Lab4TE, Decagon (Sao Jose dos Campos, SP, Brazil), Peagameter, Model Schott-gerate CG 818 (Schott,, Mainz, Germany); laminar flow cabinet, Veco (Campinas, SP, Brazil); fume cabinet, Quimis (Diadema, SP, Brazil); rotary shaker, Marconi (Piracicaba, SP, Brazil) and microbiological incubator, Quimis (Diadema, SP, Brazil); colonies counter, Phoenix (Araraquara, SP, Brazil); sieve system, mesh (2-1mm) Beffer (Caieiras, SP, Brazil); Microscopes - light (LM), CH-Bl45-2, Olympus (Shinjuku, Tokyo, Japan); O_3 gas generator, OP-35-5L, Interozone (Jundiaí, SP, Brazil), thermohigrometer, J-prolab (São José dos Pinhais, PR, Brazil), stereo microscope (SM), Opticam (SP, Brazil).

2.2 Methods

Sample collection: rice varieties were collected (1 kg) in October, 2017, by the Vegetal sanitary defense of Santa Catarina Integrated Development Agricultural company.

O3 application: The storage silos were produced with polyvinyl chloride tubes containing only two openings: one for the O3 gas inlet and one for the O3 gas outlet (25 X 10 cm diameter capacity).The three rice varieties were separated into two Groups –Control (GC) and treated Groups (GT).After grains (300 g)of each rice variety were loaded (50 g) into the O3 chambers, the generated O3 gas was pumped (through the inlet entrance) into the vessels by a compressor (equipped with a filter to prevent the entry of moisture), at continuous flow rate (5 L min-1) (Savi et al, 2016). The gas concentration applied was of 40 ppm for 60 min (Soares et al, 2018). At the end of the O3 gas exposure itseffect on fungi growths (GT) was evaluated and compared to the GC.

Humidity: MC and aw measurement where prior and after O_3 treatment. Each sample (2 g) was submitted (n=2) to drying in oven (105°C+/-5°C) up to constant weight by the gravimetric method of AOAC (2005). To determine a_w, each sample (2 g) was subjected to analysis (n = 2) using the Aqua Lab equipment, 25°C (AOAC 2005).

Mycology: The GT (O_3) and GC (no O_3 treated) rice grains were incubated (5 grains each) on PDA culture medium at 25°C+/1for 7 days. At day 3 and 5 after incubation, the colonies were observed and had their genera identified. After 7 days of incubation, the most representative fungi colony of each plate was evaluated for genus identification, both by analyzing their reverse under ultra violet light and analysis of their hyphae and conidia by SM (x60 and x100) (Ganley, 2006). Identification of fungi: The genera and the species identifications were performed according to Pitt and Hocking (2009).The colony morphology was evaluated by SM analyzes (Scussel et al, 2014).

3. Results

Humidity and fungi: It is known that the mc and a_w are important humidity factors for the development of fungi. Table 1 shows very close values among the varieties evaluated. The variety with the highest mc value had also the highest $a_w$value. Data also reveals that among the three varieties studied, the difference between nutrient availability and other factors in grain composition stands out in relation to a_w difference, since the grain (White) with lower mc (13.61%) &a_w (0.520) is the one that presents more different colonies and also more toxigenic colonies based on the fluorescence in its reverse and genera identification.

The incubated grains did not have their surfaces sterilized, thus providing favorable conditions for epiphytic fungi. These fungi may have a mutualistic relationship (absorbing nutrients and providing defense to the grain) or commensal, where it only removes nutrients (da Silva, 2006). Germination ceased at the time the colonies began to expand through the Petri dish.

Tab. 1 Humidity, fungi genera isolated fluorescence and from different rice (*Oryza sativa*) varieties

Rice Variety	Humidity		Predominant Fungi	
	mc	a_w	Genera	Fluorescence
Black	14.41	0.608	*Aspergillus*	✓
Brown	13.86	0.580	*Mucor*	ND
White	13.61	0.520	*Penicillium*	✓

mc: moisture content; a_w:water activity; ND: not detected; ✓: presence

Fungi and ozone: From the rice samples a.1 (black), a.2 (brown) and a.3 (white) of the image (Fig. 1), that were submitted to O_3 application,it was possible to observe a reduction offungi colonies formation on the grains (GT) when compared to Control (GC).

Mycoflora: By applying stereo microscopy, the reproductive structures of the fungi isolated from rice husk (tegument) surface and endosperm regions it was possible to visualize and identify different stages of reproductive structures of *Aspergillus* genera and also the species identified (*A . niger)* with their characteristic black color (Fig. 2).

Mycotoxins: In addition to the bromatological changes, the development of fungi can harm animal health and the people/workers handling the husk, due to the production of toxins, especially those related to the toxigenic fungi of the genus *Aspergillus*.

From the white rice strains isolated, where toxigenicity tests were applied, after 7 days incubation of the colonies isolated, it was possible to detect fluorescence production at the reverse of the culture medium under UV light - 365nm. That indicates possible presence of mycotoxins (aflatoxins) through the fluorescence compounds produced (Fig. 3).

Proximate composition: From the three rice samples evaluated, the Black rice had the highest lipid and protein contents (3 and 9.8 %) (Tab.2).

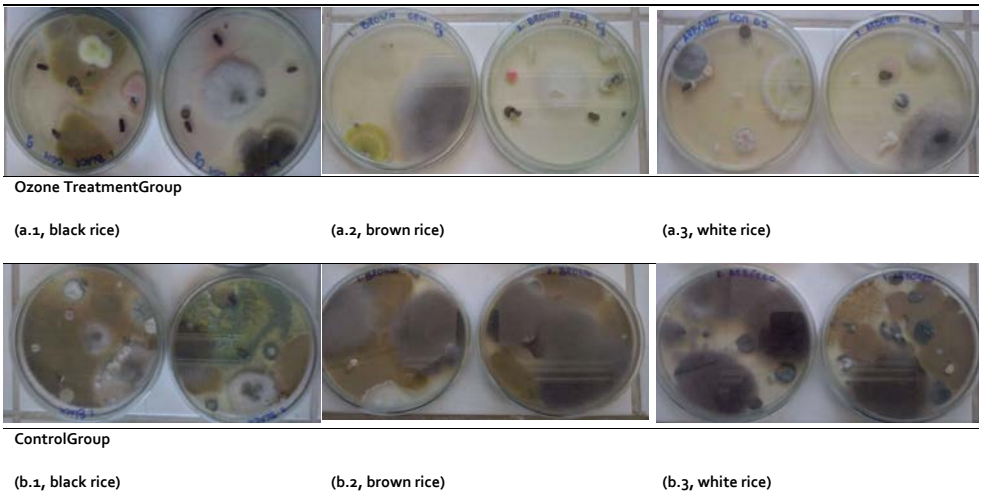

Fig.1 Fungi susceptibility to O_3 gas from three different rice (*Oryza sativa*) varieties: (a) ozone gas treated group and (b) control group.

Fig.2 Stereo micrographs of isolated fungi from rice (*Oryza sativa*) grains varieties (a, b) reproductive structures of *Aspergillus* and (c) species identified of *A. niger* [40, 100and 60x, respectively].

4. Discussion

Rice composition versus fungi: Regarding main composition rice presents the highest percentage ofstarch, followed by proteins andsmall amounts of lipids and fibers. In addition, the nutrients are not uniformly distributed in the different fractions of the grain. The (a) outer layers have higher concentrations of proteins, lipids, fibers and vitamins, while (b) the center is starch (Walter, 2008), so non-polishing causes the whole rice grain to have its starch mass protected by a layer of nutrients. Fungi have affinity for media with high concentration of starch and so the grains (Lorini, 2018). This explains the fact that black rice has been the least affected by fungi, its amount of vitamins and other components are higher than that of other varieties, likewise, white rice is polished and therefore facilitates access to fungi, which feed on this starch.After a systematic investigation of rice straw (Chen et al, 2015) verified that the mixed culture of *Trichoderma viride* and *A. niger* had a greater capacity of biodegradation when compared with the pure strains of *T. viride* and *A. niger*.

Ozone gas fungi development control: According to Botelho da Silva (2011), the application of O_3 is efficient however does not rule out the need for good storage conditions. It is noteworthy that due to the complexity of the processing and storage of these grains, O_3 does not dispense need to store under the proper humidity and temperature conditions. In addition, it was realized that even at short O_3 exposure time reduced fungi (only fewer colonies) during the incubation time.

Beber et al, 2015 reported a high reduction in total fungi, especially *Aspergillus* and *Penicillium* fungi genera. O_3 treatment applying concentrations of (10 - 40 mg/L) in silos was shown to be an effective green strategy to reduce the contamination of rice stored in the husk, maintaining safety during storage. Apparently the grains did not have their organoleptic characteristics affected by the application of O_3. Recent studies in our laboratory indicate that the application of O_3, in addition to preventing the presence of biological contaminants as shown in this work, also reduces an insecticide (deltamethrin) residues. (Savi et al, 2015).

5. Conclusions

As O_3 reduced the toxicity and contamination of rice grains in all varieties studied, a potential agent in the treatment of fungi is shown. There is a growing concern about the use of pesticides and their harmful effects on human health and the environment. Its application brings benefits in general and much lower degrees of contamination than the pesticides themselves. Combining its application and safety / control of the amount of gas, O_3 is promising the highly-consumed grain production chain around the world, such as rice.

Abstract

Poor storage capacity of soybean makes it prone to fungal spoilage and heating during storage, resulting in lower quality. Early prediction of the fungal spoilage in stored soybeans is very difficult because fungi are often too small to be seen with the naked eye. Here a new method for fungus to early detection is adopted: it is called counting fungal spores. Soybeans with moisture contents of 11.4, 12.1, 13.0, 13.9, 14.3 and 14.7%, were held at 6 temperatures 10, 15, 20, 25, 30 and 35℃ for180d. Samples were taken at regular intervals and the fungal spores counted. The safe storage conditions (temperature, moisture content, duration) were estimated by means of a curve fitted using the power function fitting. It can predict of soybean spoilage by fungus before there is visible damage.

Keywords: soybean, storage, fungal spoilage, early prediction, spores

1. Introduction

The tolerance of soybean to storage is poor, and the phenomenon of fungal spoilage and caking occurs easily. The storage of fungus is one of the main factors affecting the storage safety of soybean (Shelar and Shaikh, 2008). The study of soybean moisture, storage temperature and fungal growth is an important research direction to solve the early prediction of fungus damage in soybean storage. In recent decades, many reports on soybean storage fungi have been reported, in China and elsewhere in the world. Milner (1946) discovered that fungal infections could lead to a decline in soybean quality, and the increase of respiration and free fatty acids in soybean storage was mainly caused by the growth of harmful fungi. Kennedy (1964) conducted a survey of soybeans in five U.S. states, and found that the main growing fungus in soybeans was Aspergillus glaucus. Dorworth (1968) found that when the soybean moisture was 12.0 to 12.5% mc (moisture content), the storage fungus would slowly infect the soybean. As the moisture content increased, the infection rate increased gradually. Wilson (1993) showed that soybeans at10.5% mc can be stored at any temperature with no fungal growth. There are also some other related research reports about the safety storage and quality of soybeans (Hou et al., 2002; Wilson et al., 1995; Kong et al., 2009).

However, few studies have been reported on the early detection of fungal hazards in soybean storage.

Most of the grain storage fungi have aerobic growth characteristics. During grain storage, under suitable conditions, fungi begin to grow on the grain surface. This paper adopts a new method for early detection of grain storage fungi, which is counting fungal spores, and the prediction of the spoilage of stored soybeans by fungi. By studying the growth of fungi in soybeans with different moisture contents stored at different temperatures, the relationship between soybean moisture and temperature and initial growth time of fungi was preliminarily established, so as to provide safe storage guidelines for soybean storage.

2. Materials and Methods

Samples of soybean harvested from Heilongjiang Province

The soybean moisture was adjusted to 11.4, 11.4, 12.1, 13.0, 13.9, 14.3 and 14.7% respectively by the way of natural drying of water, or spraying water and holding at 4℃ about one month. Then the samples were packed in 1.0L bottle and kept in closed storage in a thermostat at different temperatures (10, 15, 20, 25, 30 and 35℃). Samples were taken every 10d. The moisture content was determined by oven method (105℃ for 3h). The growth of the fungus in the stored grain was determined by counting fungal spores.

Counting fungal spores

Ten g of soybeans were placed in 80 mL test tube, 30 mL of water added, stoppered, shaken for 1 min. The water was filtered through 60-80 um mesh filter cloth, and the filtrate siphoned into the count area of blood cell count board. Fungal spores were counted under a microscope at 600-800 times magnification. This method has been used for repeated experiments on wheat and rice samples with different levels of infection (n = 8), and the relative standard deviation (RSD%) range was 8.2 to 31.4% (Cheng et al. 2011). The fungal spore count correlates well with the plate colony plate counts, the correlation coefficient was $R^2 = 0.8479$ (Cheng et al., 2011). The method is based on the traditional cell counting method. By detecting the concentration limit of fungi spores ($1 \times 10^5.g^{-1}$), it eliminates the interference of fungal spores carried by the sample of no fungal growth, and achieves the purpose of only detecting fungal growth during storage. This method can detect fungal growth on the grain surface before it is seen with the naked eye. If fungi only grow a little, the growth of fungi can be detected presences of spores.

3. Results

The relationship between soybean moisture, storage temperature and the fungal growth was studied by regular sampling. The results showed that soybean storage was safe up to 11.5%mc. About 12.0%mc is the critical moisture for soybean fungus growth, and with the increase of moisture the growth of fungi will accelerate gradually. When the soybean is stored under 15℃, the low temperature inhibits the growth of fungi. Soybean stored over 20℃, might see fungi growth.

Most of the grain storage fungi have aerobic growth characteristics. During soybean storage, under suitable conditions, fungi begin to grow on the grain surface first. According to this feature, the method of counting fungal spores can detect the growth of fungi at the early stages before the infestation can be seen by the naked eye. This allows for early detection and warning of fungal growth.

The concentration of fungi spores 1 to $3 \times 10^5 g^{-1}$was determined as the initial growth limit, and the initial growth time of fungi was recorded by regular detection. The initial growth time was plotted with storage temperature and fitted using a power function curve. The predictive relationship between storage moisture and temperature and initial growth time of fungi was obtained (Fig. 1).

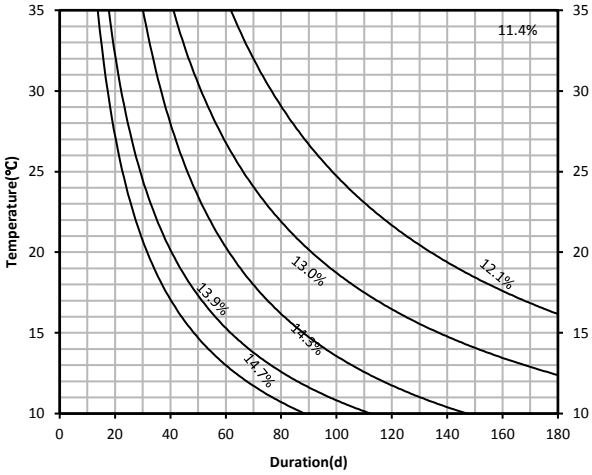

Fig.1 The conditions, temperature, time, and moisture content where there are1 to 3×10^5 g^{-1}fungal spores.

For a given moisture content with a given temperature the duration that soybean can bt safely stored is estimated. This curve is completed under isothermal conditions. Due to the large climate changes in the regional grain storages, the actual situation of local grain storage should be taken into consideration when using this curve.

Abstract

This study assessed the aflatoxin contamination and the presence of fungi in three maize varieties (*Obatanpa*, *Abontem* and *Aburohemaa*) stored using different storage methods namely storage in hermetic bags, woven polypropylene sacks and local crib in the Nkoranza-South district of the Brong-Ahafo region of Ghana. A factorial design arrangement was laid out in a randomized complete block design (RCBD). The isolation and identification of fungal pathogens associated with maize samples before and after storage were carried out on potato dextrose agar (PDA). Total flatoxin levels in the three maize varieties was determined by the use of enzyme-linked immunosorbent assay (ELISA) at 450 nm wavelength. Six fungi species were identified in the maize namely: *Aspergillus flavus, Penicillium* sp, *Fusarium* sp., *Lasiodiplodia theobromae*, *Colletotrichum gleosporioides* and *Rhizopus*. Before storage, *Abontem* variety recorded significantly higher ($p < 0.05$) total aflatoxin levels (113.56 ppb) compared to *Obatanpa* (2.91 ppb) and Aburohemaa (2.96 ppb). Maize samples stored in the polypropylene sack established significantly higher ($p < 0.05$) total aflatoxin levels of 82.9 ppb compared to hermetic bags (48.9 ppb) and local crib (48.9 ppb) after storage for six months. Aflatoxin levels under the interactive effect of variety and storage method was significant ($p < 0.05$). Overall storage of maize in hermetic bags significantly reduced aflatoxin levels hence the need to encourage maize farmers and traders to adopt hermetic bag storage technology.

Key words: aflatoxin, fungi, maize varieties, *Obatanpa*, *Abontem*, *Aburohemaa*, hermetic bag, polypropylene sack, local crib.

1. Introduction

Maize (*Zea mays* L.) is one of the most important cereal crops grown globally, and it is the third after wheat and rice in total food grain production (Anupama *et al*., 2005). It has a very high adaptability and productivity hence it is produced in most countries of the world (Dlamini *et al*., 2012). Maize is a staple food for an estimated 50% of the population of sub-Saharan Africa (FAOSTAT, 2006). The crop is grown in all the six agro-ecological zones of Ghana and has a cultivated area of 1,023459 ha and an average yield of 1.72 tonne per hectare, making it the major cereal crop (MoFA-SRID, 2015). New varieties with improved quality have been developed in Ghana to increase output. Some improved maize varieties available in Ghana include *Abeleehe, Aburotia, Dobidi, Dorke, Kawanzie, Kwadaso local, Obatanpa, Okomasa, Mamab*a, *Abontem*, and *Aburohema* (Manga, 2010; Tweneboah-Koduah, 2013).

The quality of grain is usually assessed by its germination capacity, weight, microbial contamination, insect infestation and nutritional content. Grain quality is affected by temperature, moisture content, relative humidity, storage period, and several other biological factors (Jayas and White,

2003; Chattha *et al*., 2014). Fungal infestation is the major microbial contamination in stored grains which leads to the production of mycotoxins that subsequently reduces the quality of the grains. Mycotoxins are metabolites of certain fungi. They are toxic to humans and other animal groups even at very low concentrations and are frequently responsible for health-related problems in many countries (Morris *et al.,* 2001). The FAO estimates that, 25% of agricultural crops worldwide is contaminated by mycotoxins especially aflatoxins (Shekhar *et al.,* 2011). Aflatoxins are harmful toxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* (Omari and Amoah, 2015). It was first isolated in the early 1960s and found to be the most potent naturally formed carcinogenic compounds (Shekhar *et al.,* 2011). The types of aflatoxins produced by these species are B1, B2, G1 and G2. Generally, *A. parasiticus* strains produce B1, B2, G1 and G2 while *A. flavus* produces only B1 and B2 (CAST, 2003; Abbas *et al.,* 2006). The intake of higher doses of aflatoxin can cause acute aflatoxicosis, genotoxicity, hepatocellular carcinoma, suppression of immune system and impaired childhood growth (Fung and Clark, 2004).

Maize is a staple food of most Ghanaian communities and therefore its quality and quantity must not be compromised. Maize has the potential of becoming a non-traditional export commodity of Ghana considering its high productivity but unacceptable aflatoxin levels could be a huge setback. Aflatoxin contamination has been found to occur both at pre- and post-harvest stages of the production chain. Many studies have, however, shown that the bulk of the aflatoxin contamination in Ghana occur at the postharvest stages mainly due to improper food handling and storage practices (Omari and Amoah, 2015). In most developing countries such as Ghana, health issues related to aflatoxin contamination of food stuffs are more problematic since no proper food safety regulations have been established and/or rigorously enforced. The majority of maize produced in Ghana is either used for home consumption or sold in the local markets. Thus, the human health impact will be greatest if there is no monitoring and control mechanisms for aflatoxin contamination of food. For both food safety and economic reasons, there is the need to develop effective ways to mitigate the high and unacceptable levels of aflatoxins in food as it is becoming a serious public health and economic concern throughout the world.

Investigations on aflatoxin contamination of maize have been carried out in different parts of Ghana (Kpodo, 1996; Akrobortu, 2008; Amankwa, 2009; Tweneboah-Koduah, 2013). Most of the investigations focused on the type of storage methods that could be used for managing aflatoxin contamination of maize on cobs. However, most farmers and traders remove the grain from the cob before storage. Maize in this state is generally stored in hermetic bags, polypropylene sacks, jute sacks and mud silos. Tweneboah-Koduah (2013) reported lower concentrations of aflatoxins in *Golden crystal* i.e. yellow maize (19.9 pbb) compared to *Abasa* (24.5 pbb) and *Obatanpa* (27.9 pbb) maize varieties grown and stored in the Central Region of Ghana. To the best of our knowledge, no work has been done on the levels of aflatoxins in maize grown and stored by farmers and traders in the Nkoranza South District of the Brong-Ahafo Region of Ghana.

The Nkoranza-South District is one of the major producers of maize in Ghana. It is the highest maize-producing district in the Brong-Ahafo Region. The main maize varieties cultivated in this district include *Obatanpa*, *Abontem* and *Aburohemaa*. Communities in the district are also predominantly rural with high illiteracy rate, hence, most farmers and traders employ traditional storage methods for their maize. Some of the storage methods coupled with conducive climatic conditions of high rainfall and high temperatures in the region promote fungal growth and the production and accumulation of aflatoxins in maize. Since aflatoxin contamination cannot be assessed visually and also its effect is not immediate, farmers and traders are usually less concerned about it. Furthermore, maize from the district is distributed throughout Ghana hence, high mycotoxin levels in the grains will impact negatively on the human and animal health. Thus, it is very necessary to find ways to reduce aflatoxin levels in this commodity to acceptable levels. The objectives of the study were therefore to identify the presence of aflatoxin-producing fungi species in three maize varieties (*Obatanpa*, *Abontem* and *Aburohemaa*) stored using three storage methods (hermetic bag,

polypropylene sack and local crib), and assess the aflatoxin levels in the three maize varieties stored at ambient conditions under the three storage methods.

2. Materials and methods

Study site

The field work was conducted at four communities (Nkoranza, Bibiani, Akumsa Dumase and Brahoho) in the Nkoranza South District of the Brong-Ahafo Region of Ghana between September 2015 and April 2016. (Figure 1). Nkoranza South District is one of the twenty-two administrative districts in the Brong-Ahafo Region of Ghana. It is located in the middle portion of Brong-Ahafo Region. It lies within longitudes 1° 10'W and 1° 55'W and latitudes 7° 20'N and 7° 55'N covering a total area of about 920 km^2. The district has about 105 settlements, which are mostly rural. It shares boundaries with Nkoranza North District to the North, Techiman Municipality to the West, both in the Brong-Ahafo Region and Offinso North District to the South and Ejura-Sekyeredumase to the South-East in the Ashanti Region (MoFA, 2011). The district lies within the wet semi-equatorial region, having a mean annual rainfall level ranging between 800-1,200 mm. It has its major rainy season from March to June, experiencing her minor rains in September to November. The month of August experiences a short dry season, with the prolonged one in the months of December to March. The district has an average annual temperature of about 26 °C (MoFA, 2011). The dominant occupation of people in the district is agriculture, the proportion of which is about 82% of the district's labour force. It is one of the major producers of maize in the country.

Figure 1: Maps of Brong-Ahafo region (top image) of Ghana and Nkoranza South district (bottom image). Insert in top figure is the map of Ghana.

Experimental setup in the four communities

The experiment was conducted in four communites (Nkoranza, Bibiani, Akumsa Dumase and Brahoho) in the Nkoranza South district of the Brong-Ahafo region from September 2015- April 2016. Three varieties of maize namely *Aburohemaa* (AB), *Abontem* (AN) and *Obatanpa* (OB) commonly grown in the district and three storage methods namely Hermetic bags (HT), Local crib (LC) and Woven polypropylene sack or Poly sack (PS) that are commonly employed by farmers and traders in the district were used for the study. Each maize variety (25 kg) was collected after harvest and stored for six months in each of the storage systems in the four communities. Maize in hermetic bags and woven polypropylene sacks were stored in rooms. Relative humidity and temperature in the storage systems were measured at 30 min intervals using EL-USB LCD 2 thermo-hydrometer data loggers. To determine the impact of storage method on fungal growth and aflatoxin contamination, 1 kg of the maize samples were taken out o the 25 kg sample and analysed for aflatoxin levels and fungal growth prior to storage. The analysis was repeated after six months of storage. A factorial treatment arrangement was used for the study with storage methods (Hermetic, Local crib, Poly sack) and maize varieties (*Aburohemaa*, *Abontem*, *Obatanpa*) being the main factors. The treatment combinations were; (AB×HT, AB×LC, AB×PS, AN×HT, AN×LC, AN×PS, OB×HT, OB×LC, OB×PS). The factorial treatment combination was laid out in a randomized complete block design (RCBD) with the four communities serving as replications.

Isolation and identification of fungi associated with maize samples

Isolation of fungal pathogens associated with maize samples before and after six months storage was carried out on potato dextrose agar (PDA). The PDA was prepared by dissolving 3.9 g of the maize powder in 100 mL of distilled water in a 250 mL conical flask. The conical flask was shaken well together with its content to form a uniform solution. It was covered with aluminium foil and autoclaved at 1.05 kg/cm^2 pressure and 121 °C for 15 min. The PDA was poured into 9 cm petri dishes and allowed to cool. Surface sterilization was done to each sample in 1% w/v sodium hypochlorite for 30 sec and blotted dry with lint-free paper. Five sterilised grains were plated in each Petri dish and incubated at room temperature for five days to induce growth of fungi. Morphological identification of fungus associated with maize grains was done by scraping mycelia plugs advancing from the margins of the grains with a scalpel that is flamed. The mycelia plugs were mounted on slides for microscopic examination using distilled water. Compound microscope at low and high powers was used to examine the prepared slides. Identification of the isolates was based on colour,

morphology of mycelia, conidia and sporulating structures (Agrios, 2005; Barnett and Hunter, 2006). Micrographs were taken using a digital camera.

Determination of levels of total aflatoxins in maize

Enzyme-linked immunosorbent assay (ELISA) was carried out to determine the levels of total aflatoxin in the three maize varieties before and after storage. Celer AFLA ELISA Test Kits (Tecna S.r.l., Trieste, Italy) was used for the ELISA. The kit reagents include premixing microtitre plate (non-coated wells), microtiter plate (coated with anti-aflatoxin antibody), total aflatoxin standards (0, 2, 8, 30 and 80 ppb), enzyme conjugate, washing-buffer 10X, developing solution and stop solution. Sodium chloride and methanol were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA).

Aflatoxin analysis

To extract aflatoxins from maize samples, the procedure as reported in the Techna Total Aflatoxin Kit (code MA210/MA211) was followed. Briefly, 50 g of finely ground maize sample and 10 g of NaCl were mixed in 250 mL of 70% v/v methanol. The mixture was vortexed for 10 min and filtered using Whatman Filter Paper No. 1 and the extract (filtrate) was used for the analysis. The assay kit stored in the refrigerator was allowed to thaw to room temperature before analysis. To each premixing well was added 100 μL of enzyme conjugate followed by 50 μL of each standard/sample. The components in the premixing well were thoroughly mixed and 100 μL was transferred into a corresponding anti-aflatoxins antibody coated microwell. The mixture was incubated for 10 minutes at ambient temperature after which the wells were emptied followed by washing with 1X working buffer. A 100 μL of developing solution was added to each well, thoroughly mixed and incubated for 5 minutes followed by addition of 50 μL of stop solution. The absorbance was measured at 450 nm on a Readwell Strip ELISA Analyser (Robonik) plate reader. From a calibration curve of the standard solutions, the concentration of total aflatoxins in maize was determined.

3. Results

Effect of storage method on fungi infestation of maize grains

The results obtained after culturing, isolation and identification of fungi associated with the maize grains before and after storage indicated that the maize samples were infested with different species of storage fungi. Fungi isolated on grains before storage were *Aspergillus flavus, Colletotrichum gleosporioides, Fusarium* sp., *Lasiodiplodia theobromae*, *Penicillium* sp., and *Rhizopus* sp. Six different storage fungi species were again isolated from the maize samples after six months of storage namely, *A. flavus, A. niger, Fusarium* sp., *L. theobromae, Penicillium* sp., and *Rhizopus* sp. No *Colletotrichum gleosporioides* was found in the maize after storage for six months irrespective of the storage method. On the other hand, *Aspergillus niger*, which was not present in the grains before storage was identified in all maize varieties after six months of storage.

Total aflatoxin levels in maize varieties before and after storage

Aflatoxin levels in *Obatanpa*, *Abontem* and *Aburohemaa* maize varieties before storage varied significantly ($p < 0.05$). Aflatoxin levels in *Obatanpa* (2.91 ppb) and *Aburohemaa* (2.96 ppb) were similar compared to *Abontem* (113.56 ppb), which had a significantly high level of aflatoxin ($p < 0.05$) among the three varieties. **S**imilarly, there were significant differences in aflatoxin levels ($p < 0.05$) in all the three maize varieties after six months of storage in three different storage methods. *Obatanpa* and *Aburohemaa* varieties established significantly lower ($p< 0.05$) aflatoxin contamination levels of (5.0 ppb) and (6.6 ppb), respectively compared to *Abontem* (169.3 ppb) as shown in Table 1. Aflatoxin levels among the storage methods also varied significantly. Grains stored in the hermetic bag and local crib had aflatoxin levels of 48.9 ppb each which were significantly lower ($p < 0.05$) than the levels in grains stored in the polypropylene sack (82.9 ppb).

Table 1. Mean aflatoxin levels (ppb) in three maize varieties stored for six months under three storage methods under ambient conditions

Variety (V)	Storage method (SM)			
	Hermetic	Polypropylene sack	Local crib	**Mean**
Obatanpa	4.0	05. Apr	05. Apr	**5.0**
Abontem	138.0	236.1	133.8	**169.3**
Aburohemaa	5.0	7.3	7.6	**6.6**
Mean	**49.0**	**82.9**	**48.9**	
LSD (0.05)	**V**	**SM**	**V*SM**	
	24.88	**24.88**	**43.10**	

Aflatoxin levels under the interactive effect of variety and storage methods was significant ($p < 0.05$). The trend shows that the three maize varieties (*Obatanpa*, *Abontem* and *Aburohemaa*) had low aflatoxin levels when stored in the hermetic bags. The contamination levels increased in poly sack storage but reduced in all the three varieties when stored in the local crib. After storing the three maize varieties in hermetic bags, *Obatanpa* and *Aburohemaa* established contamination levels of 4.1 ppb and 4.7 ppb, respectively which was significantly lower ($p < 0.05$) than contamination levels in *Abontem* variety (137.9 ppb). Aflatoxin levels for the three maize varieties followed the same trend when stored in polypropylene sack and local crib. Contamination levels in *Obatanpa* (5.4 ppb) and *Aburohemaa* (7.3 ppb) when stored in polypropylene sack were similar and significantly ($p < 0.05$) lower than contamination levels in *Abontem* variety (236.1 ppb). Maize varieties stored in the local crib had contamination levels of 5.4 ppb for *Obatanpa* and 7.6 ppb for *Aburohemaa* which were significantly ($p < 0.05$) lower than *Abontem* (133.8 ppb).

4. Discussion

Six different fungi species were isolated on the maize samples before and after storage for six months. The fungal growth could be due to late harvesting of maize by farmers which predisposed the maize grains. It has been shown that maize grains are infested with microorganism right from the field and late harvesting is a contributory factor to field infestation (Widstrom, 1992).

There was varied aflatoxin levels among *Obatanpa*, *Abontem*, and *Aburohemaa* maize varieties before storage. The differences in contamination levels could be due to varied infection levels of the aflatoxin-producing fungus, *A. flavus* in maize grains on the field even before harvest. *Aspergillus flavus* infection can occur at pre-harvest, especially when the crop is in the field (Kuchareck and Raid, 2000; Hurburgh *et al*, 2005). Agriculture in Ghana is rain-fed. Coupled with high temperatures and unavailability of regular rains, the crop is left under stress. Aflatoxin presence at pre-harvest is a common phenomenon when high temperature and drought stress are present during the growth cycle (Cotty and Jaime-Garcia, 2007). This may explain the presence of aflatoxins on maize grains before storage. *Abontem* variety is an extra early maturing maize variety compared to early maturing and intermediate maturing varieties of *Aburohemaa* and *Obatanpa*, respectively. Most farmers do not cultivate one variety and also delay harvest because they want uniform drying of their cobs. Thus, *Abontem* variety will stay on the field for extra days after maturity than *Aburohemaa* and *Obatanpa* before they are harvested together. This might have predisposed that particular variety to moisture and lodging thereby promoting the infection and growth of *Aspergillus*. Different maize varieties have different susceptibilities to microbial attacks (Lokesha *et al*., 1987). Yellow maize is more susceptible to microbial and fungal attack than white maize which could be due to the high nutritive content of the yellow maize variety (Nwogu *et al.,* 1979). This could also explain the high aflatoxin levels in *Abontem* variety before storage.

The high levels of aflatotoxins in *Abontem* variety after six months of storage could be due to the high levels of the mycotoxin in the maize grains prior to storage. Aflatoxin once produced is very stable and storage conditions can only prevent further accumulation but do not reduce aflatoxin concentrations (Bani, 2014).

Maize stored in the woven polypropylene bags had the highest aflatoxin levels after six months of storage, confirming the findings of Udoh *et al.* (2000). Maize stored by traders in Uganda (majority in woven polypropylene bags) for six to seven months had mean aflatoxin levels of 107 ppb which suggests the grains were not suitable for the export and local markets (Kayaa and Warren, 2005). The possible reason for this observation may be the high temperature and high moisture content recorded in the polypropylene sack. Major factors reported for aflatoxin production in maize seeds include moisture content (Manoch *et al*., 1988), relative humidity and temperature in storage (Moreno and Kang, 1999), storage period (Chattha *et al*, 2014) and storage types (Roy and Chourasia, 2001). Grains should therefore be stored at 20 °C, 40-50% relative humidity and 11.5% grain moisture content in order to maintain grain quality (Abba and Lovato, 1999). The most important function of any storage structure is to provide hermetic conditions to the stored product and also give high protection from pests and fungi (Chattha *et al*, 2015). That could have contributed to the low aflatoxin levels in the grains stored in the hermetic bags. The interactive effect of storage method and maize varieties on aflatoxin contamination was significant with the hermetic bag storage giving comparatively lower aflatoxin levels in *Obatanpa* and *Aburohemaa* maize varieties. *Abontem* maize variety, however, had the lowest aflatoxin levels when stored in the local crib compared to the other two storage methods. This could be attributed to the efficiency of the local crib in terms of air flow and circulation which give grains lower moisture contents and subsequently reducing the development of aflatoxins. Low temperatures recorded in the local crib during storage period could also be contributory factor to the low aflatoxin levels observed in *Abontem* variety.

5. Conclusions

Quantitative studies carried out on three maize varieties from the Nkoranza-South District of the Brong-Ahafo Region of Ghana has shown that there are high levels of aflatoxins in the maize. Storage under hermetic conditions drastically reduced the levels of aflatoxins in maize. Improper storage practices such as storage in polypropylene sacks and storage in cribs promote the growth of aflatoxin-producing fungi. There is the need to intensify education for all stakeholders involved in the maize supply chain on aflatoxin contamination in maize and its negative effects on the health of humans and animals and national economy. Most farmers in Ghana are peasant and live below the poverty line. Embracing proper handling and storage practices will reduce post-harvest losses due to fungal infection and improve their income levels. Contaminated grains can be sold to ethanol producers since aflatoxins are eliminated during ethanol production. Farmers should also be educated on timely harvesting of maize and proper drying before storage. Hermetic bags are recommended for the storage of maize since they result in lower aflatoxin levels.

Acknowledgement

We are grateful to Mr. Philip Datuah of the Ministry of Food and Agriculture, Nkoranza-South District for his assistance during data collection and Mr. E. Appiah, Mr. R. Otoo, Mrs. Matilda Otchere and Mr. Kurt Martey for technical support. We wish to thank Mr. Michael Akuamoah-Boateng for his assistance in data analysis. The SATTIFS Project funded by the EU (Grant # AFS/2013/329-258) at the University of Energy and Natural Resources provided laboratory space and equipment for aflatoxin analysis and financial support for the field work.

Abstract

Cold plasma is a novel non-thermal food processing technology that uses energetic, reactive gases to inactivate contaminating microorganisms such as fungi and bacteria. This flexible sanitizing method uses electricity and a carrier gas (air, oxygen, nitrogen, or helium) antimicrobial chemical agents are not required. The primary modes of action are due to UV light and reactive chemical products of the cold plasma ionization process. *Aspergillus flavus* is the predominant species responsible for fungal contamination and subsequent production of aflatoxins mainly in grains during postharvest operations and storage. Due to their relatively high contamination risk, decontamination methods for fungi are of great interest for economic and environmental reasons, as well as in public health. Improved post-harvest processing followed by further prevention of fungal growth is an effective way to restrict aflatoxin contamination and would have major impact on reducing health related risks and on production economics. Thus, the objective is to evaluate the inactivation of *A. flavus* by cold plasma. The experiment was conducted with 3 mm sample *A. flavus*in PDA culture medium. Plasma was applied at different durations (2, 5, 10, 12, 15 and 20 min). After application, the Petri dishes with treated samples were stored at 25°C for 6 days. There was fungal growth after 2 days in the treatments with2 and 5 min durations, 4 days with the treatments with 10 and 12 min durations and there was no fungal growth with the treatments of 15 and 20 min after 6 days. The durationof 15 and 20 min with the plasma parameters tested, were efficient for the inactivation of *A. flavus*. Cold plasma may be a promising green method to be applied in this microorganisms present in grains and other products during storage.

Keywords: cold plasma, fungi, storage, inactivation

1. Introduction

The term "plasma" applies to an ionized gas, containing neutral and electrically charged species, electrons, positive and negative ions, atoms and molecules (Alves, 1995). It is formed from the excitation of a gas or gas mixture by the application of a pressure and energy, which may be the latter mechanical, thermal, nuclear or most common, electric current (Misra et al., 2014).

Cold plasma is a novel non-thermal food processing technology that uses energetic, reactive gases to inactivate contaminating microorganisms such as fungi and bacteria. This flexible sanitizing method uses electricity and a carrier gas (air, oxygen, nitrogen, or helium) antimicrobial chemical agent are not required (Niemira, 2012; Pankaj et al., 2017).

Plasma sterilization can offer an alternative for disinfection methods. This gas presents uniform treatment, can perform the activity at low temperature and without food alteration (taste, odor, structure), and finally, the plasma does not require chemicals, therefore, they do not leave toxic residues (Selcuk; et al. 2008).

Cold plasma has a variety of applications for the food industry, including decontamination of microorganisms in foods such as meats, dairy products, fruits and vegetables, granular and particulate foods (grains, herbs and spices) and germinated seeds. This technology has also been successfully applied for surface sterilization in packaging materials (Mir et al., 2016; Misra et al., 2015, Pankaj et al., 2014, Scholtz et al., 2015).

Cold plasma inactivates microorganisms by three primary mechanisms. The first is the chemical interaction of radicals, reactive species, or charged particles with cell membranes. The second is by damage to membranes and internal cellular components by UV radiation. Finally, DNA strands may be broken by UV generated during recombination of the plasma species. While on a given commodity, one mode of action may be more significant than another, the greatest sanitizing efficacy results from plasma with multiple antimicroorganism's mechanisms (Geyter and Morent, 2012; Fridman et al., 2007; Choi et al., 2006).

Aspergillus flavus is the predominant species responsible for fungal contamination and subsequent production of aflatoxins mainly in grains during postharvest operations and storage (Scussel, 2017). *Aspergillus flavus* is an aflatoxin producer (AFLs) in storage grains in tropical and subtropical climates, especially AFB_1 which is the predominant and most potentially mutagenic, teratogenic and hepatocarcinogenic mycotoxin according to the International Agency for Research on Cancer (IARC, 1993).

Due to their relatively high contamination risk, decontamination methods for fungi are of great interest for economic and environmental reasons, as well as in public health. Improved post-harvest processing followed by further prevention of fungal growth is an effective way to restrict aflatoxin contamination and would have major impact on reducing health related risks and on production economics.

2. Materials and Methods

2.1. Fungi strains

The fungi strains *A. flavus* were obtained from the Food Mycology Laboratory of Mycotoxicology and Food Contaminants (LABMICO) culture collection at the Federal University of Santa Catarina, Florianopolis, SC, Brazil.

2.2.Culture media and chemicals

Culture media - potato dextrose agar (PDA), Kasvi (São Jose dos Pinhais, PR, Brazil) andchloramphenicol, Vetec (Duque de Caxias, RJ, Brazil).

2.3.Equipment

Microbiologicalincubator, Quimis (Diadema, SP, Brazil), autoclave, Phoenix (Araraquara, SP, Brazil), microwaveoven, Philco (Sao Paulo, SP, Brazil); laminar flowcabinet, Veco (Campinas, SP, Brazil). Cold plasma reactor corona discharge type built in borosilicate glass (11.5 x 10.5 cm). The geometry of the reactor is tip-plane in relation to the metal electrodes. The electrical system used consisted of a variac for input voltage adjustments and a 16 kV power supply. For the plasma generation, alternating current was used with no oxygen gas inlet.

2.4. Cold plasma application

A disc (3 mm) with *A. flavus* mycelia material and conidia, taken from the edge of 7-days-old-fungal culture was placed individually inside the reactor. Plasma was applied at different time durations in duplicate (2, 5, 10, 12, 15 and 20 min), whereas the fungi in the control received room air at the same exposure times. Afterward, the Petri dishes containing fungi, including the control, were held in an incubator at 25◦C for 6 days. The efficiency of cold plasma treatment was evaluatedafter 2, 4 and 6 days by measuring the fungi colony diameter (Fraternale et al. 2003; Savi and Scussel, 2014).

2.5. Statistical analysis

The data of fungi colonies growthwere analyzed by analysis of variance (ANOVA).

3. Results and Discussion

The strain of *A. flavus* that received cold plasma exposure for 15 and 20 min did not grow during the 6 days incubation, showing that the plasma parameters used were effectiveat these durationsto inactivate *A. flavus*. For the treatment durationsof 2 to 12 minutes, growth was significantly lower than controls (Figure 1).

After 2 days application of the plasma, there was growth of fungi in the times of 2 and 5 min (10 mm) and control (18mm). In the treatments of 10 and 12 min, the growth was observed after 4 days (16 and 19 mm, respectively).

Allresultscomparedwiththecontroltreatmentdifferedstatistically. In Figure 2, images show the growth of fungi in petri dish containing PDA after 6 days of incubation after treatment.

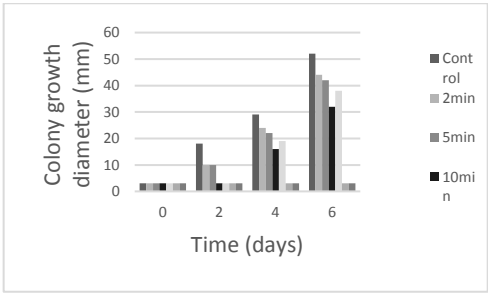

Figure 1. Effect of cold plasma (2, 5, 10, 12, 15, 20 min of exposure) on *A. flavus* growth.

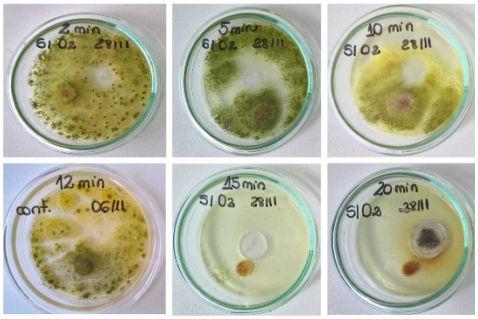

Figure 2. Colony growth of *A. flavus* in Petri dish containing PDA after 6 days of incubation after treatment.

There are fewer studies on the use of cold plasma as a decontaminant agent in fungi in foods than studies involving bacteria. The most studied foods were oilseeds (pistachios, almonds, peanuts and hazelnuts), dates and seeds (tomato, wheat, beans, oats, soya, barley, maize and rye). In relation to fungi, the genus *Aspergillus* and *Penicillium* were the most tested.

No studies were found in the literature to evaluate fungal growth after cold plasma treatment. However, many papers report their efficiency in decontamination and / or reduction of fungi on food surfaces. Dasan et al. (2016) investigated the decontamination of inoculated fungi (*A. flavus* and *Aspergillus parasiticus*) on cold plasma hazelnut surfaces. Significant reductions of 4.50 log (cfu / g) in *A. flavus* and 4.19 log (cfu / g) in *A. parasiticus*were achieved after 5 minutes of 655 W treatments. No growth was observed in *A. flavus* and *A. parasiticus* during storage of plasma-treated hazelnuts, while in the control samples the fungi continued to grow under storage conditions (30 days at 25°C).

In rice cereal bars, Suhem et al. (2013) studied the effect of cold plasma treatment to inhibit the growth of *A. flavus*. The treatment was applied to the surface of the cereal bars with 40W potency and exposure time of 20 min, reducing approximately 4 logcfu/g and also preventing growth of the fungus on the surface of the bars for at least 20 days.

Selcuk et al. (2008) successfully decontaminated the seeds of wheat, bean, chickpea, soybean, barley, oat, rye, lentil, and corn, contaminated with *Aspergillus* and *Penicillium sp.* to less than 1% of initial count depending on treatment times. The treatment times varied from 30 s to 30 min. The results suggested that after plasma treatment food quality of wheat and beans were not affected or only marginally affected. The seeds were found to be viable post plasma processing.

The mechanism by which plasma causes the cell death of microorganisms is due to reactive species of O_2, OH, NO2, etc. which have been extensively associated with direct oxidative effects on the outer surface of microbial cells. Reactive oxygen species are expected to significantly affect membrane lipids due to their location along the cell surface of the microorganisms, allowing them to be bombarded by these strong oxidizing agents (Scholtz et al., 2015; Laroussi, 2005; Mendis, Rosenberg, Azam, 2000). Oxidation of amino acids and nucleic acids can also cause changes that result in death or injury of the microorganism such as bacteria and fungi (Mir; Shah; Mir, 2016; Guo et al., 2015).

4. Conclusions

*Aspergillusflavus*treated was significantly reducedby cold plasma treatment application. The best results of antifungal effect were observed on 15 and 20 min of exposure, that were completely inhibited showing to be an effective method for this storage fungus. Cold plasma may be a promising green method to be appliedto control this microorganism present in grains and other

products during storage. It also could be a promising method of decontamination in industries and storage units, in order to avoid contamination and ensure food security to the consumer.

Abstract

Computer-aid molecular docking is a simulative process that receptors and ligands recognize each other through energy matching and geometric matching. It is widely used in bioactive compounds simulative screening and preliminary exploring the bioactivity and toxicity of molecular, which plays important guiding role in toxicity and bioactivity study of molecular entities. In our study, we used the computer-aid molecular docking software-discovery studio 3.1 client to test the mechanism of aflatoxins such as aflatoxin B1, B2, M1, M2, G1, G2 and the results of our experiment help to illustrate the pathway of aflatoxin's toxication. We also used this technology to test the preliminary toxicity of zearalenone (ZEN) and its two degradation products: α-zearalenol (α-ZOL) and β-zearalenol (β-ZOL), which indicates that these three products possessed significant estrogenic activity. The order of the estrogenic activity is: α-zearalenol > zearalenone >β-zearalenol.

Key words: computer-aid molecular docking, aflatoxin, zearalenone, toxicity

1. Introduction

Over the last few decades, computer-aid molecular docking technology has grown significantly in the development of new drug molecules. As a powerful technique, it relives the tension in drug discovery such as time-consuming, high-cost and low success rates. Additionally, with rapid development of biological structures and computer technology, this technology is widely used in mycotoxin toxicity pathway research (Shoichet et al., 2002; Powers and Setzer, 2015).

Using direct docking methods or virtual high-throughput screening, affinity of molecules to targets can be estimated based on compounds' conformation and complementarity with residues in binding site. Through analysis of binding free energies, further filtering and optimization of possible molecules subsequently follow, a limited number of lead molecules are selected for *in vitro* bioactivity tests. Automatic docking is aimed at the determination of the optimal position and orientation of molecule in binding pocket of particular protein target (Verdonk et al., 2011; Śledź and Caflisch, 2017). Quality of protein–ligand interactions are usually qualified by ligand efficiency (LE) and average binding energy per non-hydrogen atom of the ligand. While virtual high-throughput screening is performed to evaluate libraries of molecules for binding affinity to the protein target. This HTS strategy can shortlist compounds that are most likely to bind to the selected target with the highest affinity. A plethora of software have been developed for molecular docking including Dock, GOLD, and AutoDock, et. In addition, other docking strategies such as flexible ligand docking, fragment docking and fragment growing have been used in high-throughput docking campaigns (Macalino et al., 2015; Leelanada and Lindert, 2016).

In our research, we used the computer-aid molecular docking software-Discovery Studio 3.1 client (Accelrys, USA) to test the mechanism of aflatoxins and illustrate the pathway of aflatoxin's toxication. We also used this technology to test the preliminary toxicity of zearalenone and its two degradation products: α-zearalenol and β-zearalenol, which indicates that these three products possessed significant estrogenic activity.

2. Materials and Methods

The 2D structure of Aflatoxin B1 and Oltipraz was generated by ChemDraw Ultra 12.0 (CambridgeSoft, Cambridge, MA, USA). A homology model of protein receptor was constructed from crystal structure of PDB: obtained from the RCSB protein Data Bank,

Water molecules were removed and H atoms were added to the structure. 3D structures of the compounds were generated and optimized by the Discovery Studio 2.1 package (Accelrys, San Diego, CA, USA). The receptor-grid files were carried out using a grid-receptor generation program using default settings after ensuring that the ligands and the protein are in correct form. The GOLD program in the Discovery Studio software was used to perform the docking simulations, which allows full flexibility of the ligand.

The structures of the aflatoxins， zearalenone, α-zearalenol and β-zearalenol were drawn in chem3D with standard lengths and angles. The Gasteiger–Huckel charge, with a distance-dependent dielectric function, and AM1 docking calculations were applied for the minimization of

the molecules. To modify the structure of receptor, missing atoms, bonds, and contacts were checked, hydrogen atoms were added to the enzyme structure, and water molecules were removed. Intercalation models were optimized using the CHARMm forcefield with the added parameters. After performing the docking simulation, the scores of the docked conformers were ranked the best binding modes in the cavity was picked out.

3. Results and Discussion

3.1. Aflatoxin toxicity analysis

Aflatoxins are among the most potent natural hepato-carcinogenic products, which are produced mainly by the fungi *Aspergillus flavus* and *A. parasiticus*. Twelve aflatoxins analogues including aflatoxin B1, B2, G1, M1, P1, Q1, H1, GM, B2a and aflatoxicol have been separated and identified. The basic structures of aflatoxins are dihydrofuran, coumarin and aflatoxin B1(AFTB1), which is the analogue of dihydrofuran oxynaphthalene, contains two furan rings (the basic toxic structure) and one cumarin (Eaton and Gallagher, 1994; Koudande, 2013).

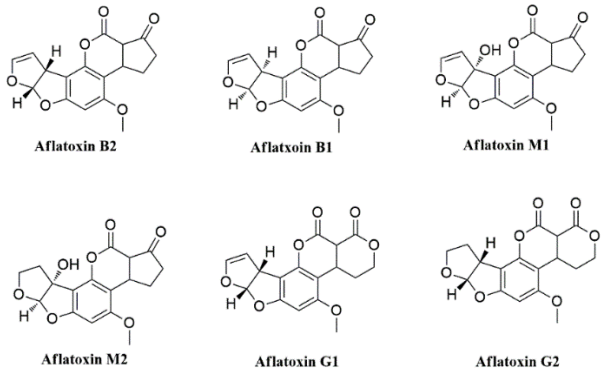

Fig. 1 The chemical structures of aflatoxin's metabolic products

The interaction between AFTB1 and receptor proteins

In our research, we chose some kinds of proteins which play significant roles in cell apoptosis, estrogen metabolism, immunosuppression and digestive system function as the potential targets of the toxic pathway of aflatoxin b1, including Caspase-1, cell division protein kinase 2, serine/threonine protein kinase chk1, progesterone receptor, androgen receptor, estrogen receptor, alpha-thrombin, prostaglandin g/h synthase 2, estradiol 17-beta-dehydrogenase 1, macrophage migration inhibitory factor and estrogen sulfotransferase. We made AFTB1 molecular docked with the above proteins by molecular docking software, the results was shown in **Tab 1.** As the results shown, estrogen sulfotransferase was proved to be the best dock receptor of AFTB1 and the score were 130.22 and -10.9013 by Libdock and CDocker, respectively.

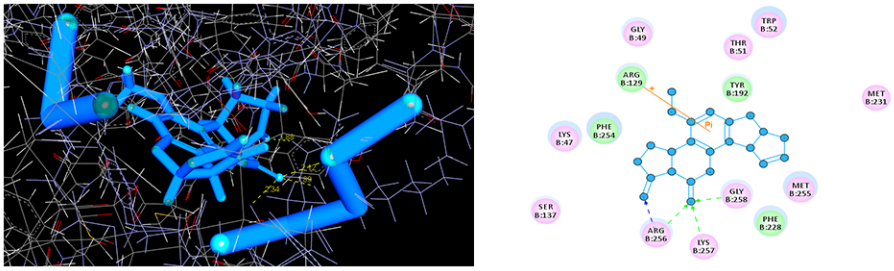

Fig. 2 The interaction between AFTB1 and estrogen sulfotransferase

Tab. 1 AFTB1 targets predicted by Libdock and CDocker

Protein	PDB	Libdock score	CDocker score
caspase-1	3D6F	828.002	/
cell division protein kinase 2	1HCK	972.643	-0.549952
serine/threonine-protein kinase chk1	1IA8	100.060	/
progesterone receptor	1A28	986.966	/
androgen receptor	5DIU	113.528	-209.024
estrogen receptor	1QKM	110.000	-221.885
alpha-thrombin	1ABI	822.093	/
prostaglandin g/h synthase 2	1PD2	117.653	/
estradiol 17-beta-dehydrogenase 1	1BHS	986.731	/
macrophage migration inhibitory factor	1MFI	908.723	-968.253
estrogen sulfotransferase	1HY3	130.022	-109.013
sex hormone-binding globulin	1D2S	111.558	-162.633

The interaction between AFTB1 and estrogen sulfotransferase

We made AFTB1 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 2.** AFTB1 could perfectly docked into the formed cavity of estrogen sulfotransferase protein and there was formed cation-π interaction between the benzene ring and arginine residue (ARG B:129). The carbonyl group in coumarin formed hydrophobic interactions with tyrosine residue（TYR B:192）and the oxygen atom in furan ring formed hydrophobic interactions with arginine residue (ARG B:256).

The interaction between AFTB2 and estrogen sulfotransferase

We made AFTB2 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 3.** AFTB1 could perfectly docked into the formed cavity of estrogen sulfotransferase protein and there was formed cation-π interaction between the benzene ring and arginine residue (ARG B: 129). The carbonyl group in coumarin formed hydrophobic interactions with arginine residue（ARG B:256），allysine residue (LYS B:257) and glycine residue (GLY B:258).

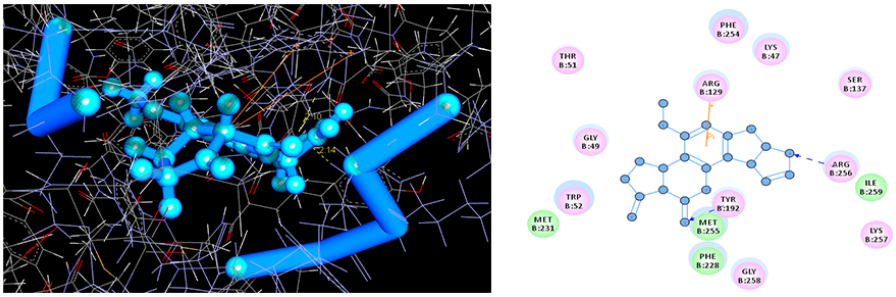

Fig. 3 The interaction between AFTB2 and estrogen sulfotransferase

The interaction between AFTBM1 and estrogen sulfotransferase

We made AFTB M1 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 4.** AFTB1 could perfectly docked into the formed cavity of estrogen sulfotransferase protein and there was formed cation-π interaction between the benzene ring and arginine residue (ARG B:129). The phenolic hydroxy group furan ring hydrophobic interactions with arginine residue（ARG B:256), allysine residue (LYS B:257) and glycine residue (GLY B:258). The oxygen atom in furan ring formed

hydrophobic interactions with arginine residue (ARG B:256).

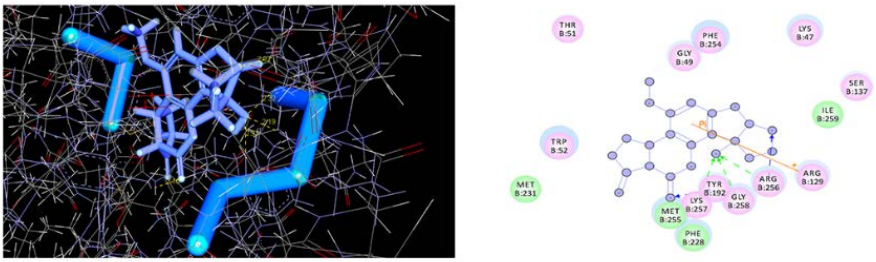

Fig 4. The interaction between AFTB M1 and estrogen sulfotransferase

The interaction between AFTB M2 and estrogen sulfotransferase

We made AFTB M2 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 5.** There was formed cation-π interaction between the benzene ring and arginine residue (ARG B:129). The phenolic hydroxy group furan ring hydrophobic interactions with arginine residue（ARG B:256），lyrosine residue（TYR B:192），and glycine residue (GLY B:258). The oxygen atom in furan ring formed hydrophobic interactions with arginine residue（ARG B:256），the carbonyl group in coumarin formed hydrophobic interactions with tyrosine residue (TYR B:192).

The interaction between AFTB G1 and estrogen sulfotransferase

We made AFTB G1 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 6.** There was formed cation-π interaction between the benzene ring and arginine residue (ARG B:129). The inside carbonyl group in coumarin formed hydrophobic interactions with arginine residue (ARG B:256)， allysine residue (LYS B:257) and glycine residue (GLY B:258). The outside carbonyl group in coumarin formed hydrophobic interactions with allysine residue (LYS B:47), The oxygen atom in furan ring formed hydrophobic interactions with arginine residue(ARG B:256).

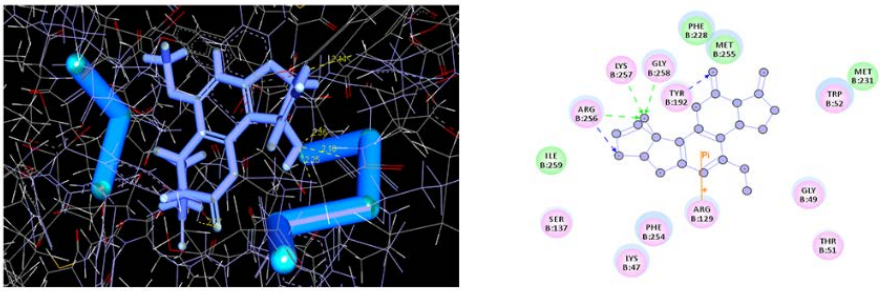

Fig. 5 The interaction between AFTB M2 and estrogen sulfotransferase

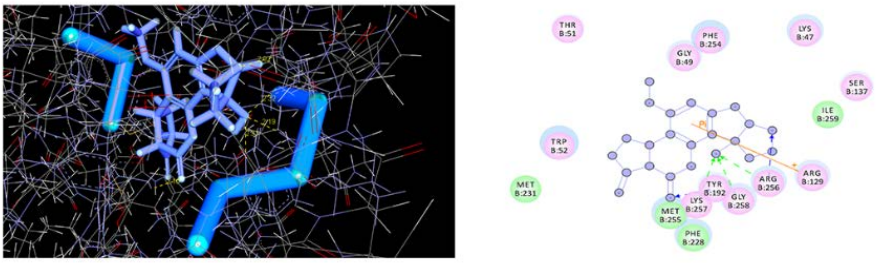

Fig. 6. The interaction between AFTB M2 and estrogen sulfotransferase

The interaction between AFTB G2 and estrogen sulfotransferase

We made AFTB G1 docked with estrogen sulfotransferase, the docking result was shown in **Fig. 7.** There was no formed cation-π interaction between the benzene ring and any residue. The inside carbonyl group in coumarin formed hydrophobic interactions with arginine residue (ARG B:256), allysine residue (LYS B:257) and glycine residue (GLY B:258). The outside carbonyl group in coumarin formed hydrophobic interactions with allysine residue (LYS B:47).

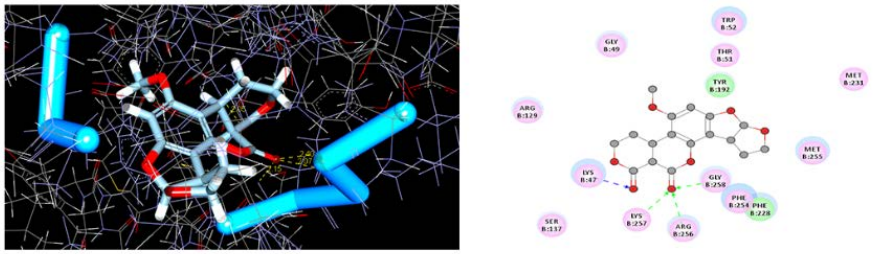

Fig.7 The interaction between AFTB G2 and estrogen sulfotransferase

The Binding energy and docking score between ligand and receptors

The results of binding energy and docking score between aflatoxin B1, B2, M1, M2, G1, G2 and estrogen sulfotransferase were shown in **Tab 2**. The binding energy between AFTB1, AFTB2, AFTB M1, AFTB M2, AFTB G1, AFTB G2 with estrogen sulfotransferase was -10.9013 kcal/mol, -20.2356 kcal/mol, -8.5654 kcal/mol, - 8.2156 kcal/mol, -19.5298 kcal/mol, -14.1768 kcal/mol. AFTB M1 was proved to be the best binding ligand with estrogen sulfotransferase receptor.

Tab 2 the Binding energy and docking score between ligand and receptors

Ligand	Binding energy	Number
Aflatoxin M2	-8.21584	10
Aflatoxin M1	-8.5654	10
Aflatoxin B1	-10.9013	10
Aflatoxin G2	-14.1769	10
Aflatoxin G1	-19.5298	10
Aflatoxin B2	-20.2356	10

3.2. Estrogenic effect in zearalenone

Zearalenone [6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)-resorcylic acid lactone, abbreviated as ZEN] is a mycotoxin that is produced by *Fusarium roseum* and is usually isolated from moldy corn (Reed et al, 2004). Zeranol a synthetic tetrahydro-derivative of ZEN, has been used as a growth promoter

for food-producing animals (Caldwell et al., 1970). Earlier studies have shown that ZEN and ZOL have strong estrogenic effects, and each of them was reported to have a similar dose–response curve pattern in stimulating uterine weight gains in neonatal rats or immature mice (Urry et al, 1966). The most commonly ZOL are α-ZOL and β-ZOL, which are shown in **Fig. 8.**

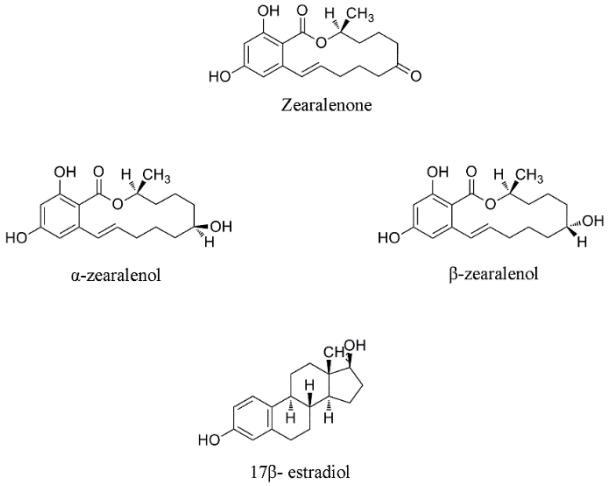

Fig. 8 Chemical structure of ZEN, α-ZOL, β-ZOL and β-estriol

The interaction between ZEN and α-estrogen receptor protein

In order to prove the estrogen effect of ZEN in molecular stage, we used the molecular docking software to simulate the binding situation between ZEN and α-estrogen receptor protein, as **Fig. 9** shown, ZEN can perfectly docked into the cavity of estrogen receptor protein crystal structure, and the hydroxy group of benzene ring formed strong hydrophobic interactions with contiguous alanine residue (ALA350) and glutamic acid residue (GLU353), which strengthen the binding ability between the ligand sand the receptors.

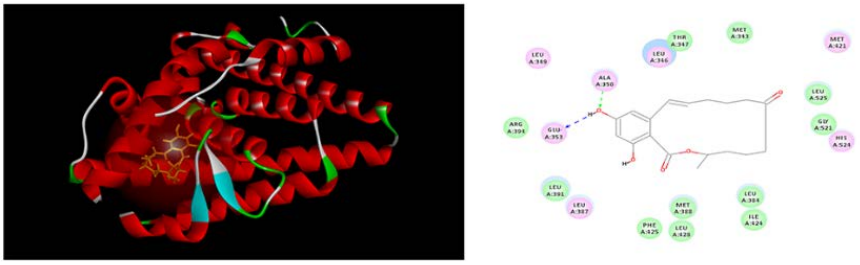

Fig. 9 The interaction between ZEN and α-estrogen receptor protein

The interaction between ZEN and β-estrogen receptor protein

We used the molecular docking software to simulate the binding situation between ZEN and β-estrogen receptor protein, as **Fig 10** shown, the 3-hydroxy group in benzene ring of ZEN formed strong hydrophobic interactions with contiguous histidine residue (HIS475) and glycine residue (GLY472), which strengthen the binding ability between the ligand sand the receptors.

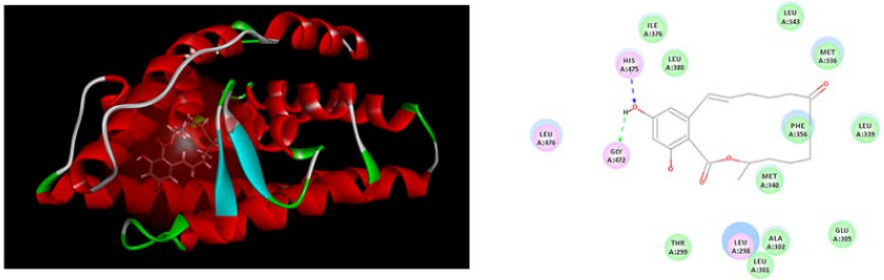

Fig. 10 The interaction between ZEN and β-estrogen receptor protein

The interaction between ZOL and estrogen receptor protein

We have proved that ZEN molecule had favorable binding ability with α-estrogen receptor protein and β-estrogen receptor protein, which demonstrated that ZEN possessed strong estrogen effect. In the following study, we would prove whether ZOL had the similar estrogen effect.

We used the molecular docking software to simulate the binding situation between α-ZOL, β-ZOL and α- estrogen receptor protein, β-estrogen receptor protein. From Fig 11, It was proved that α-ZOL can perfectly docked into the cavity of estrogen receptor protein crystal structure, 3-hydroxy group in benzene ring of α-ZOL formed strong hydrophobic interactions with contiguous arginine residue (ARG394) in α- estrogen receptor protein and glycine residue (GLY472) in β-estrogen receptor protein; aliphatic hydroxyl group in aliphatic chain formed strong hydrophobic interactions with methionine (MET421) in α- estrogen receptor protein and glutamic residue (GLU305) in β-estrogen receptor protein. The binding ability between β-ZOL and estrogen receptor protein was relatively weak and there only one existed hydrophobic interaction according to the docking results (Fig. 12)

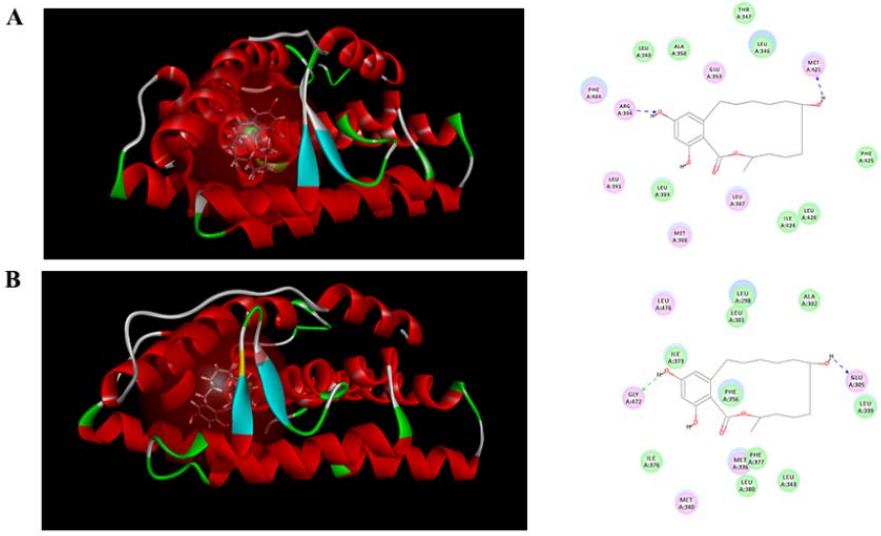

Fig. 11 The interaction between α-ZOL and estrogen receptor protein

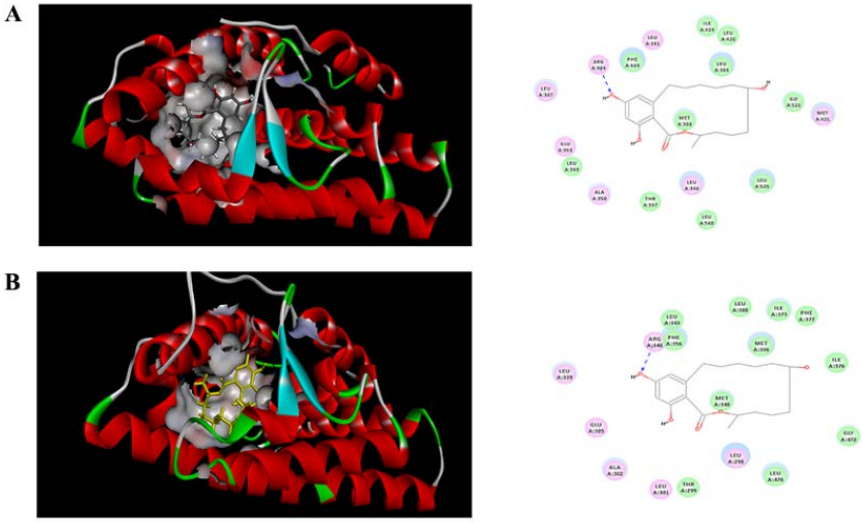

Fig. 12 The interaction between β-ZOL and estrogen receptor protein

The binding ability and docking score between ligands and recepor

The results of binding energy and docking score between 17β- estradiol (positive control), ZEN, α-ZOL, β-ZOL and estrogen receptor protein were shown in Tab 3. The order of the estrogenic activity is: α-zearalenol > zearalenone >β-zearalenol.

Tab3 the Binding energy and docking score between ligand and receptors

Ligand	Estrogen receptor protein	Binding energy （kcal/mol）	Libdocks score
17β- estradiol	α- estrogen receptor protein	-26.8334	98.9602
17β- estradiol	β-estrogen receptor protein	-26.8334	108.235
ZEN	α- estrogen receptor protein	-38.9894	113.57
ZEN	β-estrogen receptor protein	-38.9894	106.956
α-ZOL	α- estrogen receptor protein	-41.937	94.0647
α-ZOL	β-estrogen receptor protein	-41.937	72.6476
β-ZOL	α- estrogen receptor protein	-27.6144	115.28
β-ZOL	β-estrogen receptor protein	-27.6144	107.458

Abstract

In Brazil beans are an important protein source and the great variety of *Phaseolus* and *Vigna* beans grains are sold in retail markets. The objective of this study was to isolate fungi from insects and *Phaseolus vulgaris* (var. Pinto) from 15 samples of different retail stores in São Paulo. The samples were placed in Petri dishes containing culture medium of potato-dextrose-agar and incubated at 25°C for 7 days. Fungi were identified in several insects: *Callosobruchus maculatus* (yeasts - 50%), *Sitophilus* spp. (*Chaetomium* spp. – 3.1%; *Rhizopus stolonifer*- 3.1%; Non Sporulating Fungi (NSF) – 12.5% and *Eurotium chevalieri* - 9.4%, *Acanthoscelides obtectus* (*Penicillium* spp. – 18.5% and yeasts – 18.5%) and *Zabrotes subfasciatus* (*Alternaria alternata* – 13.6 % and *Penicillium* spp. – 41 %). No fungi were observed in the parasitoid *Dinarmus basalis*. In grain samples, the following fungi were found: *Penicillium* spp. (6%), *E. chevalieri* (5%), *R. stolonifer* (0.3%), *Aspergillus flavus* (3 %), NSF (8 %), Yeasts (2.6%), *Phoma* spp. (1.6%) and *Alternaria alternata* (3.6%).

Keywords: bean, grain, fungi, insects

1. Introduction

The common bean (*Phaseolus vulgaris* L.) is one of the most widely consumed legumes in the world (Barros and Prudencio, 2016). Bean growers are looking for new storage options that maintain the quality of seed beans for use in planting and also for beans produced for the retail market. The most frequent causes of losses in storage beans are: insects, fungi and rodents. This causes the decrease in quality, as taste and the appearance of grain (Bragantini, 2005). The stored beans are mainly attacked by *Acanthoscelides obtectus* (Say), *Zabrotes subfasciatus* and *Callosobruchus maculatus* (Botelho, 2002). Insects are vectors for fungi and cause physical damage to the grain. The control of both effects is important in the safety and quality of stored grains (Aquino and Potenza, 2013). This study analyzed the insects and mycobiota in samples of *Phaseolus vulgaris* (pinto beans) purchased in several retail markets in São Paulo.

2. Materials and methods

Fifteen 1-kg samples of *Phaseolus vulgaris* (pinto bean) were purchased in retail markets of São Paulo. Samples were sieved and the insects collected using aspirator. Samples were held at 27 ± 2º C and 70 ± 5% relative humidity for 45 days, sieved and the emerged insects collected. For the fungal isolation, the samples were submitted to direct plating on potato dextrose agar (PDA) and

incubated at 25 ± 1 °C for 7 days (Berjak, 1987). The counting of fungal genera was quantified in percentage and subsequently, the different morphological mycelium was isolated in test tubes containing PDA and submitted to the technique of microculture for the species identification (Riddell, 1950).

3. Results

Fifty percent of the *C. maculatus* individuals - present in the samples - were positive for yeasts. *Sitophilus* spp. was the insect species associated with the greatest variety of fungi: *Chaetomium* spp. (3.1%), *Rhizopus stolanifer* (3.1%), NFS (12.5%) and *Eurotim chevalieri* (9.4%). No fungi were isolated in *D. basalis* individuals. The fungi *Penicillium* spp. and yeasts were isolated for 18.5 of *A. obtectus*. Plated individuals of *Z. subfasciatus* presented 13.6% of *A. alternata* and 41% of *Penicillium* spp. (Table 1).

Table 1 - Frequency (%) of yeasts and fungi isolated from insects collected in samples of *Phaseulos vulgaris*.

Insects	Microorganism isolated	Insects with microrganisms (%)	Number of Insects
Callosobruchus maculatus	Yeasts	50.0	4
***Sitophilus* spp.**	*Chaetomium* spp.	03. Jan	38
	Rhizopus stolanifer	03. Jan	
	NSF	12. Mai	
	Eurotim chevalieri	09. Apr	
Dinarmus basalis	(---)	(---)	2
Acanthoscelides obtectus	*Penicillium* spp.	18. Mai	27
	Yeasts	18. Mai	
Zabrotes subfasciatus	*Alternaria alternata*	13. Jun	22
	Penicillium spp.	41.0	

Non Sporulated Fungi – NSF.

(---) - No fungal grow th.

In the bean samples it was observed 6 % of *Penicillium* spp.; 5% of *E. chevalieri*; 0.3% of *R. stolonifer*, 3% *A. flavus*; 8 % NFS; 2.6% Yeast; 1.6% of *Phoma* spp. and 3.6% of *A. alternate* (Figure 1).

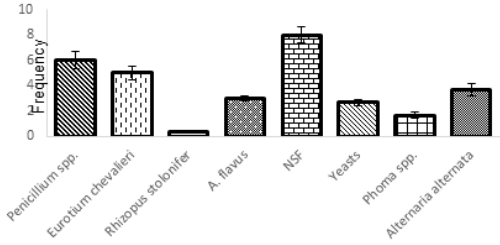

Figure 1 - Frequency of fungi species isolated from *Phaseolus vulgaris*.

4. Discussion

According to Bull (1993), grain quality can be affected even in the field before harvest, where infestation by insects and fungus contamination begins. Storage fungi are always present in high numbers and in all types of materials such as air, dust, water, which are normal constituents of grain and seed film (Lazzari, 1997). (Tseng et al, 1995) identified the fungi genera from grains of *P. vulgaris* collected in Taiwan: *Aspergillus* (48.5%), *Penicillium* (27.6%), *Eurotium* (6.7%), *Rhizopus* (5.3%) and *Curvularia* (2.4%). (Domijan et al, 2005) in a study to identify fungi transmitted by seeds of *Phaseolus vulgaris*: *Cladosporium* spp. (98%) *Alternaria* spp. (75 %), *Aspergillus* spp. (73%), *Rhizopus* spp. (73%), *Penicillium* spp. (69%), *Fusarium* spp. (38%), *Botrytis* spp. (27%), *Trichothecium* spp. (24%) and *Chaetomium* spp. (18%). It was concluded that the storage conditions should be monitored in the retail market to prevent loss of quality caused by insects and fungi.

Abstract

Entomopathogenic fungi have been investigated to control stored product pests, as an alternative strategy to chemical insecticides. Although many studies evaluated isolates from various sources, few studies surveyed fungi naturally infecting stored product pests, revealing predominantly *Beauveria* isolates. This study aimed to reveal the amount of *Beauveria* carried on the surface of stored wheat kernels, and their pathogenicity against *Rhyzopertha dominica* and *Sitophilus oryzae* adults. Sixteen wheat samples from different storage facilities in four cities were examined for existence of *Beauveria*. One-hundred g of wheat was washed in 100 mL of 2% Tween80 solution. After increasing concentration of possible fungi by centrifugation, the liquid was spread on medium with dodine and monitored at 25±2°C. Nine of the isolates were tested for pathogenicity at 500 ppm (w/w) at 25±2°C, 65±5% r.h. in darkness with five replicates. While only four samples did not have *Beauveria*, others had 17-2992 cfu/100 g wheat. Six samples had 17-50, four samples 150-858, one sample 1625 and one had 2992 cfu/100 g wheat. Mortalities against *R. dominica* adults ranged between 5-86% and 32-100% in 7 and 14 days, respectively. Mortality of *S. oryzae* ranged from 3-45% and 8-83% in 7 and 14 days, respectively. This study demonstrated that wheat kernels can naturally carry *Beauveria* with various levels of pathogenicity. Potential naturally occurring entomopathogenic fungi can be isolated directly from stored commodities to be evaluated as biological control agents for stored product pest control.

Keywords: microbial control, biological control, entomopathogen, survey.

1. Introduction

Cereals are important for human consumption and livestock in the world. After harvesting they are usually stored for various lengths of time. During storage, they need to be protected against insect and mite pests. Unless suppressed, the populations of these pests cause reduction in the weight and value as well as decline of seed germination (Moino et al., 1998; Padin et al., 2002; Haq et al., 2005; Stejskal et al., 2015). The use of synthetic insecticides to suppress pest populations has been commonly practiced (Athanassiou & Palyvos, 2006); however, its negative effects such as pest resistance to the chemicals (Arthur, 1996), residue accumulation in grains (Ferizli et al., 2005), and

detrimental effects on humans and the environment (Michalaki et al., 2007) have directed researchers to seek nontoxic and environmentally friendly methods to suppress stored product pests. One alternative that has been considered is the use of entomopathogenic fungi (Moino et al., 1998; Michalaki et al., 2007; Sewify et al., 2014; Wakil & Schmitt, 2014) due to their organic nature and low hazard to human and the environment (Moore et al., 2000). The potential of entomopathogenic fungi as bioinsecticides against insect pests of stored products has been reported in many literature (Cherry et al., 2005; Wakil & Ghazanfar, 2010; Shams et al., 2011; Barra et al., 2013; Khashaveh & Chelav, 2013; Sewify et al., 2014). The potential of entomopathogenic fungi in combination with diatomaceous earth has also been reported (Athanassiou & Steenberg, 2007; Athanassiou et al., 2008; Wakil et al., 2011; Riasat et al., 2011, 2013; Shafighi et al., 2014). There are few studies investigated the natural occurrence of entomopathogenic fungi in stored product pests (Odour et al., 2000; Wakefield et al., 2005; Wakil et al., 2014; Er et al., 2016). Most commonly, *B. bassiana* has been found and most of the literature evaluated this species as a biocontrol agent. In this study wheat kernels are examined for existence of *Beauveria* as source of inoculum and the pathogenicity of obtained isolates was tested against adults of two coleopteran pests of stored grains, *Rhyzopertha dominica* and *Sitophilus oryzae*.

2. Materials and Methods

Insect cultures

Rhyzopertha dominica and *Sitophilus oryzae* cultures have been maintained in our laboratory. Starting insects had been originally obtained from surrounding storage facilities. Durum wheat with 12% moisture content was used for the cultures. Glass jars of 1 L capacity with 250 g of wheat were used. Adults of mixed sex were placed into the jars and kept for three days for oviposition. After removing the adults, the cultures were incubated for the emergence of new generation adults. One-week old adults were used for the bioassays. All the cultures were maintained at 26±2 ºC and 65±5% relative humidity in darkness.

Wheat samples

Sixteen wheat samples from different storage facilities in four cities in Turkey were taken as described in Er et al. (2016) and examined for existence of *Beauveria*. Eight samples were from Osmaniye, 5 from Hatay, 2 from Adana and one from Kahramanmaraş.

Processing samples and isolation of fungi

Each sample is mixed and 100 g of it was used for fungus isolation. Wheat kernels were washed by placing in 100 mL of 2% Tween 80 solution and agitating. After removing the kernels, particles in the liquid were sedimented in two 50 mL capacity tubes by using a fixed angle centrifuge at 8000 g for 10 mins. Sediments in both tubes were combined and filled to 5 mL. After increasing concentration of possible fungi by centrifugation, 200 µL of the liquid was spread on oat meal agar supplemented with 650 µL/L dodine and 1% streptomycin + penicillin. The experiment was conducted with three replicates. Growth of fungi was monitored at 25±2ºC and number of *Beauveria* colonies in each petri dish was recorded. Selected *Beauveria* samples are subcultured and purified on potato dextrose agar at the same conditions. Nine *Beauveria* isolates were used for spore production following mass production procedure described by Barış (2016). One-hundred g of rice was soaked overnight with tap water and the excess water was drained. The rice supplemented with 1.5 g of $CaSO_4$ and $CaCO_3$ was sterilized in a polyethylene bag (25 cm x 38 cm). After cooling, it was inoculated with 10 mL of spore suspension ($2x10^7$ spores/mL) and sealed. Following fungal growth at 25±2°C, 12/12 photoperiod for 14 days the culture was dried at 25±2°C. Spores were separated from substrate by using a 500 µm sieve.

Pathogenicity tests

Centrifuge tubes of 50 mL capacity each with 40 g of wheat were used for the tests. Wheat in each tube was mixed with 20 mg of spores producing a final concentration of 500 ppm (w/w) by shaking for 5 minutes. Twenty adults were released in each tube and kept at 25±2ºC, 65±5% relative humidity in darkness. Wheat kernels without spores were used as control. The experiment had five replicates.

3. Results

Among the 16 samples, 12 had *Beauveria* colonies in at least one of the Petri plates, while only four samples did not have *Beauveria* colonies. The mean number varied between 17 and 2992 cfu/100 g wheat. Six samples had 17-50, four samples 150-858, one sample 1625 and one had 2992 cfu/100 g wheat. When these fungi were tested, *R. dominica* adult mortalities ranged between 5-86% and 32-100% in 7 and 14 days, respectively. *S. oryzae* mortalities were lower and recorded as 3-45% and 8-83% in 7 and 14 days, respectively.

4. Discussion

This study demonstrated that stored wheat kernels can naturally carry *Beauveria* at various levels, but in rather low concentrations. These results support the findings of previous survey studies for natural fungal infections on stored product pests (Odour et al., 2000; Wakefield et al., 2005; Wakil et al., 2014; Er et al., 2016). In all these studies, a low percentage of insects were found to be naturally infected by *Beauveria*. The reason could be the existence of low *Beauveria* inoculum in their habitats as shown in this study.

Testing the isolates in the study resulted in various levels of mortalities in both insect species. Such variation in the pathogenicity of isolates within the same species was commonly reported (Moino et al., 1998; Kassa et al., 2002; Wakefield et al., 2005; Sewify et al., 2014). The efficacy of the isolates against *S. oryzae* adults was lower than that against *R. dominica* adults. Similarly, Moino et al. (1998) and Sewify et al. (2014) found that *R. dominica* is more susceptible than *S. oryzae*. All the findings together suggest that diversity of *Beauveria* isolates obtained in this study is similar to those reported earlier in terms of their pathogenicities. Therefore, naturally occurring potential entomopathogenic fungi can be isolated directly from stored commodities to be evaluated as biological control agents for stored product pest control.

DOI 10.5073/jka.2018.463.248

Abstract

The storage conditions are of extreme importance with regards to grains (cereal & pulses) components (carbohydrates, lipids, proteins) preservation and quality for industry (that may interfere to whole process and quality of the final product). In addition, the vegetarian consumers' interest of protein supplement (capsules)

from pulses such as beans (*Phaseolus vulgaris* L.), chickpeas (*Cicer arietinum L.*), lentils (*Lens culinaris* L.), peas (*Pisum sativum* L.), peanuts (*Arachis hypogaea* L.), also soybeans (*Glycine max* L.) has grown considerably, mainly due to their non-lactose&non-animal-based ingredients and also non-transgenic in some of the pulses. Therefore, there is a need of information regarding pulses storage conditions on their components' quality/quantity and so for safety of the raw material utilized for protein extract purposes. In addition, to get safe pulses raw materials for protein extraction aimed for vegetarian supplements, one needs to take into account (a) quite controlled storage conditions, apart from (b) pesticide residues and mycotoxins contamination control. Therefore, the present reviewgathers and compiles the characterization of six different pulses by evaluating amino acids profile as indicators of protein quality, and compares them with different varieties for further protein extraction.

Key words: pulses, beans, peas, lentils, storage, protein, denaturation, fungi, mycotoxins.

1. Introduction

1.1 Pulses consumption and proteins

Pulses, are dry seeds from Fabaceae or Leguminosae family, which are cultivated throughout the world due to its easy adaptation to different climates. They are highly nutritious and play an important role on human diet (Aykroyd et al, 1982; Ofuya, 2005). They include beans (*Phaseolus vulgaris* L.), chickpeas (*Cicer arietinum L.*), lentils (*Lens culinaris* L.), peas (*Pisum sativum* L.), peanuts (*Arachis hypogaea* L.) and soybeans (*Glycine max* L.). Furthermore, vegetarian protein supplements consumption makes the pulseslikely to grow considerably, since they are lactose-free and non-animal based protein products (FAO, 2016; Aykroyd et al, 1982). Among the different pulses, the high oil content - soybeans followed by peanuts, as well as lentils and beans are the main protein sources, with 42.0, 32.0, 31.0, and 30.0%, respectively (Table 1).

1.2 Storage conditions and protein quality

There are physicochemical and biological changes that occur during pulses storage and affect considerably their components' quality and quantity. Therefore the storage conditions require a special care to maintain the quality and safety of the raw material utilized for protein extraction (Nasar-abbas et al, 2008). Data reported in the literature (especially during hot seasons) lead to protein denaturation. Inactivation starts taking place at temperature around 35°C. The same for humidity, as most proteins have globular shape, low moisture content (mc) and water activity (a_w) lead to their 3D structure alteration (the opposite - high humidity contents - lead to living organisms proliferation). That includes also the storage *length of time*, which, when pulses are kept under adverse conditions for long time, they may add to the other components reactions and so to the proteins (Labuza et al, 1982). Regarding *pH*, its reduction, causes pulses alterations (due to fermentation and oxidative reactions by fungi/bacteria & insects/mites activities to carbohydrates and lipids, respectively) leading to protein denaturation (including enzymes inactivation affecting catalysis) (Klupsaite et al, 2015). Furthermore, the Living Organisms (L.O.) infestation/ infection, such as insects, mites and fungi, can lead to protein reduction (components consumed by (L.O.), thus interfering with quality and quantity. In addition, pesticide residues (from field and storage applications) and mycotoxins (from toxigenic fungi) play a role in contamination of peas/lentils protein extracts (Cegielska et al, 2003). Regarding the impurities that may come from the field (foreign matter & broken/deteriorated/toxin contaminated pulses), despite of their pre-cleaning and cleaning reduction, they can bring also contamination to pulse in storage (Waliyar et al, 2014).

Considering the lack of information regarding specifics on pulses proximate composition, aiming the proteins and amino acids profile, also their alterations under storage conditions: the current work gathered literature data regarding pulses characteristics, storage specifics for protein quality/quantity improvement and extraction methodologies, including contaminants and impurities that may be brought into the protein process.

Tab 1. Protein percentages in the proximate composition of different pulses

Pulses	Proximate composition (%)						
	Protein	Carbohydrate	Lipid	Fiber	Ash	mc[a]	Kcal/100 g
Beans[b]	27.1-29.5	54.3-64.1	0.5-16.3	12.7-24.9	2.70-4.30	9.0-13.4	333-409
Chickpeas[b]	22.9-24.8	60.8	6.2	17.4	2.64	11.5	36
Lentils[b]	26.1-31.3	58.2	2.1	30.5	2.55	10.8	353
Peas[b]	22.8-26.5	60.4-63.2	0.8-1.5	15.0-25.5	2.70-3.45	0.6-10.6	341-343
Peanut[b]	28.8-32.0	1.8	47.0	3.7	3.80	5.8	620
Soybean[b]	38.6-42.0	29.8-33.3	22.2-23.8	5.8	5.24-5.57	5.4	172

2. 2. Pulses *versus* amino acids profile and proteins

2.1 Bean (*P. vulgaris*)

They represent nearly 80% of total pulse production in Latin America (Pachico, 1989), in which Brazil remains the largest grower and consumer of common beans worldwide (Torres et al, 2009; Duranti, 2006).Table 2 presents the amino acids profile and protein range among 6 Northern American (Canadian) beans varieties (Pires et al, 2005). Their protein content ranges from 27.1 to 29.5% (Freya and Ed Hoff varieties, respectively). Amino acids amounts are similar for all bean varieties, however, beans show high levels of Glutamic and Aspartic Acid, followed by Arginine. There is evidence that environmental factors such as geographic location and season may significantly influence the protein content and lipids of beans (Bhatty et al, 1976). Raw beans are also good source of water-soluble B vitamins; however, they are poor sources of lipo-soluble vitamins and vitamin C (Pires et al, 2005).

2.2 Chickpeas (*C. arietinum*)

Chickpeas are one of the oldest and most widely consumed pulses in the world, especially in India (Angulo et al, 2018; McVay et al, 2016). It is a healthy vegetarian food, a good source of fiber, vitamins (thiamine, riboflavin and niacin) and micro-minerals. However the chemical composition of crops changes with their varieties, soil and area climatic conditions (Iqbal et al, 2016). Table 3 shows the amino acid profile of different chickpea varieties grown in Pakistan. The protein content ranges from 22.9 to 24.8% (Nifa-95 and Nifa-88 varieties, respectively). Although amino acid amounts vary among varieties, they are rich in Glutamic, Aspartic Acids and Leucine (Radhakrishnan et al, 2014).

2.6 Lentils (*L. culinaris*)

Lentils are a staple food grown in West Asia, Africa and India, being their primary component of farming systems. Lentil plays a significant role in human and animal nutrition, besides the maintenance and improvement of soil health. They are particularly high in protein and low in fat (Iqbal et al, 2006), an excellent source of both soluble and insoluble fibers, as well as complex carbohydrates, B vitamins and minerals (Adsule et al., 1989; Muehlbauer et al., 1985; Yadavet al, 2007). Table 4 presents the range of protein of lentil varieties grown in Chile and Iraq (27.7 to 31.3% for Pioneer Red and Amasya varieties, respectively). Lentils show high levels of Glutamic and Aspartic Acid, followed by Arginine. ´

2.4 Peas (*P. sativum*)

Peas are widely produced in Russia and China, followed by Canada, Europe, Australia and United States (Henchion et al, 2017). Sevey (2008) showed that peas have by far the highest protein content (21-25%) and total digestible nutrients (86-87%). Pea contains 5 to 20% less Trypsin inhibitors than soybean, that allows it to be fed directly to livestock without having to go through the extrusion heating process (Amarakoon, 2012). Globulins (up to 80-90%), followed by albumins and glutenins are the main pea proteins. Separate groupings of salt-soluble proteins contain unequal amount of essential amino acid, limiting nutritional value (Methionine, Tryptophane and Cysteine). Their low content is characteristic of vicilines and viciline-related protein (Shelepina et al, 2016). Table 5

presents the range of protein (22.1-26.6%) content with the amino acids profile, showing high levels of Glutamic and Aspartic Acids, followed by Arginine.

2.5 Peanuts (*A. hypogaea*)

Also known as groundnut, is originated in South America and it's one of the world's major food pulse (oil seed) (Singh et al, 1992). It became the fourth most important source of edible oil and thethird most important source of vegetable proteins (Hammons, 1994; Savage, 1994). Its concentrate and isolate products have the advantage of removing the insoluble and partly indigestible carbohydrates (one third of the raw material) (Singh, 1991; Lusas, 1985). Protein makes from 12.0 to 36.4% of the peanuts kernel (Sekhom et al, 1970), but can also cause hypersensitivity reactions (angioedema, asthma, abdominal discomfort and anaphylactic shock), (Moneret et al, 1998), being the second food to produce such allergic symptoms, only after milk and eggs (Hammons, 1994; Yu et al, 2007). Table 6 presents Korean peanuts varieties amino acid profile (high in Isoleucine, Glutamic and Aspartic acid) and protein content (from 28.8 to 32.0% for Suwon 88 and Pungan, respectively).

2.6 Soybean (*G.max*)

The oil seed, native of Southeastern Asia, has the highest protein content and the highest gross output of vegetable oil among the cultivated crops in the world (Morse et al, 1949; Singh, 2010), with high expansion in Brazil. (Agroanalysis, 1996; Vieira et al, 1999; Fearnside, 2001). The Food and Drug Administration (FDA) approved in 1999 a health claim on food labels for products containing soy protein about the association between soy protein and a reduced risk of coronary heart disease, and the beneficial effects of isoflavones, saponins and fiber (Barbosa, 2006). Various epidemiological studies have demonstrated a lower incidence of breast, prostate and colon cancer in Asian populations (for which consumption is 20 to 50 times higher than for occidental populations).Based on six varieties aimed to human consumption, it is possible to see the difference in amino acid (Table 7). All varieties present a superior and excellent balance of essential amino acids by the FAO/WHO pattern (protein: 39.5 to 45.0 g protein) and high levels of Glutamic and Aspartic Acids, followed by Phenylalanine and Tyrosine (Vieira et al, 1999).

Tab. 2. Protein amino acids profile from BEANS (*P. vulgaris*) - Canadian varieties

Amino acid	FAO[a]	Bean - Canadian varieties (%)					
		Ed Hoff	Erfordia	Frey a	Fribo	Klein-K.	Maris Bread
ESSENTIAL							
Histidine	1.6	2.7	2.6	2.6	2.6	2.6	2.6

3. Pulses composition

3.1 Protein and nutritional quality

Protein-calorie malnutrition is a big problem that has been affecting mankind, also indicating that the protein gap may increase in the future unless something addresses the issue. Access adequate proteins of animal origin are difficult and expensive (Reach, 2012). An alternative to improve the nutritional status of those countries is to supplement the diet with pulse proteins (Leterme, 2002).

Vieira et al (1999) [a] adults essential amino acid reference pattern from Food and Agriculture Organization, [b] considered essential or non-essential, [c]NI: NotInformed.

According to FAO (2011), it is necessary to increase food production by 70%. It should be satisfied by the most promising and valuable crops (low-cost and complete vegetable protein). The main types of protein preparations obtained from pea, for example, are defatted flour (56–59% of protein), concentrated pea protein (65–72% of protein) and isolate (90% of protein). According to Shelepina et al (2016), in terms of amino acid composition and assimilation of pulses protein (isolates and concentrates), they are close to proteins of animal origin.

Pulses have many good qualities and can be considered most suitable for protein extraction. They are mainly storage proteins belonging to the groups of albumins, globulins and glutelins, with the salt-soluble globulins constituting the main proteins found in the seeds. These proteins are part of the defensive mechanism of the seed, but are considered as anti-nutritional factors for the human diet (Tiwari et al, 2011).

Apart from their nutritional properties, pulses proteins also possess functional properties (gelling and emulsifying), playing an important role in food formulation and processing. Intrinsic factors (amino acid composition), extrinsic (pH, temperature, solvent, salt) or environmental factors, besides processing treatments (heating, drying, concentrating) or other intentional modifications (chemical or enzymatic modification) can all contribute to influence the functional properties of these proteins (Klupsaite et al, 2015).

3.2 Pulses anti-nutritional factors

To reduce the ANFs and improve quality, seeds are processed by several physical and chemical methods to remove the undesirable compounds: soaking, cooking, germination, fermentation, selective extraction, membrane filtration, irradiation and enzyme treatments (Vidal-valverde, 1994). Those treatments lead to a significant reduction or total elimination of ANFs. Germination and fermentation processes lead to catabolism of the seed components whereas other processes (cooking) may cause thermal degradation or may involve extraction of non-nutritional components. ANFs found in pulses can be separated into several groups based on their chemical and physical properties (non-protein amino acids, quinolizidine alkaloids, cyanogenic glycosides, pyrimidine glycosides, isoflavones, tannins, oligosaccharides, saponins, phytates, lectins or protease inhibitors) (Bell and Charlwood, 1980). Many ANFs are toxic, unpalatable or indigestible, but can be eliminated

by selection of plant genotypes or postharvest processing (germination, boiling, leaching, fermentation), including protein extraction (Ali et al, 2000).

4 Pulses` contaminants and storage conditions

The quality of post-harvest conditions (cleaning, sorting, drying, storage, transport and marketing) can cause high amount of losses and health risks that conflict with national and international standards regulations. It is important to avoid the microorganism's development, especially due to the fungi contamination, with potential production of micotoxins (Anderson, 1954).

Freshly harvested pulses can be safely stored in silos, with a filling and a proper sealing to prevent its deterioration. During uploading, the quantity of air must be minimized, decreasing pulses and microorganism's respiration (21- 0.02%) and pH (due to fermentation). Immediate treatment is essential to prevent quality and quantity deterioration from mold development, ensuring short and long-term preservation of pulses. That includes sealed storage, chemical treatment, chilling and drying. Otherwise, pulses were not being appropriate to further protein extraction (Brooker, 1992)

4.1 Environmental contaminants

It is becoming increasingly apparent that although the major part of the food supply is both safe and nutritious, some risk is unavoidable. The very nature of the industrial society, which includes a substantial part of the world`s population, has increased the risk that foods may become contaminated by a wide variety of chemicals introduced into the environment by man, intentionally or accidentally (Hathcock, 2012).

The polychlorinated biphenyls, polybrominated biphenyls, aflatoxins, nitrites, nitrates and nitroso compound, and metals such as mercury and lead, havedifferent contaminant properties which make them potential problems in the environment. That includes relatively widespread use or distribution of the chemical, in some cases a long biological half-life persistence in the environment, increased residue levels along the food chain, and the potential of an increased risk for adverse health effects in human and food producing animals (Cordle et al, 1982; Hathcock, 2012).

4.2 Fungal and mycotoxins contamination *versus* storage conditions

A high number of toxic microbial metabolites contaminates agricultural products due to the diversity of fungal and bacterial species that coloniesthem from field to storage (Maciorowskiet al, 2007). One of the most important effects of post harvest decays of seed and feed by fungi is the induction of mycotoxicoses, in animals and humans. This is caused by foods and feed consumption invaded by toxigenic fungi (producing mycotoxins). They are secondary metabolites produced by filamentous fungi which may contaminate food, feed and raw materials used in producing them (Agrios, 1978; Moss, 1989; Amadi et al, 2009; Savi et al, 2015; Scussel et al, 2018). Mycotoxicoses caused by widespread fungi such as *Aspergillus*, *Penicillium*, *Fusarium* and *Stachybotrys* can result in severe illness and death. *Aspergillus* and *Penicillium* produce their toxins mostly in stored seeds, hay or commercially processed foods and feeds although infection of seeds usually takes place in the field. Adams (1977) has reported that storage fungi especially *Aspergillus*, *Penicillium*, *Rhizopus* and *Mucor* species infect grains after harvest and can grow on them during storage, although other toxigenic fungi are also found on grains, such as *Alternaria*, *Trichoderma*, *Fusarium*, *Paecilomyces*, *Chaetomium* and *Acremonium*. Generally, mycotoxins have been implicated as causative agents of different health disorders (Ciegler and Bennett, 1980). Both, the toxigenic fungi and the mycotoxins they produce, are potential problems economy perspectives wise. Aflatoxinsare the most commonand widespread mycotoxin, and it is known to be produced by different species of *Aspergillus* (*A.flavus, A.oryzae and A.terreus*). The liver is the target organ, but it is also hepatoxic and carcinogenic (Eaton et al, 1994). While more than 25 different species of fungi are known to invade stored grains and pulses (Duan et al., 2007), species of *Aspergillus* and *Penicillum* are responsible for most spoilage and germ damage during storage. They cause reduction on cooking / baking quality, nutritive values, produce undesirable odors and color, also change appearance of stored food grade

grains. In addition, they make products unacceptable for edible purposes or lower their market quality (Embaby et al, 2003).

5. Conclusions

Pulses are widely cultivated, and a good food resource, once it has easy adaptation to different climates and highly nutritious. It is considered most suitable for protein isolates preparation due to their high protein content, low cost and wide acceptability. Several methods are used for protein extraction and every technique has its own advantages. The functionality of pulse proteins is closely related to their physical and chemical properties, such as molecular weight, amino acid composition and sequence, structure, surface electrostatic charge, and effective hydrophobicity. Storage conditions (impaired/ aggressive temperature/humidity) can lead to physical, chemical, enzymatic or genetic proteins modifications thus altering their functionality, interfering also to food industries final products (Klupsaite et al, 2015).

Mites infest stored goods, especially when the environment is hot and humid. Infested foods may have their taste altered and, in some cases, cause diseases to consumers. In this way, the detection of arthropods in food must be carried out throughout the production chain, as the external and internal markets are increasingly demanding for the quality and health of food. Aromatic, condiment and medicinal dehydrated plants are largely sold in bulk, but little is known about infestations by mites. The objective of this work was to evaluate the diversity of mites in 10 samples of *Coriandrum sativum*, *Pimpinella anisum*, *Petroselinum sativum*, *Chamomila recutita*, *Baccharis trimera*, *Bixa Orellana*, *Cassia angustifolia*, *Origanum vulgare*, *Ocimum basilicum*, *Melissa officinalis*, *Mentha piperita*, *Rosmarinus officinalis*, *Peumusboldus*, *Salvia officinalis*, *Thymus vulgaris*, *Laurus nobilis*, *Hibiscus sabdariffa*, *Myristica fragans*, *Capsicum annum* and *Curcuma longa* acquired in the establishments of bulk sale in the city of São Paulo. A total of 2,589 specimens of mites corresponding to 10 species, *Tyrophagus putrescentiae*, *Glycyphagus destructor*, *Ameroseius* sp., *Blattisocius tarsalis*, *Typhlodromus transvaalensis*, *Tetrabdella* sp., *Cheyletus malaccensis*, *Pronematulus* sp., *Raphignatus* sp. and *Tydeus* sp. The mite *Typhlodromus transvaalensis* was recorded for the first time in Brazil infested stored products.

Key words: Mite, stored products.

Mitochondrial genome organization varies among different groups of the booklouse, *Liposcelis bostrychophila*

Abstract

The booklouse, *Liposcelis bostrychophila* is an important stored pest worldwide. The mt genome of an asexual strain (Beibei, China) of the booklouse, *L. bostrychophila*, comprises two chromosomes; each chromosome contains approximate half of the 37 genes typically found in animals. The mt genomes of two sexual strains of *L. bostrychophila*, however, comprise five and seven chromosomes respectively; each chromosome contains one to six genes. To understand mt genome evolution in *L. bostrychophila*, we sequenced the mt genomes of six strains of asexual *L. bostrychophila* collected from different locations in China, Croatia and USA. The mt genomes of all of the six asexual strains of *L.* bostrychophila collected in China, Croatia and USA have two chromosomes. Phylogenetic analysis of mt genome sequences divided nine strains of *L. bostrychophila* into four groups. Each group has a distinct mt genome organization and substantial sequence divergence (48.7-87.4%) from other groups. Furthermore, the seven asexual strains of *L.* bostrychophila including the published Beibei strain are more closely related to two other species of booklice, *L. paeta* and *L. sculptilis*, than to the sexual strains of *L. bostrychophila*. Our results revealed highly divergent mt genomes in the booklouse, *L. bostrychophila*, and indicated that *L. bostrychophila* is a cryptic species.

Keywords: Mitochondrial genome, *Liposcelis bostrychophila*, intraspecific variation, cryptic species, evolution

Extended abstract

The booklouse, *Liposcelis bostrychophila* Badonnel is an important pest of stored products around the world (Nayak *et al.* 2014) and has two types of reproductive mode: parthenogenesis and sexual reproduction (Mockford *et al*. 2008). Its interception number at a number of entry points into China is increasing with the development of international trade. DNA barcode was used to identify different species of booklice. However, it cannot distinguish *L. bostrychophila* as different strains for this species differs greatly in *cox1* gene fragment sequences. The *cox1* gene belongs to the mitochondrial (mt) genome which included normally 13 protein coding genes, two ribosome genes and 22 transfer RNA genes. The sequence diversity in cox1 gene of different strains of *L. bostrychophila* implied there may be divergence in mt genome sequences in intra-specific level (Yang *et al.* 2013). The mt genome of *L. bostrychophila* was reported to split into two minichromosomes (Wei *et al.* 2012). Every minichromosome accounted for a half the length and the gene number of regular mt genomes. However, the sexual *L. bostrychophila* collected outdoors was reported to have five or seven minichromosomes in their mitochondrial genomes which added the complexity of this species (Perlman *et al.* 2015; Yang *et al.* 2015). Subsequently, to explore further the mt genome variations in *L. bostrychophila*, we sequenced the mt genomes of six strains of asexual *L. bostrychophila* collected from different locations in China, Croatia and USA.

To reconstruct the mitochondrial genomes of the six strains of *L. bostrychophila*, *cox1*, *rrnS* and *rrnL* gene fragments were chosen as "anchors" to get the mitochondrial genome sequences. We firstly sequenced the *cox1*, *rrnS* and *rrnL* gene fragments by using universal primer pairs (Folmer *et al*. 1994; Kambhampati *et al.* 1995). Then, Long PCR primers were designed to amplify the chromosomes where the gene fragments located. The prepared libraries were then sent to the BGI company for next generation sequencing by using an Illumina sequencer. The mt genomes of all six asexual strains of *L. bostrychophila* collected in China, Croatia and USA have two chromosomes (Figure 1). The six newly sequenced mt genomes could be divided into three groups based on their mt genome rearrangements and sequence similarities. Each group has a distinct mt genome organization and substantial sequence divergence (48.7-87.4%) from other groups. Furthermore, all published mt genomes in *Liposcelis* genus, including one published asexual strain in China (Wei *et al.* 2012) and two published sexual strains of *L. bostrychophila*, *L. entomophila* (Chen *et al.* 2014)*, L. paeta, L. decolor* (Chen *et al.* 2014) and *L. sculptilis* (Shi *et al.* 2016) together with data in this research were included in the phylogenetic analysis. After fundamental bioinformatic analysis and annotation, phylogeny of the genus *Liposcelis* was inferred by using MrBayes (Ronquist *et al.* 2003) and RAxML (Stamatakis *et al.* 2006) softwares with two concatenated datasets. Phylogenetic analysis of mt genome sequences divided nine strains of *L. bostrychophila* into four groups. The seven asexual strains of *L. bostrychophila* are more closely related to *L. paeta* and *L. sculptilis*, than to the sexual strains of *L. bostrychophila*. The two sexual strains formed the monophyly.

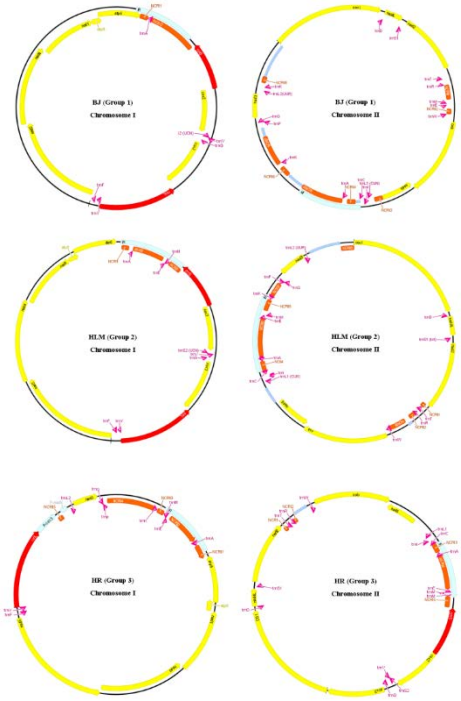

Figure 1. The mitochondrial genome organizations of three groups of *L. bostrychophila*. The transcriptional direction is indicated with arrows. Coding genes are shown in grey, non-coding regions in black, the identical region between the two chromosomes in white. Abbreviations of gene names are: cox1–3 for cytochrome oxidase subunits 1–3, cob for cytochrome b, nad1–6 and nad4L for NADH dehydrogenase subunits 1–6 and 4L, rrnL and rrnS for large and small rRNA subunits, atp6 and atp8 for ATP synthase subunits 6 and 8. tRNA genes are indicated with their one-letter corresponding amino acids.

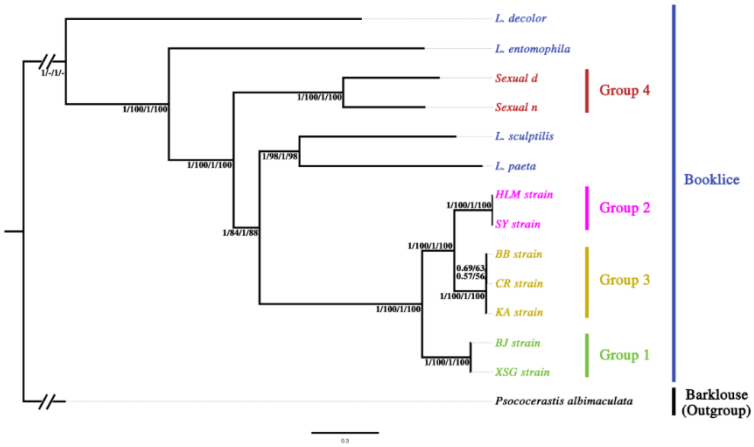

Figure 2. Bayesian inference (BI) and Maximum likehood (ML) phylogenetic trees inferred from mitochondrial genomes of booklice. Numbers above the branches show support for tree nodes from nucleotide sequences of the two datasets: Bayesian posterior probability of PCG12, ML bootstrap support values of PCG123, Bayesian posterior probability of PCG12, ML bootstrap support values of PCG123. Group 1 is in green, Group 2 in pink, Group 3 in brown, Group 4 in red, other species of booklice in blue, the outgroup in black.

Our results revealed highly divergent mt genomes in *L. bostrychophila* and indicated that *L. bostrychophila* is a cryptic species. Cryptic species is a common question in plant quarantine, mt genome sequencing and phylogenetic analysis maybe as one way to resolve it.

Acknowledgements

We thank Charles Lienhard, Fasheng Li, Zuzana Kučerová for identifying the species of the *L. bostrychophila*. This work was supported by the National Natural Science Foundation of China (Nos. 31372230, 31420103902, 31401991), the Beijing Natural Science Foundation (No. 6144027).

Note: All related content in this research was published online on January 19, 2018 with the title "The highly divergent mitochondrial genomes indicate that the booklouse, *Liposcelis bostrychophila* (Psocoptera: Liposcelididae) is a cryptic species" on *G3-Genes Genomes Genetics*, 2018, 8(3): 1039-1047.

Das **Julius-Kühn-Archiv** setzt die seit 1906 erschienenen Mitteilungshefte, eine Reihe von Monographien unterschiedlichster Themen von Forschungsarbeiten bis zu gesetzlichen Aufgaben fort. Alle bisher erschienenen Ausgaben sind OPEN ACCESS kostenfrei im Internet (https://ojs.openagrar.de) zu lesen.

Öffentlichkeit und Fachwelt versorgen wir zusätzlich mit verschiedenen Informationsangeboten über alle Aspekte rund um die Kulturpflanzen. Hierfür stehen Broschüren, Faltblätter, Fachzeitschriften und Monographien, Datenbanken und Themenportale im Internet zur Verfügung.

Seit 2009 wird vom Julius Kühn-Institut als wissenschaftliches Fachorgan das **Journal für Kulturpflanzen – Journal of Cultivated Plants** (vormals Nachrichtenblatt des Deutschen Pflanzenschutzdienstes) monatlich herausgegeben (https://www.journal-kulturpflanzen.de).

Weiterführende Informationen über uns finden Sie auf der Homepage des Julius Kühn-Instituts unter **https://www.julius-kuehn.de.**

Spezielle Anfragen wird Ihnen unsere Pressestelle (**pressestelle@julius-kuehn.de**) gern beantworten.
