DOUBLE-PRECONDITIONING FOR FRACTIONAL LINEAR SYSTEMS. APPLICATION TO STATIONARY FRACTIONAL PARTIAL DIFFERENTIAL EQUATIONS

XAVIER ANTOINE∗ AND EMMANUEL LORIN†

Abstract. This paper is devoted to the numerical computation of fractional linear systems. The proposed approach is based on an efficient computation of Cauchy integrals allowing to estimate the real power of a (sparse) matrix $A$. A first preconditioner $M$ is used to reduce the length of the Cauchy integral contour enclosing the spectrum of $MA$, hence allowing for a large reduction of the number of quadrature nodes along the integral contour. Next, ILU-factorizations are used to efficiently solve the linear systems involved in the computation of approximate Cauchy integrals. Numerical examples related to stationary (deterministic or stochastic) fractional Poisson-like equations are finally proposed to illustrate the methodology.

Key word. Real power of a matrix; Cauchy integral; preconditioning; deterministic and stochastic fractional stationary partial differential equations; unbounded domain.

1. Introduction. This paper is devoted to the efficient computation of the real power $\alpha \in \mathbb{R}_+^*$ of a large and sparse matrix $A \in \mathbb{C}^{n \times n}$ or $\mathbb{R}^{n \times n}$ which is supposed to be diagonalizable in $\mathbb{R}$ or $\mathbb{C}$, and to the solution to fractional linear systems

$$A^\alpha u = f,$$

where $f \in \mathbb{C}^n$ is given. The most natural method, also used in this paper, is based on the approximation of a Cauchy integral with a closed contour enclosing the spectrum of $A$. In this case, classical quadrature rules can be used for an accurate approximation of $A^\alpha$ [3]. Alternatively, $A^\alpha$ can be performed [6] by using Padé’s approximants for $z^\alpha$.

Another approach, proposed in [6] and more specifically devoted to the computation of $A^\alpha b$ for a given vector $b$, is based on the solution to a differential system. A common point to all these approaches is that they require estimates of matrix inverses or solutions to linear systems. More generally, we refer to [6] for a discussion about the computation of $g(A)b$ for a holomorphic function $g$.

As said above, our strategy is based on the approximation of a Cauchy integral by a numerical quadrature rule [3, 6] involving $J_A$ quadrature nodes/points, which is clearly expected to be embarrassingly parallel. Unless when specified, we assume that the spectrum of the matrix $A$ is unknown so that a direct spectral decomposition in an orthonormal basis cannot be a priori used. Then, for $k \geq 0$, $A^\alpha$ is defined as (see e.g. Theorem 6.2.28 from [7])

$$A^\alpha = (2\pi i)^{-1} A^k \int_{\Gamma_A} z^{-k} (zI - A)^{-1} dz,$$

where $\Gamma_A$ is a closed contour in the complex plane enclosing the spectrum of the matrix $A$, $I$ is the identity matrix in $\mathbb{R}^{n \times n}$ and $i = \sqrt{-1}$. In practice, when using the Cauchy integral to estimate $A^\alpha$, it is clearly necessary to have some informations about the spectrum of the matrix $A$ to define the contour path (see Section 3). Selecting $k$
in (1.2) can be dependent on the location of the spectrum of $A$ and the value of $\alpha$. We refer to Subsection 4.6 for a discussion on the choice of the value of $k$. When using the Cauchy integral approach, two important issues related to the question of preconditioning can penalize the efficiency of the algorithm for solving a fractional linear system:

- first, the length $\ell(\Gamma_A)$ of the contour integral must be as small as possible to reduce the cost of the quadrature rule. Indeed, the number of linear systems to solve linearly grows according to the number $J_A$ of quadrature points. To reduce this cost, we propose to use a preconditioned Cauchy integral formula based on a preconditioner $M$, leading to a contour length $\ell(\Gamma_{MA}) \ll \ell(\Gamma_A)$.

- Second, when the $J_A$ (or $J_{MA}$) linear systems must be resolved, they also need to be preconditioned to be solved in conjunction with (for instance) a GMRES solver.

Proceeding this way, we then propose in Section 4 a double-preconditioning technique to efficiently estimate the real power of $A$. The first preconditioner allows for a reduction of the contour length, while the second preconditioner is used for efficiently solving the induced linear systems. Different Cauchy integral preconditioners are proposed and numerically tested. In Section 5, we present an efficient computational method for solving fractional linear systems, using the double-preconditioning method developed in Section 4.

This work is partially motivated by the computation of approximate solutions to deterministic or stochastic stationary fractional PDEs, and more specifically general fractional Poisson-like equations [9]. Such stationary equations can be solved approximately by using traditional finite difference methods which can require the solution to a so-called fractional linear system: find $u$ such that $A^\alpha u = f$, for $A$, $f$, $\alpha$ given. A Cauchy integral preconditioning is then proposed in Section 6 to efficiently solve this problem for various cases of equations (deterministic or stochastic). Let us remark that this strategy, used here to solve Poisson-like equations, can also be naturally extended e.g. to fractional diffusion or Schrödinger equations (see again [9]). We propose several numerical experiments to illustrate the properties of the proposed approach for the stationary case.

Along the paper, some basic numerical experiments are presented to illustrate the main ideas and concepts. A discussion about the computational complexity of the derived method and a comparison with a direct finite difference approximation of the fractional Poisson equation is also proposed in Subsection 6.2. Some more elaborated experiments are reported in Subsection 6.3. We conclude in Section 7.

2. Fast computation of $A^\alpha$ when $\text{Sp}(A)$ is given. An explicit knowledge of the spectrum $\text{Sp}(A) := \{\lambda_k\}_{1 \leq k \leq n}$ of the matrix $A$ leads to an efficient computation of $A^\alpha$. Such a situation occurs for instance when considering that the matrix $A$ is a 3-, 5- or 7-points approximation of the Laplace operator with null Dirichlet boundary conditions on a finite interval, a square or a cube, respectively. In this case, the full spectrum (eigenvalues and eigenvectors) of the discrete laplacian $A$ is indeed analytically known. Assuming that the transition matrix $P_A$ and diagonal matrix $\Lambda_A$ are explicitly known ($A = P_A\Lambda_A P_A^{-1}$), we then have: $A^\alpha = P_A\Lambda_A^\alpha P_A^{-1}$. Indeed, from (1.2) we can write that

\[
A^\alpha = (2\pi i)^{-1} A \int_{\Gamma} z^{\alpha - 1} (zI - A)^{-1} dz = (P_A\Lambda_A P_A^{-1})^\alpha = P_A(2\pi i)^{-1} \Lambda_A \int_{\Gamma} z^{\alpha - 1} (zI - \Lambda_A)^{-1} dz P_A = P_A\Lambda_A^\alpha P_A^{-1}.
\]
Consequently, to solve $A^\alpha u = f$, with $f \in \mathbb{C}^n$ and $A$ invertible, we can proceed as follows $u = A^{-\alpha}f = P_A^{-1}A^{-\alpha}P_A f$, which in practice leads to solving
\[
\begin{align*}
\begin{cases}
v & = \Lambda^{-\alpha}P_A f, \\
P_A u & = v .
\end{cases}
\end{align*}
\]
Equivalently, for $A \in \mathbb{R}^{n \times n}$, by using the residue theorem one gets
\[
A^\alpha = \frac{1}{2\pi i} \int_{\Gamma} z^{\alpha - 1}(zI - A)^{-1} dz = P_A^{-1} \sum_{k=1}^{n} \text{Res}(z^{\alpha}(zI - A)^{-1}, \lambda_k) P_A
\]
where $D_A = \{d_{A,ij} \}_{1 \leq i,j \leq n}$, and
\[
d_{A,ij}^{(k)} = \begin{cases} 
\lambda_j^\alpha & \text{if } j = k \\
0 & \text{if } j \neq k 
\end{cases}, \quad d_{A,ij} = 0, \text{ if } i \neq j .
\]
Obviously, we have $\Lambda_A = \sum_{k=1}^{n} D_A^{(k)}$. In this paper, we will exclude this situation, which makes trivial the computation of the solution to fractional linear systems.

3. Construction of the integral contour. In the general case, the direct strategy detailed in Section 2 cannot be used. We propose to develop an approach based on the discretization of the contour integral formula (1.2). Let us first consider the problem of building the contour $\Gamma_A$. When the spectrum location of the matrix $A$ is known, $\Gamma_A$ can be chosen such that its length is as small as possible. However, this is usually not the case, the crucial property of $\Gamma_A$ being that it must enclose the whole spectrum of $A$. Various simple contours can be considered.

- A rectangular contour $\mathcal{G}(a, b, c, d)$ with left lower corner $a + ib$ and right upper corner $c + id$.
- A circular contour $\mathcal{C}(z, R) := \{ z + \Re e^{i\theta}, \theta \in [0, 2\pi] \}$, centered at $z \in \mathbb{C}$ and with radius $R$.

In the following, $\Gamma_A$ will refer to a rectangular contour and $C_A$ to a circular one. The most natural and simple approach consists in evaluating the eigenvalue of $A$ with largest modulus, i.e. $\lambda^{(A)} := \max_{1 \leq i \leq n} |\lambda_i^{(A)}|$, where $\{\lambda_i^{(A)}\}_{1 \leq i \leq n}$ denotes the (complex) eigenvalues of $A$ (with possible multiplicity). As a consequence, we can define the contour as a circle $\mathcal{C}(\lambda^{(A)} + \varepsilon)$, where $\varepsilon$ is a strictly positive number. When the contour is circular (with $k = 1$ in formula (1.2)), the Cauchy integral can be reformulated as follows
\[
A^\alpha = (2\pi i)^{-1} A \int_{\mathcal{C}(\lambda^{(A)} + \varepsilon)} z^{\alpha - 1}(zI - A)^{-1} dz = (2\pi)^{-1} A \int_0^{2\pi} ((\lambda^{(A)} + \varepsilon)e^{i\theta})^{(\alpha - 1)}((\lambda^{(A)} + \varepsilon)e^{i\theta}I - A)^{-1}(\lambda^{(A)} + \varepsilon)e^{i\theta} d\theta .
\]
Alternatively, we can construct $\Gamma_A$ as $\mathcal{G}(\lambda^{(A)} - \varepsilon, \lambda^{(A)} - \varepsilon, \lambda^{(A)} + \varepsilon, \lambda^{(A)} + \varepsilon)$.

This general approach can unfortunately be inefficient from a practical point of view to numerically approximate the Cauchy integral by a quadrature formula, for instance with a clustered spectrum. If the matrix $A$ is hermitian, the contour can naturally be constructed more precisely. Typically, if $\lambda^{(A)}_{\min} = \min_{1 \leq j \leq n} \lambda_j^{(A)}$ and $\lambda^{(A)}_{\max} = \max_{1 \leq j \leq n} \lambda_j^{(A)}$ are computed by using a standard eigenvalue solver, then the simplest contour is a rectangle $\mathcal{G}_A(\lambda^{(A)}_{\min} - \varepsilon, -\varepsilon, \lambda^{(A)}_{\max} + \varepsilon, \varepsilon)$.
4. Cauchy integral preconditioner. In this section, we propose a Cauchy integral preconditioning strategy which potentially allows for a drastic reduction of the integral contour (1.2), then leading to a much faster algorithm than with a direct computation of $A^\alpha$.

4.1. General consideration. A Cauchy integral preconditioner is a matrix $M$ such that

\[
(MA)^\alpha = (2\pi i)^{-1} MA \int_{\Gamma_{MA}} z^{\alpha-1} (zI - MA)^{-1} dz,
\]

where we expect that $\ell(\Gamma_{MA}) \ll \ell(\Gamma_A)$, $\ell$ denoting the length of a curve in the complex plan. Typically, $M$ will be chosen as a preconditioner for solving the linear system $Ax = b$, i.e. $M \approx A^{-1}$. However, additional constraints need to be added. The integral preconditioner of interest is two-fold

1. clustering of the spectrum of the preconditioned matrix $MA$,
2. accurate estimate of the center of the spectrum of $MA$, more specifically $1$.

This idea is summarized in Fig. 1. Getting a shorter integration path for the Cauchy integral, i.e. leading to a small ratio $\lambda_\infty(I-MA)/\lambda_{\infty}(A)$, hence reduces the cost of the numerical quadrature used to approximate the Cauchy integral. Computing (1.2) from

\[
\begin{aligned}
\text{Fig. 1. Clusterized spectra of the matrices } A \text{ and } MA, \text{ and their respective circular contours } C_A \text{ and } C_{MA} \text{ by using the above strategy.}
\end{aligned}
\]
Proof. The proof is straightforward. For the matrix $A = \{A_{ij}\}_{1 \leq i, j \leq n}$, we introduce $M = p_k(A)$, for $K \geq 1$. Then, one gets $AM = MA$ and (for $k = 1$ in (1.2))

$$(MA)^\alpha = (2\pi i)^{-1} MA \int_{\Gamma_{MA}} z^{\alpha-1}(zI-MA)^{-1}dz$$

and

$$(2\pi i)^{-1} AM \int_{\Gamma_{MA}} z^{\alpha-1}(zM^{-1} - A)^{-1}M^{-1}dz = (2\pi i)^{-1} AM \int_{\Gamma_{MA}} z^{\alpha-1}(zI-MA)^{-1}dz.$$
Next, setting $z \leftarrow M^{-1} z$ and $\Gamma_A = M^{-1} \Gamma_M$, we deduce that

\[(MA)^\alpha = (2\pi i)^{-1} AM \int_{\Gamma_M} M^{\alpha-1} z^{\alpha-1} (zI - A)^{-1} M^{-1} M dz\]

\[(4.4)\]

\[= (2\pi i)^{-1} A \int_{\Gamma_A} M^{\alpha} z^{\alpha-1} (zI - A)^{-1} dz\]

\[= M^{\alpha} (2\pi i)^{-1} A \int_{\Gamma_A} z^{\alpha-1} (zI - A)^{-1} dz = M^{\alpha} A^\alpha.\]

\[
\square
\]

Using a polynomial preconditioning leads to a reduction of the computational complexity of $p_K^\alpha(A)$ compared to $A^\alpha$. In particular, we can easily prove that:

\[
(p_K(A))^{\alpha} = p_K^\alpha(A) A^\alpha,
\]

which means formally that $A^\alpha = p_K^\alpha(A)(p_K(A))^{\alpha}$. However, evaluating $A^\alpha$ from $p_K^\alpha(A)$ is a priori not a simple task, although an iteration algorithm could be explored. At this stage, we propose an alternative preconditioning, particularly efficient for diagonally dominant matrices.

**4.4. Differential-based preconditioner.** We propose now a preconditioning method based on the solution to a differential system, used typically for computing $A^\alpha b$, for $b \in \mathbb{R}^n$. For $\alpha \in \mathbb{R}$, we recall [2, 3, 6] that the $n$-dimensional dynamical system

\[(4.5)\]

\[y(\tau) = -\alpha(A - I)(I + \tau(A - I))^{-1} y(\tau), \quad y(0) = b,\]

is such that $y(\tau) = (I + \tau(A - I))^{-\alpha} b$, $y(1) = A^{-\alpha} b$. Therefore, (4.5) can be used for computing $u = A^{-\alpha} f$. We can then approximate $A^{-\alpha} f$ as follows: $y(\tau) \approx (I - \alpha \tau(A - I)) f =: M_{\tau} f$. Thus, we have

\[(M_{\tau} A)^{-\alpha} = \frac{M_{\tau} A}{21\pi} \int_{\Gamma_M, A} z^{-\alpha-1} (zI - M_{\tau} A)^{-1} dz = \frac{M_{\tau}}{21\pi} \int_{\Gamma_M, A} z^{-\alpha-1} (zA - M_{\tau})^{-1} dz.\]

Since $M_{\tau}$ is nothing but a parameterized polynomial preconditioner, we trivially have $M_{\tau} A = M_{\alpha} A$ and then $(M_{\tau} A)^{-\alpha} = M_{\tau} A^\alpha$. This approach is partially relevant for non-diagonally dominant matrices when the approximations are accurate, i.e. for $\tau$ and $\alpha$ small enough. The preconditioning strategy is parallel to the one proposed with Cauchy integral, but this time applied to a differential system solver (Crank-Nicolson). This approach will be further investigated in a forthcoming paper.

**4.5. Numerical approximations and experiments on contour integrals.**

From a practical point of view, the contour integral is numerically computed by using a quadrature rule leading to the approximate matrix computation (for $k = 1$ in (1.2))

\[A^\alpha_k := (2\pi i)^{-1} A \sum_{1 \leq j \leq J_A} \tilde{h}_j w_j z_j^{\alpha-1} (z_j I - A)^{-1},\]

where $\{w_j\}_{1 \leq j \leq J_A}$ are the quadrature weights and $\{z_j\}_{1 \leq j \leq J_A}$ the integration nodes. The local discretization steps of the path are denoted by $\tilde{h}_j$, and $\tilde{h} = \max_{1 \leq j \leq J_A} \tilde{h}_j$.

In matrix norm, the order of convergence $\sigma$ is such that

\[\|A^\alpha_k - (2\pi i)^{-1} A \int_{\Gamma_A} z^{\alpha-1} (zI - A)^{-1} dz\| \leq C h^\sigma.\]

In the following, we propose some numerical illustrations.
Experiment 1. Let us start by considering the one-dimensional operator $-\Delta + V$ defined on the computational domain $] - 2; 2[$ with homogeneous Dirichlet boundary conditions. The potential $V$ is $V(x) = x \exp(-20 x^2)$. We use a 3-points finite difference discretization based on $n = 101$ interior points to approximate $-\Delta$. On Fig. 2, we represent two rectangular contours $\Gamma_A$ and $\Gamma_{MA}$, where $A$ is symmetric and $M$ is the polynomial preconditioner $p_K(A)$ as defined in (4.3) for $K = 5$. We numerically get $\ell(\Gamma_A) \approx 5 \times 10^3$ and $\ell(\Gamma_{MA}) \approx 2$. Since $\ell(\Gamma_A)/\ell(\Gamma_{MA}) \approx 2.5 \times 10^3$, the numerical discretization based on $\Gamma_{MA}$ is expected to be much faster than with $\Gamma_A$, for the same accuracy, since it needs far less discretization points.

![Fig. 2. Experiment 1. (Left) Spectrum of the complex-valued matrices $A$ and $MA$, and associated contours. (Right) Zoom on the spectrum of $MA$ and contour $\Gamma_{MA}$.](image)

Experiment 2. In this second example, we consider a complex-valued random matrix $A \in \mathbb{C}^{n \times n}$ such that, for $1 \leq i, j \leq n$, $A_{ij} = \text{rand}(0, 1) + i \text{rand}(0, 1)$, where $\text{rand}(0, 1)$ denotes a real number randomly chosen between 0 and 1 (that is taking its value in state space for a uniform distribution $U(0, 1)$). Moreover, we report the results for both $n = 101$ and $n = 1001$. We draw in Fig. 3 the corresponding spectra in the complex plane, including the contours $\Gamma_A$ and $\Gamma_{MA}$ for $n = 101$ (top) and $n = 1001$ (bottom). This shows the drastic clustering of the spectrum for the preconditioned matrix.

Experiment 3. Let us introduce the matrix $A = \{A_{ij}\}_{i,j} \in \mathbb{R}^{n \times n}$, defined by the two matrices $B$ and $C$ such that, for $1 \leq i, j \leq n$ : $B_{ij} = \text{nrand}(0, 1)$, $C_{ij} = 20n + \text{rand}(0, 1)\delta_{ij}$, with $n = 100$, and $A = B + B^T + C$, which then has a real-valued spectrum. For $\alpha = 0.9$, we compare the relative error $\|A_{ref}^\alpha - A^\alpha\|_2/\|A^\alpha_{ref}\|_2$ vs the number of quadrature points $J_A$ and $J_{MA}$, with and without scaling preconditioner $M = I/\|A\|_2$ (see Subsection 4.2), for circular and rectangular contours in the preconditioned and non-preconditioned cases. The reference solution $A_{ref}^\alpha$ is computed by $\text{matlab}$ through a spectral decomposition (see Subsection 2) and we use a composite midpoint quadrature rule. We first report on Fig. 4 (Top-Left) $\text{Sp}(A)$, $\text{Sp}(MA)$, the circular contours $C_A$ and the preconditioned one $C_{MA}$ with a scaling preconditioner, as well as the rectangular contours $\Gamma_A$ and $\Gamma_{MA}$ (with the same preconditioner). We then zoom in the neighborhood of $\text{Sp}(A)$ in Fig. 4 (Top-Right), and in the neighborhood of $\text{Sp}(MA)$ in Fig. 4 (Bottom-Left). We then compare in Fig. 4 (Bottom-Right) the convergence with respect to the contour choice (rectangle, circle). More specifically, we plot the relative error as a function of the number of quadrature points $J_{A,MA}$. As expected, the preconditioning improves the convergence rate for both the rectangular and circular contours. We also remark that the non-preconditioned rectangular
Fig. 3. **Experiment 2.** $\text{Sp}(A)$ and $\text{Sp}(MA)$, and rectangular contour: (Top-Left) : $n = 101$; (Top-Right) : zoom for $n = 101$; (Bottom-Left) $n = 1001$; (Bottom-Right) : zoom for $n = 1001$.

d contour allows for a slightly more precise estimate of the Cauchy integral than for the non-preconditioned circular one. This is mainly due to the structure of the spectrum which is concentrated around 0. As a consequence, the rectangle contour is very thin, then leading to a more accurate computation of the approximate operator $A^\alpha_h$. The choice of the contour is naturally highly correlated to the structure of the spectrum.

**Experiment 3bis.** To complete the illustrations, let us consider the matrix $A = B + 0.75B^2 + C$, where $B_{ij} = n \text{rand}(0,1)$ and $C_{ij} = 20n + \text{rand}(0,1)\delta_{ij}$, $1 \leq i,j \leq n$, for $n = 100$. The matrix $A$ has a complex-valued spectrum. For $\alpha = 0.9$, $\text{Sp}(A)$ is reported in Fig. 5 (Left) and a zoom on $\text{Sp}(MA)$ is given in Fig. 5 (Right). We observe that the circular contour is more efficient here than the rectangular one (see Fig. 6).

### 4.6. Selection of the parameter $k$ in the Cauchy integral formulation

We discuss now the selection of the Cauchy integral formulation, and more specifically the value of $k \in \mathbb{N}$ in formula (1.2). Since $z \in \Gamma_A$, we have $|z| > \rho(A)$, where $\rho(A)$ denotes the spectral radius of $A$. Denoting by $A_h$ the approximate Cauchy integral using an order $\sigma$-composite-quadrature rule with $h = \sup_j |z_{j+1} - z_j|$, there exists $c = c(A,\sigma) > 0$ such that

$$
\|A^\alpha_{\text{ref}} - A^\alpha_h\| \leq c \|A^\alpha_{\text{ref}}\| \sup_{z \in \Gamma_A} \left\| \frac{d^\sigma}{dz^\sigma} z^{\alpha-k} (zI - A)^{-1} \right\|
$$

To minimize the error, this suggests that, if $\rho(A)$ is large, we should typically take $k \geq \lceil \alpha \rceil$, so that $k - \alpha \leq 0$. In practice, it is natural to simply select $k = \lceil \alpha \rceil$. 

This manuscript is for review purposes only.
However, whenever \( \rho(A) \) is small, a natural choice in relation (1.2) is \( k = 0 \). Indeed, in this case, as \(|z|\) is larger but close to \( \rho(A) \), a small error (4.6) is expected and taking \( k < \alpha \) could even deteriorate the approximation. For instance, it looks reasonable to use (1.2) with \( k = \lceil \alpha \rceil \) for a direct evaluation of \( A^{\alpha} \) and to use \( k = 0 \) for evaluating \((MA)^{\alpha}\) when \( M \) is an accurate (in the sense that \( \rho(MA) \) is very small, typically \(<1\)) Cauchy integral preconditioner. If \( \rho(MA) \) is still larger than 1, it is preferable (theoretically) to take \( k = \lceil \alpha \rceil \) to evaluate \((MA)^{\alpha}\). In the following, we arbitrary fix \( k = 1 \) (or \( k = 0 \), as most of the computations are done for \( 0 < \alpha < 1 \) (or \( 1 < \alpha < 2 \)) and that \( \rho(MA) \) will still be large enough to justify the fact that \( k = \lceil \alpha \rceil \) provides a
Experiment 3bis. Relative error ($\alpha = 0.9$) vs the number of integration points. 

better approximation than for $k = 0$. Notice that in the chosen benchmarks, we did not observe any noticeable effect of the selected formulation.

**Experiment 4.** To illustrate the discussion, we compare the relative error in 2-norm of $A^\alpha$ for $\alpha = 0.5$, where the matrix $A = \{A_{ij}\}_{1 \leq i,j \leq n}$ is defined as: $A_{ij} = \text{rand}(0,1) + \text{inrand}(0,1)$, with $n = 400$. We compare the error (4.6) for $k = 0,

\begin{equation}
A^\alpha = \frac{1}{21\pi} \int_{\Gamma_A} z^\alpha (zI - A)^{-1} dz,
\end{equation}

and $k = 1$

\begin{equation}
A^\alpha = \frac{A}{21\pi} \int_{\Gamma_A} z^{\alpha-1} (zI - A)^{-1} dz.
\end{equation}

We consider a circular contour where the number of quadrature nodes varies between 2 and 4096, and report in Fig. 7 the convergence of $\|A^\alpha - A^\alpha_h\|_2/\|A^\alpha\|_2$ for $k = 0, 1$, in the non-preconditioned case, vs the number of quadrature points. We notice that taking $k = 0$ or $k = 1$ does not impact the behavior of the error.

**Fig. 7.** Experiment 4. Relative error ($\alpha = 0.5$) vs the number of integration points.

5. Fractional linear systems $A^\alpha u = f$. In the previous subsections, we developed an efficient methodology to estimate the real power of a matrix. In this paper, we
are more specifically interested in the solution to fractional linear systems $A^\alpha u = f$, with $A \in \mathbb{C}^{n \times n}$, $f \in \mathbb{C}^n$, for some $\alpha \in \mathbb{R}_+$. For invertible matrices, we formally have $u = A^{-\alpha} f$.

5.1. Solution to fractional linear systems $A^\alpha u = f$, with $[M, A] = 0$. We assume here that $M^\alpha$ can efficiently be estimated numerically. If not, it is then more appropriate to proceed as in Subsection 5.2. We recall that for any matrix $M$ such that $(MA)^\alpha = M^\alpha A^\alpha$, we can compute $A^{-\alpha} f$, from $(MA)^{-\alpha} f$, and this approach being a priori valid for any invertible matrix $A \in \mathbb{C}^{n \times n}$. We can formally proceed as follows (e.g. for $k = 0$ in (1.2))

$$u = A^{-\alpha} f = (2\pi i)^{-1} \int_{\Gamma_A} z^{-\alpha}(zI - A)^{-1} f dz$$

where $\Gamma_A$ encloses the spectrum of the matrix $A$. To estimate $(2\pi i)^{-1} \int_{\Gamma_A} z^{-\alpha}(zI - A)^{-1} f dz$, a Cauchy integral preconditioner is proposed. We denote by $M$ a preconditioner for $A^{-\alpha}$, such that $A$ and $M$ commute: $[M, A] = 0$. Since $A^{-\alpha} = M^\alpha (MA)^{-\alpha}$, one gets

$$(MA)^{-\alpha} f = (2\pi i)^{-1} \int_{\Gamma_{MA}} z^{-\alpha}(zI - MA)^{-1} f dz.$$ 

Computed on a finite grid $\Gamma_{MA}^{(h)} \subseteq \Gamma_{MA}$, with spatial resolution $h = \max_{1 \leq j \leq J_{MA}} h_j$ and a quadrature of order $\sigma$, the approximate Cauchy integral to $(MA)^{-\alpha}$ is denoted by $S_{h}^{(-\alpha)} = (MA)^{-\alpha}$ and is defined as

$$(5.2) \quad S_{h}^{(-\alpha)} = (2\pi i)^{-1} \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha}(z_j I - MA)^{-1},$$

where \{w_j\}_j are some interpolation weights. More precisely

- in the case of a rectangular contour, $z_j \in \Gamma_{MA}^{(h)}$ and $z_{j+1} = z_j + h_{j+1}$, with $h_j = \delta x_j + i \delta y_j$. Denoting $(z_j I - MA)^{-1} f = u_j$, we have

$$u_{h} := M^\alpha S_{h}^{(-\alpha)} f = (2\pi i)^{-1} M^\alpha \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha} u_j,$$

i.e. $u_{h} = M^\alpha S_{h}^{(-\alpha)} f$.

- In the case of a circular contour of center $z_c$ and radius $r_c^{(A)}$, we have $z_j = z_c + r_c^{(A)} e^{i \theta_j} \in \mathbb{C}_{MA}$ and $z_{j+1} = z_c + (z_j - z_c) e^{i \theta_{j+1}}$, with $\theta_{j+1} = \theta_j + \delta \theta_{j+1}$. We then consider the following quadrature

$$u_{h} = (2\pi i)^{-1} M^\alpha \sum_{1 \leq j \leq J_{MA}} \delta \theta_j w_j r_c^{(MA)} e^{i \theta_j} (r_c^{(MA)})^{-\alpha} e^{-i \alpha \theta} u_j,$$

i.e. $u_{h} = S_{h}^{(-\alpha)} f$, for all $1 \leq j \leq J_{MA}$.

A double-preconditioning is then implemented, the first one to reduce the contour length in the Cauchy integral, and then the second one to efficiently evaluate $(zI - MA)^{-1} f$, thus leading to

$$(5.4) \quad S_{h}^{(-\alpha)} f = (2\pi i)^{-1} \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha}(z_j I - MA)^{-1} f.$$
We notice that performing a full LU-factorization on \(A\) can be analytically diagonalized, the matrix power can be very efficiently computed, as stated in the following proposition.

**Proposition 5.1.** If \(MA\) is diagonalizable, then we have \(MA = P_MA D_MAP_M^{-1}\) and

\[
S_h^{(\alpha)} f = (2\pi i)^{-1} P_MA \left[ \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha} (z_j I - D_{MA})^{-1} \right] P_M^{-1} f,
\]

where \(D_{MA}\) is a diagonal matrix. As a consequence, in this case only one linear system (related to \(P_MA\)) has to be solved. However, except in some very simple cases (including low dimensional cases), \(P_MA\) and \(D_{MA}\) cannot be analytically calculated or computed.

**Proof.** Since \(MA\) is diagonalizable, we have

\[
(MA)^\alpha = (2\pi i)^{-1} \int_\Gamma z^\alpha (zI - MA)^{-1} dz = (P_MA D_MAP_M^{-1})^\alpha
\]

\[= P_MA(2\pi i)^{-1} \int_\Gamma z^\alpha (zI - D_{MA})^{-1} dz P_MA = P_MA D_{MA}^\alpha P_M^{-1}.
\]

Next, we discretize the integral by using a classical quadrature formula:

\[
S_h^{\alpha} = (2\pi i)^{-1} P_MA \left[ \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha} (z_j I - D_{MA})^{-1} \right] P_M^{-1},
\]

which concludes the proof. \(\square\)

In order to efficiently solve the linear systems (5.3), we simply compute in parallel the incomplete LU-factorizations \([5]\): for any \(1 \leq j \leq J_{MA}\), \(z_j I - MA \approx -L_j U_j\). We then define the preconditioners \(N_j = -U_j^{-1} L_j^{-1}\) used to solve: \(N_j(z_j I - MA)u_j = N_j f\). The \(J_{MA}\) linear systems are preconditioned and solved independently. On the other hand, if the systems are solved sequentially, \(u^{(k)}_j \to u_{j+1}\) in \(\mathbb{R}^n\) in at most \(n\) iterations and we can benefit from the previous computations.

- From given \(u_0^{(0)}\), solve \(N_0(z_0 I - MA)u_0 = N_0 f\), for \(z_0 \in \Gamma_{MA}^{(h)}\) (or \(C_{MA}^{(h)}\)), by using the above algorithm, where \(N_0 = -U_0^{-1} L_0^{-1}\).
- At index \(j + 1\): assuming \(u_j\) was previously computed, take as initial guess \(u_{j+1}^{(0)} = u_j\) since for \(J_{MA}\) large enough, that is \(|z_j - z_j'|\) small enough, we expect that \(u_{j+1}\) is close to \(u_j\).
- It is not necessary to implement an ILU-factorization for any \(1 \leq j \leq J_{MA}\). Basically, only a few ILU-factorizations are sufficient. By denoting \(N_j = L_j U_j\), for \(j'\) close to \(j\) and by using continuity arguments, we expect that, in terms of conditioning, we have

\[
\text{cond}(N_j(z_j I - A)) \approx \text{cond}(N_j(z_j' I - A)) \leq \text{cond}(z_j I - A).
\]

- Deduce \(u = A^{-\alpha} f\), by estimating first \(S_h^{(-1-\alpha)} f\), then we have \(u \approx u_h := A^{\alpha+1} S_h^{(-1-\alpha)} f\).

We notice that performing a full LU-factorization on \(A\) provides a matrix \(M\) such that \([M, A] = 0\). However, computing \(M^\alpha\) may be as almost complex as computing \(A^\alpha\). We therefore prefer to use ILU-factorizations.
5.2. Solution to fractional linear systems \( A^\alpha u = f \), with \([M,A] \neq 0\). The most general and interesting case occurs when \( A \) and \( M \) do not commute. Then, we can no longer directly deduce the solution to \( A^\alpha u = f \), from the solution to \( M^\alpha (MA)^{-\alpha} f \). The natural procedure then consists in solving
\[
M^\alpha (MA)^{-\alpha} A^\alpha u = M^\alpha (MA)^{-\alpha} f,
\]
meaning that we precondition the linear system \( A^\alpha u = f \) by \( M^\alpha (MA)^{-\alpha} \) which is now only an (accurate) approximation to \( A^{-\alpha} \). It is still necessary to be able to efficiently compute \( M^\alpha (MA)^{-\alpha} x \) for any vector \( x \). From a practical point of view, we have \( M^\alpha (MA)^{-\alpha} x \approx M^\alpha S_h^{(\alpha)} x \), where \( S_h^{(\alpha)} x \) is defined by (5.4) (setting \( f = x \)). The linear system is numerically solved by using an iterative scheme, but also requires intermediate solutions to sparse linear systems in order to estimate \( M^\alpha (MA)^{-\alpha} x \).

First, we approximate \((MA)^{-\alpha} x \) by \( v_h \) such that
\[
(5.5) \quad v_h = \frac{(2\pi i)^{-1} M^\alpha \sum_{1 \leq j \leq J} h_j w_j z_j^{-\alpha} u_j}{x}, \quad \text{for } 1 \leq j \leq J_M.
\]

Next, we evaluate \( M^\alpha v_h \), which is more or less computationally complex. If \( M \) is a diagonal matrix (Jacobi) preconditioner, computing \( M^\alpha v_h \) is straightforward, while for ILU-preconditioning additional operations are needed, as described below.

5.3. Jacobi Cauchy integral preconditioner. Let us consider a Jacobi preconditioner, assuming that \( A \) is diagonally dominant and that \( A_{ii} \neq 0 \), for all \( 1 \leq i \leq n \). Setting \( M = \text{diag}(A_{11}^{-1}, \ldots, A_{nn}^{-1}) \), we then have
\[
(MA)^{\alpha} = (2\pi i)^{-1} \int_{\Gamma_M} z^{\alpha} (zI - MA)^{-1} dz.
\]

Similarly to the proof of Proposition 4.1 but noticing that a priori \( AM \neq MA \) (in particular when the diagonal terms of \( A \) are not all equal), then \( A^\alpha \neq M^{-\alpha}(MA)^{\alpha} \), with \( \alpha \in \mathbb{R}^* \). Interestingly, \( M^\alpha \) can however be very efficiently computed since \( M \) is diagonal.

5.4. ILU Cauchy integral preconditioner. Incomplete-LU factorizations appear as some natural candidates for solving fractional linear systems for two main reasons. First, they usually allow for a better preconditioning than Jacobi. Secondly, the triangular structure of the \( L \) and \( U \) matrices leads to an efficient computation of intermediate sparse linear systems. More specifically, we propose the following approach. We first implement an ILU-factorization \( LU \) of the matrix \( A \), with a threshold parameter \( \zeta > 0 \), and formally denote \( M = (LU)^{-1} \). In addition to (5.5), it is needed to approximate \( M^\alpha v_h \). In this goal, and unlike Jacobi preconditioning, it is necessary to solve additional triangular linear systems, i.e. we approximate \( M^\alpha v_h \), by \( u_h \) such that
\[
(5.6) \quad u_h = (2\pi i)^{-1} \sum_{1 \leq j \leq J} h_j w_j z_j^{-\alpha} v_j,
\]
\[
(z_j LU - I)v_j = LU v_h, \quad \text{for } 1 \leq j \leq J_M.
\]

These new linear systems can be very efficiently solved since they are sparse and triangular. In addition, in order to improve the efficiency of the computation of \( M^\alpha v_h \), a Jacobi Cauchy integral preconditioner or scaling of \( M \) itself can be used as well, so that the quadrature is applied on a contour of reduced length which can be a priori as long as \( \Gamma_A \), as proposed in Subsection 4.2.
5.5. Parallelization aspects. The computation of \((MA)^{-\alpha}\) can then be performed in parallel as follows. For \(p\) processors, we decompose \(\Gamma\) in \(p\) subcontours \(\Gamma_\ell\):
\[
\Gamma = \bigcup_{\ell=1}^{p} \Gamma_\ell, \quad \ell(\Gamma_\ell) = \ell(\Gamma)/p
\]
and write
\[
(MA)^{-\alpha} = \sum_{\ell=1}^{p} (MA)^{-\alpha}_\ell = \sum_{\ell=1}^{p} (2\pi i)^{-1} \int_{\Gamma_\ell} z^{-\alpha}(zI-MA)^{-1} dz.
\]
We first implement an ILU-factorization and construct \(\tilde{L}\) and \(\tilde{U}\). For any fixed value of \(\ell\),
\begin{itemize}
  \item we solve, for \(\{z_\ell^{(\ell)}\}_j \in \Gamma_\ell: (z_\ell^{(\ell)}\tilde{L}\tilde{U} - A)u_\ell^j = f_\ell^j,\)
  \item send&receive to the root processor the contribution of each \(\Gamma_\ell\), that is:
\end{itemize}
\[
\sum_{z_\ell^{(\ell)}} \in \Gamma_\ell (2\pi i)^{-1} h_j \tilde{d}_\ell^{-\alpha} u_\ell^j.
\]

5.6. Numerical experiments on fractional linear systems. We provide now a few examples of numerical simulations to illustrate the methodology.

Experiment 5. In this experiment, we compare the efficiency of the different preconditioners implemented in GMRES for solving (1.1), where \(f\) is the unit vector. We report the convergence rate, represented as the residual history vs the GMRES iteration, where the solution is computed from
\begin{itemize}
  \item a direct evaluation of the Cauchy integral without preconditioning (labelled No-precond.),
  \item by using an ILU preconditioner \(M^{-\alpha}(MA)^{\alpha}\), with \(M = \tilde{L}\tilde{U}\) for a drop tolerance at \(10^{-4}\), and a rectangular (ILU-precond. rect.) and circular contours (ILU-precond. circ.),
  \item with an ILU preconditioner \(M\) directly built on the sparse matrix \(A\), and then the preconditioner \(M^{\alpha}\) is used on \(A^{\alpha}\) (and denoted \(M_\alpha\)-precond.),
  \item and finally with an ILU preconditioner directly constructed from the full matrix \(A^\alpha\) that we assume to be given (ILU-precond. on \(A^\alpha\)).
\end{itemize}
The matrix \(A\) is defined as \(A = (B + C) + (B + C)^T \in \mathbb{R}^{200\times200}\), where
\[
B_{ii} = 75\mathrm{rand}(0,1) + 15, \quad B_{ii\pm1} = 5\mathrm{rand}(0,1) + 8, \quad B_{i\pm2} = \mathrm{rand}(0,1) + 1/2,
\]
and \(C_{ij} = \mathrm{rand}(0,1)\). We fix the tolerance to \(10^{-15}\) in the GMRES, where the restart parameter is equal to 50. We report in Fig. 8 the results for the ILU-Cauchy integral preconditioner (Left) \(J_{A,MA} = 8\) and (Right) \(J_{A,MA} = 128\). The number of GMRES iterations for the different preconditioners for a fixed number of quadrature nodes illustrates the efficiency of the proposed Cauchy integral preconditioning. For completeness, the same tests are performed by using a Jacobi Cauchy integral preconditioner (see Fig. 9).

Experiment 6. We now solve \(A^{\alpha}u = f\), where \(A\) is a symmetric diagonally dominant full matrix which models a randomly perturbed Laplace operator, i.e. \(-\Delta + dW\), where \(dW\) is a small amplitude \((2 \times 10^{-2})\) random and symmetric process, \(n = 51\) and \(f\) is identically equal to 1. Moreover, we consider 3 values of the fractal order, i.e. \(\alpha = 0.25\), \(\alpha = 0.75\) and \(\alpha = 1.5\). We then apply the Jacobi preconditioning for solving the linear systems related to \((z + r(c)^{\alpha}e^{i\theta})I - MA)u_j\), in the following quadrature
\[
u_{\alpha} = (2\pi)^{-1}M^{\alpha}(MA) \sum_{1 \leq j \leq J_{MA}} \delta \theta_j r(c)^{\alpha}e^{i\theta_j} (r(c)^{\alpha})^{-\alpha - 1}e^{-i(\alpha + 1)\theta_j} u_j,
\]
\[
((z + r(c)^{\alpha}e^{i\theta_j})I - MA)u_j = f, \quad \text{for } 1 \leq j \leq J_{MA}.
\]
Fig. 8. **Experiment 5.** Comparison of the residual history vs iterations of the GMRES algorithm (restarted at 50 iterations, and tolerance $10^{-15}$) for various preconditioners: ILU Cauchy integral preconditioner (threshold at $10^{-4}$), ILU-preconditioner on $A^\alpha$. (Left): $J_{A,MA} = 8$ (Right): $J_{A,MA} = 128$.

Fig. 9. **Experiment 5.** Comparison of the residual history vs number of iterations of the GMRES (restarted after 50 iterations, and for a tolerance $10^{-15}$) for different preconditioners: Jacobi preconditioner, ILU-preconditioner on $A^\alpha$. (Left): $J_{A,MA} = 8$ (Right): $J_{A,MA} = 128$.

with $u_h \approx u = A^{-\alpha}f$. Let us recall that $r^{(A)}_\varepsilon = r^{(A)} + \varepsilon$ and that the initial guess for computing $u_{j+1}$ is taken as $u_j$. We report in Figs. 10 (Top/Bottom Left) the 2-norm error $\|u_h - u_{\text{ref}}\|_2$ (in logscale) as a function of $J_{A,MA}$. We also provide the corresponding CPU-time with/without Jacobi preconditioning, as well as $\|A^{-\alpha}_h - A^{-\alpha}\|_2$, where we have numerically estimated $A^{-\alpha}_h$ from a direct (D) computation

\[ (A^{-\alpha}_h(D))^{-\alpha} = (2\pi i)^{-1}A \sum_{1 \leq j \leq J_A} h_j w_j z_j^{-\alpha-1}(z_j I - A)^{-1}, \]

or with a preconditioning $(A^{-\alpha}_h(P))$, from

\[ (A^{-\alpha}_h(P))^{-\alpha} = (2\pi i)^{-1}MA \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha-1}(z_j I - MA)^{-1}. \]

The same test as above is also performed with $n = 501$ and $\alpha = 0.75$. The results are reported in Fig. 11, with $r^{(A)} = 5.15$ and $r_{MA} = 0.33$, i.e. with a ratio of about 15.5, illustrating the improved computational time.
Fig. 10. **Experiment 6.** (Top-Left) CPU-time (in seconds) in logscale, and $\|A^{-\alpha} f_h - u_{ref}\|_2$, where $A^{-\alpha} f_h = u_{\alpha}$, as a function of the number of quadrature points $J_{A,M,A}$, with $\alpha = 0.25$. (Top-Right) $\|A^{-\alpha} - A^{-\alpha}_{ref}\|_2$ in logscale as function of the number of quadrature points $J_{A,M,A}$. (Middle-Left) and (Middle-Right) : $\alpha = 0.75$. (Bottom-Left) and (Bottom-Right) : $\alpha = 1.5$.

**Experiment 7.** We propose the following numerical experiment to illustrate the differential-based preconditioner derived in this subsection for solving $A^\alpha u_h = f_h$, with $\alpha = 0.25$ in a case where $[M,A] = 0$. More precisely, we estimate $A^{-\alpha} f_h =$
Fig. 11. Experiment 6. (Top-Left) CPU-time (in seconds) in logscale, and $\|A^{-\alpha} f_h - u_{\text{ref}}\|_2$ as a function of the number of quadrature points $J_{A,MA}$, with $\alpha = 0.75$. (Top–Right) $\|A^{-\alpha} h^{-A}_{\text{ref}}\|_2$ in logscale as a function of the number of quadrature points $J_{A,MA}$, with $n = 501$. (Bottom) Direct contour $C_A$ and preconditioned contour $C_{MA}$.

We consider $A$ as a 3-point approximation of the Laplace operator on a segment $[-1;1]$, with $n = 101$ grid-points. We use some circular contours for both the non-preconditioned and preconditioned Cauchy integrals. In Fig. 12 (left), we report in logscale i) the CPU-time (in seconds) for the direct method (with $C_A$) and double-preconditioned method (with $C_{MA}$), and ii) $\|u_h - u_{\text{ref}}\|_2$. We more precisely compare a Jacobi Cauchy integral preconditioner with a differential-based preconditioner $M_\tau$ with $\tau = 8 \times 10^{-1}$, $\tau = 9 \times 10^{-1}$, $\tau = 1$ and $\tau = 1.2$, and with a direct integral computation without preconditioner. We also use a Cauchy ILU-preconditioner ($L\tilde{U}$) with a drop-tolerance fixed to $10^{-1}$, although in this case $[(\tilde{L}\tilde{U})^{-1}, A]$ is not necessarily close to zero. We also report $\|A^{\alpha}_{h} - A^\alpha_{\text{ref}}\|_2$ in logscale in Fig. 12 (Right).
brates that for a moderately dominant diagonal matrix, the differential-based preconditioning may be an alternative to Jacobi preconditioning, but an ILU-factorization can be used as well, if the drop tolerance is small enough.

where

\[ A^{-\alpha}f_h = u_h, \]  

as a function of the number of quadrature points \( J_{A,MA} \), with \( \alpha = 0.25 \). (Right) \( \| A_h^{-\alpha} - A_{rH}^{-\alpha} \|_2 \) in logscale as a function of the number of quadrature points \( J_{A,MA} \), with \( n = 101 \). (Right) Direct contour \( C_A \) and preconditioned contour \( C_{MA} \).

6. Application to the approximation of stationary fractional PDEs. The approximation of stationary and time-dependent fractional PDEs is currently a very active research area in particular due to the development of fractional models from physics (see e.g. [9]). We are here interested in the efficient computation of the solution to fractional Poisson-like equations thanks to the solutions to induced "fractional linear systems" \( A^\alpha x = b \). The fractional Poisson equation on a bounded domain \( \Omega \subset \mathbb{R}^d (d = 1, 2, 3) \) with null Dirichlet boundary condition on \( \partial \Omega \) writes

\[
(-\Delta)^\alpha u = f, \quad \text{in } \Omega, \\
u = 0, \quad \text{on } \partial \Omega,
\]

where \( \alpha \in (0, +\infty) \), \( f \in L^p(\Omega), 1 < p < \infty \). The well-posedness of this problem is for instance studied in [1] for \( \alpha \in (0, 1) \). In particular, it is proved that, for any function \( f \in L^p(\Omega) \), with \( 1 < p < \infty \), the unique solution to the Dirichlet problem belongs to the functional space \( L^p_{2\alpha,\text{loc}}(\Omega) \), where \( L^p_{2\alpha,\text{loc}}(\Omega) := \{ u \in L^p(\Omega) : u\varphi \in L^p_{2\alpha}(\Omega) \text{ for any } \varphi \in C^\infty_0(\Omega) \} \), and \( L^p_{2\alpha}(\Omega) := \{ u \in L^p(\Omega) : (-\Delta)^\alpha u \in L^p(\Omega) \} \). For any \( u \in S(\mathbb{R}^d) \) (i.e. the Schwartz’s space of rapidly decaying \( C^\infty \)-functions [11]) and \( \alpha \in (0, 1) \), we have \((-\Delta)^\alpha u \in L^2(\mathbb{R}^3) \). An equivalent definition [4] in \( \mathbb{R}^2 \) can be stated for \( \alpha \in (0, 1) \) and any \( u \in S(\mathbb{R}^2) \) [11] as

\[
(-\Delta)^\alpha u(x) = C(\alpha) \text{p.v. } \int_{\mathbb{R}^2} \frac{u(x) - u(y)}{|x - y|^{2+2\alpha}}dy = C(\alpha) \lim_{\varepsilon \to 0^+} \int_{B_\varepsilon(x)} \frac{u(x) - u(y)}{|x - y|^{2+2\alpha}}dy,
\]

where \( B_\varepsilon(x) \) is the ball of radius \( \varepsilon \) and center \( x \), \( C(\alpha) \) being the constant defined by

\[
C(\alpha) := \left( \int_{\mathbb{R}^2} \frac{1 - \cos(\xi_1)}{\xi_1^{2+2\alpha}}d\xi \right)^{-1}.
\]
The fractional laplacian can also be rewritten \([4]\), for \(\alpha \in (0, 1)\) and any \(u \in \mathcal{S}(\mathbb{R}^2)\), as
\[
(6.4) \quad (-\Delta)^\alpha u(x) = -\frac{1}{2} C(\alpha) \text{p.v.} \int_{\mathbb{R}^2} \frac{u(x + y) - 2u(x) + u(x - y)}{|y|^{2+2\alpha}} dy.
\]

Although nonlocal, this last equality is potentially interesting from a computational point of view (see formula \((6.7)\)).

### 6.1. Fractional laplacian approximation.

For the 2d computational domain \(\Omega := \prod_{i=1}^{2} L_i \ell_i\), we introduce the inner uniform cartesian grid \(\Omega_h\), with \(n := \prod_{i=1}^{2} N_i\) total discretization points, defined by \(\Omega_h = \{(x_{i,j} = (x_{1,i}, x_{2,j}))\}_{(i,j) \in \mathcal{I}}\), with \(x_{1,i} := -L_1 + ih_1, x_{2,j} := -L_2 + jh_2, \mathcal{I} := \{(i,j) \in \mathbb{N}^2\}\) such that \(1 \leq i \leq N_1, 1 \leq j \leq N_2\), setting \(h_\ell := 2L_\ell/(N_\ell + 1), \ell = 1, 2, \) and \(h := (h_1, h_2)\). When all the uniform discretization steps are equal along the directions, we define : \(h := h_1 = h_2\), and then \(n = N^2\), with \(N := N_1 = N_2\).

To fix the ideas, let us now consider the following finite-difference approximation of the Laplacian operator \(-\Delta\) based on a 5-point approximation scheme \([10]\) along each direction for a function \(\varphi := (\varphi_{i,j})\) set on the grid \(\Omega_h\)
\[
\begin{aligned}
-\Delta_{h_1}\varphi_{i,j} &= \varphi_{i+2,j} - 16\varphi_{i+1,j} + 30\varphi_{i,j} - 16\varphi_{i-1,j} + \varphi_{i-2,j}, \\
-\Delta_{h_2}\varphi_{i,j} &= \varphi_{i,j+2} - 16\varphi_{i,j+1} + 30\varphi_{i,j} - 16\varphi_{i,j-1} + \varphi_{i,j-2},
\end{aligned}
\]
A fourth-order approximation of the laplacian is then: \(\Delta_h u_h := (\Delta_{h_1} + \Delta_{h_2}) u_h\). Let \(f_h = \{f_{i,j}\}_{(i,j) \in \mathcal{I}}\) be the projection of the function \(f\) on \(\Omega_h\), such that \(f_{i,j} = f(x_{i,j})\), \((i,j) \in \mathcal{I}\). Any other real space method (e.g. finite volume or finite element) could also be used within the method developed below. The approximate solution to system \((6.1)\) is obtained by solving the fractional linear system \(A_h^\alpha u_h = f_h\), corresponding to the discrete operator \((-\Delta)^\alpha\). Let us assume that the approximation of \(\Delta\) is at order \(q\) with discretization step \(h\) on the bounded domain \(\Omega_h\). The construction to the approximate solution \(u_h\) is performed by computing
\[
(6.5) \quad u_h = A^{-\alpha} f_h.
\]
For the sake of conciseness, we use hereafter the notation "\(A = A_h\)". For a smooth function \(\varphi\), one gets: \(\Delta_h \varphi = \Delta \varphi + O(h^q R_1(\varphi))\), so that as we use a null Dirichlet boundary condition \([9]\) we obtain: \(\Delta_h^\alpha \varphi = \Delta^\alpha \varphi + O(h^{q\alpha} R_\alpha(\varphi))\), with \(R_1\) and \(R_\alpha\) some smooth differential operators. To compute \(u_h\), we propose to apply the strategy based on the efficient computation of Cauchy integrals. Inhomogeneous Dirichlet boundary conditions would complicate the approximation \([9]\). Let us also remark that usually real space approximations of the fractional Poisson equation are performed by directly approximating \((-\Delta)^\alpha\) by polynomials (see for instance \([8]\)). The approach developed below is intended instead to illustrate that the efficient computation of matrix powers is an attractive alternative by numerically solving \((6.5)\).

### 6.2. Computational complexity analysis in 2d.

We recall that the fractional laplacian can also be rewritten \([4]\) under the form \((6.2)\), for \(\alpha \in (0, 1)\) and any \(u \in \mathcal{S}(\mathbb{R}^2)\). A direct finite-difference approximation to \((6.2)\) on a \(n\)-grid \(\Omega_h = \{x_{i,j} = (x_{1,i}, x_{2,j}) : 1 \leq i \leq N, 1 \leq j \leq N\}\) reads
\[
(6.6) \quad A_\alpha u_h = f_h,
\]
where \( u_h := \{ u_{i,j} \}_{1 \leq i \leq N; 1 \leq j \leq N} \in \mathbb{C}^{N^2} \), with \( u_{i,j} \approx u(x_{i,j}) \), and where the matrix \( A_h \) is constructed by approximating (6.4) on the finite grid by

\[
(-\Delta)^\alpha u(x_{i,j}) \approx \frac{1}{2} C(\alpha) \sum_{k=1}^{N} \sum_{l=1}^{N} \frac{u_{i+k,l+j} - 2u_{i,j} + u_{i-k,l-j}}{|y_{k,l}|^{2+2\alpha}} h_1 h_2.
\]

The overall computational complexity to obtain the full matrix \( A_h \) is at worst \( O(n^2) \), where the solution to (6.6) requires \( O(n^\beta) \) operations with \( 1 < \beta \leq 3 \) related to the complexity for solving a full linear system (once) by a given brute force or specific algorithm. In contrast, for any (deterministic or stochastic) stationary operator, the methodology developed in Section 4 requires

- \( O(n) \) operations in order to construct a sparse approximation of the solution \( A \).
- the computation of \( J_{MA} \) sparse linear systems, i.e. \( O(J_{MA} n^\gamma) \) operations, with \( \gamma > 1 \). This also contains the cost of the eigenvalue solver to estimate the largest and smallest eigenvalues to design the integral contour.
- The rest of the computation is a sparse matrix-vector product, thus requiring \( O(n) \) operations.

In fine, the overall computational complexity of the proposed method is \( O(J_{MA} n^\gamma) \), which must be compared to \( O(n^\beta + n^2) \). We conclude that a good preconditioned Cauchy integral approach allows for i) the use of sparse matrices, ii) efficient quadratures on short length contours, and thus is theoretically much more efficient than a direct approach.

We now state an important result of this paper. Consider the following system

\[
(-\Delta)^\alpha u = f, \text{ in } \Omega,
\]

\[
\begin{cases}
  u = 0, & \text{on } \partial \Omega,
\end{cases}
\]

where \( \Omega \in \mathbb{R}^2 \) is an open and bounded domain, and \( f \in C^0(\Omega) \). Let us introduce the numerical solution \( u_{h,\Omega} := M^\alpha S_{h,\Omega}^{-\alpha} f_h \), where

\[
S_{h,\Omega}^{-\alpha} = (2\pi)^{-1} M A \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha-1} (z_j I - MA)^{-1}.
\]

Therefore, \( u_{h,\Omega} \) is an approximation of the solution \( u_h = A^{-\alpha} f_h \), the latter being itself an approximation to the solution \( u \) to system (6.8). In the sequel, we need the following discrete norms: for \( v \in \ell^\infty(\Omega_h) \), \( \| v \|_{\ell^\infty(\Omega_h)} := \max_{1 \leq i \leq N; 1 \leq j \leq N} |v(x_{i,j})| \), and for \( v \in \ell^2(\Omega_h) \), \( \| v \|_{\ell^2(\Omega_h)} := (h_1 h_2 \sum_{1 \leq i \leq N; 1 \leq j \leq N} |v(x_{i,j})|^2)^{1/2} \).

**Theorem 6.1.** We consider system (6.8). Let us denote by \( A \) an order \( q \in 2\mathbb{N}^* \) finite-difference approximation to \(-\Delta\) on the grid \( \Omega_h \), and by \( \Pi_h \) the projection operator from \( C(\Omega) \) to \( \ell^\infty(\Omega_h) \), such that \( f_h := \Pi_h f = \{ f(x_{i,j}) \}_{1 \leq i \leq N; 1 \leq j \leq N} \). The approximate solution \( u_{h,\Omega} \) on \( \Omega_h \) to the fractional linear system \( A^\alpha u_h = f_h \) is constructed as follows:

\[
\begin{align*}
  u_{h,\Omega} := (2\pi)^{-1} M^\alpha (MA) \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha-1} u_j, \\
  (z_j I - MA) u_j = f_h, & \text{ for } 1 \leq j \leq J_{MA},
\end{align*}
\]

where i) \( M \) is a Cauchy integral preconditioner such that \([M,A] = 0\), ii) \( J_{MA} \) is the total number of quadrature nodes on \( \Gamma_{MA} \) (or \( C_{MA} \)), iii) \( \{ w_j \}_{1 \leq j \leq J_{MA}} \) are the quadrature weights, and iv) \( \{ z_j \}_{1 \leq j \leq J_{MA}} \in \Gamma_{MA} \) (or \( C_{MA} \)) the quadrature nodes. Then, the following results hold
1. Let us assume that the Cauchy integral quadrature is of order \( \sigma \in \mathbb{N}^* \), then there exists \( C = C(\alpha, \Omega, A, M, \Gamma_{MA}) > 0 \) and \( D = D(f, \alpha, \Omega, A) > 0 \), such that

\[
\|u - u_h\|_{\mathcal{E}(\Omega_h)} \leq C \max_{1 \leq j \leq J_{MA}} |h_j|^\sigma \|f_h\|_{\mathcal{E}(\Omega_h)} + D(h_1 h_2)^\alpha.
\]

2. Setting \( n = N_1 N_2 \) and for \( A \in \mathbb{C}^{n \times n} \), a direct estimate of \( A^{-\alpha} u_h \) requires \( O(J_A n^\beta_A) \) operations, with \( 1 < \beta_A < 3 \). By using a Cauchy integral preconditioner \( M \), only \( J_{MA} \ll J_A \) linear systems have to be solved along \( \Gamma_{MA} \). Performing \( p \) (parallel) ILU-factorizations \( N_j \) on \( z_j I - A \) such that \( \text{cond}(N_j(z_j I - MA)) \ll \text{cond}(z_j I - MA) \), the overall computational complexity of the double-preconditioning method is at most \( O(J_{MA} n^{\beta_{ILU}}) \), with \( \beta_{ILU} \gtrsim 1 \) thanks to the cost for building the ILU-preconditioners.

**Proof.** We first prove (6.9). The approximate solution to (6.1) is defined by

\[
u_h = A^{-\alpha} f_h = (2\pi i)^{-1} A \int_{\Gamma_A} z^{-\alpha-1}(z I - A)^{-1} f_h dz.
\]

Assuming that an order \( \sigma \in \mathbb{N}^* \) quadrature formula is used to approximate (6.10), we have

\[
S_h^{(-\alpha)} = (2\pi i)^{-1} MA \sum_{1 \leq j \leq J_{MA}} h_j w_j z_j^{-\alpha-1}(z_j I - MA)^{-1}.
\]

In addition, one gets

\[
(MA)^{-\alpha} f_h = (2\pi i)^{-1} MA \int_{\Gamma_{MA}} z^{-\alpha-1}(z - MA)^{-1} f_h dz.
\]

We therefore deduce that there exists \( C_1 = C_1(\alpha, A, M, \Gamma_{MA}) > 0 \) such that

\[
\|S_h^{(-\alpha)} - (MA)^{-\alpha}\|_2 \leq C_1 \max_{1 \leq j \leq J_{MA}} |h_j|^{\tau}.
\]

Next, we have: \( u_h \), \( u_h = M^\alpha S_h^{-\alpha} f_h = A^{-\alpha} f_h \). According to Proposition 5.1, the identity \( A^{-\alpha} = M^\alpha (MA)^{-\alpha} \) yields

\[
\|u_h \|_{\mathcal{E}(\Omega_h)} = \|M^\alpha S_h^{-\alpha} f_h - M^\alpha (MA)^{-\alpha} f_h\|_{\mathcal{E}(\Omega_h)}
\]

\[
\leq \|M^\alpha\|_2 \times \|S_h^{(-\alpha)} - (MA)^{-\alpha}\|_2 \times \|f_h\|_{\mathcal{E}(\Omega_h)}.
\]

From (6.11), we prove that there exists a positive constant \( C = C(\alpha, \Omega, A, M, \Gamma_{MA}) \) such that: \( \|u_h \|_{\mathcal{E}(\Omega_h)} \leq C \max_{1 \leq j \leq J_{MA}} |h_j|^{\tau} \|f_h\|_{\mathcal{E}(\Omega_h)} \). Next, according to [9], one can find \( D = D(f, \alpha, A, \Omega) > 0 \) such that: \( \|u - A^{-\alpha} f_h\|_{\mathcal{E}(\Omega_h)} \leq D(h_1 h_2)^\alpha \).

We finally have

\[
\|u - u_h\|_{\mathcal{E}(\Omega_h)} \leq \|u_h \|_{\mathcal{E}(\Omega_h)} + \|u - A^{-\alpha} f_h\|_{\mathcal{E}(\Omega_h)}
\]

\[
\leq C \max_{1 \leq j \leq J_{MA}} |h_j|^{\tau} \|f_h\|_{\mathcal{E}(\Omega_h)} + D(h_1 h_1)^\alpha.
\]

The second part of the theorem is straightforward. A direct estimate, i.e. without any preconditioner, requires the solution to \( J_A \) linear systems, each requiring \( O(n^{\beta_A}) \)

This manuscript is for review purposes only.
operations, for $1 < \beta_A < 1$. When a Cauchy integral preconditioner is used, only

$J_{MA} \ll J_A$ linear systems have to be solved. For ILU-preconditioners, the overall

complexity is simply $O(J_{MA}^{\beta_{ILU}})$, where $\beta_{ILU} < \beta_A$. \hfill \square

The following remark is of interest for matrices with complex eigenvalues.

Remark 6.1. For matrices with a complex spectrum, the circular contour can also
be used as follows: $C_{MA} = C(z_c, r_{MA})$, with center $z_c$ and radius $r_{MA}$, and enclosing
$\text{Sp}(MA)$ corresponding to $n$ poles to $(z J - MA)^{-1}$. In the following, we define

$p_{MA} = J_{MA}/2$. In the case of a circular path, one also gets

$$(z J - MA)^{-1} = \frac{1}{2} \int_{\Gamma} \left( (re^{i\pi \theta} + z_c + z) I - MA \right)^{-1} \frac{e^{i\pi \theta}}{(e^{2i\pi \theta} + z_c e^{2i\pi \theta}/r)} d\theta.$$  

We set $z_j = \sigma_j^{-1} + z_c$ (see [12]), where

$$\sigma_j^{-1} = \left\{ \begin{array}{ll}
    r_{MA} e^{-i\pi x_j}, & k = 1, \ldots, p_{MA}, \\
    r_{MA} e^{-i\pi x_j - p}, & k = p_{MA} + 1, \ldots, 2p_{MA} = J_{MA}.
\end{array} \right. $$

and

$$\sigma_j = \left\{ \begin{array}{ll}
    \sigma_j^{p_{MA}}, & k = 1, \ldots, p_{MA}, \\
    \sigma_j^{-p_{MA}}, & k = p_{MA} + 1, \ldots, 2p_{MA} = J_{MA}.
\end{array} \right.$$  

We first consider the construction of a preconditioner solving $(z J - MA)u_j = f_h$, for

$n \in 2N^*$,

$$(\sigma_j J - A) \approx \left\{ \begin{array}{ll}
    L_{j+p_{MA}} U_{j+p_{MA}}, & j = 1, \ldots, p_{MA}, \\
    L_{j-p_{MA}} U_{j-p_{MA}}, & j = p_{MA} + 1, \ldots, 2p_{MA}.
\end{array} \right.$$  

These LU-factorizations can be used as preconditioners. Theorem 6.1 can easily be

established for circular contours.

We can extend the methodology to equations of the form

$$-(-\Delta)^{\alpha} u + Vu = f, \text{ in } \Omega, $$

$$u = 0, \text{ on } \partial \Omega,$$

where $\alpha \in (0, 1)$, $f \in L^p(\Omega)$ and $V := V(x) \in L^\infty(\Omega)$, and with null Dirichlet

boundary conditions on $\partial \Omega$. We propose the following finite difference approximation

$$(A^\alpha + V_h) u_h = f_h, \text{ where i) the vector } f_h \text{ and the matrix } V_h \text{ are respectively the }$$

projection on $\Omega_h$ of $f$ and $V$, ii) $A = A_h$ is a finite difference approximation of $-\Delta$

on $\Omega_h$ and iii) $u_h$ is the approximate solution to $u$ in (6.12). We formally have:

$$((I + A^{-\alpha} V_h)u_h = A^{-\alpha} f_h).$$ We then proceed as follows. We compute $A^{-\alpha} f_h$ and

$A^{-\alpha} V_h$ by using the method developed above. Next,

1. we define $g_h$ as an approximation to $A^{-\alpha} f_h$ following

$$g_h := (2\pi i)^{-1} A \sum_{1 \leq j \leq J_A} \frac{h_j w_j z_j^{-\alpha-1} g_j}{z_j I - A},$$

where i) $J_A$ is the total number of quadrature nodes on $\Gamma_A^{(h)}$, ii) $\{w_j\}_{1 \leq j \leq J_A}$

are some interpolation weights, and iii-a) $z_j \in \Gamma_A^{(h)}$ with $z_{j+1} = z_j + h_{j+1}$ and

$h_j = \delta x_j + i \delta y_j$ or iiii-b) $z_j = z_c + r(\theta_j) e^{i \theta_j}$ and $z_{j+1} = z_c + (z_j - z_c) e^{i \theta_j+1} =

z_j e^{i \delta \theta_j+1}$, with $\delta \theta_{j+1} = \theta_j + \delta \theta_{j+1}$, where $\delta \theta_{j+1}$ is an angular increment.

This manuscript is for review purposes only.
2. Similarly, $B_h$ is an approximation to $A^{-\alpha}V_h$

$$B_h^{(i)} := (2\pi 1)^{-1} A \sum_{1 \leq j \leq J_A} \mathbf{h}_j w_j z_j^{-\alpha-1} v^{(i)}_j,$$

$$(z_j I - A) v^{(i)}_j = V_h^{(i)}, \text{ for all } 1 \leq j \leq J_A,$$

where $V_h = [V_h^{(1)}, \ldots, V_h^{(n)}] \in \mathbb{R}^{n \times n}$ (resp. $B_h = [B_h^{(1)}, \ldots, B_h^{(n)}] \in \mathbb{R}^{n \times n}$), setting $(V_h^{(i)})_{1 \leq i \leq n}$ (resp. $(B_h^{(i)})_{1 \leq i \leq n}$) as the column vectors of $V_h$ (resp. $B_h$).

3. Finally, we solve: $(I - B_h)u_{h,\delta h} = g_h$.

The computation of $B_h^{(i)}$ is naturally embarrassingly parallel. Let us remark that Cauchy integral preconditioning can easily be combined with the above methodology for solving (6.12).

### 6.3. Numerical experiments on fractional Poisson equations.

This section is devoted to some numerical experiments to illustrate the above approaches.

**Experiment 8. 1d modified fractional Poisson equation.** We consider:

$$-(-\Delta + V)^{\alpha} u = f \text{ on } \Omega = [-2, 2], \text{ with } f(x) = \exp(-15x^2), \alpha = 0.6 \text{ and } V = 5.$$ We use a 5-point stencil approximate laplacian on $\Omega_h$, where $n = 500$ and $A \in \mathbb{R}^{500 \times 500}$.

To analyze the performance of the proposed approach, we proceed as follows. We numerically compute $\lambda^{(A)}_{\text{min}}$ and $\lambda^{(A)}_{\text{max}}$ with a power and inverse-power methods, respectively, and define a circular contour $C_A = \mathcal{C}(0, \lambda^{(A)}_{\text{min}} + \varepsilon^{(A)}_{\theta})$, with $\varepsilon^{(A)}_{\theta} = 5 \times 10^{-2}$. The so-called direct method consists in computing

$$(6.13) \quad u_{h,\delta h} = (2\pi 1)^{-1} \sum_{1 \leq j \leq J_A} \mathbf{h}_j (\frac{z_j + z_{j+1}}{2})^{-\alpha} (z_j I - A)^{-1} f_h,$$

with $z_j = z_c + r^{(A)}_{\varepsilon} e^{i \theta_j}$. We define a Jacobi pre conditioner $M = \text{diag}(a_{11}^{-1}, \ldots, a_{nn}^{-1})$ and consider $\mathcal{C}_{MA} = \mathcal{C}(0, \lambda^{(MA)}_{\text{min}} + \varepsilon^{(MA)}_{\theta})$, where $\varepsilon^{(MA)}_{\theta} = 5 \times 10^{-2}$. In the following, we compute only one CROUT (row) ILU factorization with tolerance $10^{-6}$, setting the restart parameter to 20 iterations, $LU \approx \tilde{z} I - A$ with $\tilde{z} = \lambda^{(MA)}_{\text{min}}$.

We find $r^{(A)}_{\varepsilon} \approx 2.7$ and $r^{(MA)}_{\varepsilon} \approx 0.4$, corresponding to a gain factor equal to 6.7. In Fig. 13 (Right), we report in logscale i) the CPU-time (in seconds) for the direct method (with $C_A$) and double-preconditioned method (with $C_{MA}$), and ii) $\|u_{h,\delta h} - u_{r,\delta r}\|_{\ell^2(\Omega_h)}$.

The preconditioned approach converges much faster than the direct method which also requires more resources.

**Experiment 9. 2d fractional Poisson equation.** For $\Omega = [-5, 5 \times [-1, 1]$, we consider the fractional laplacian problem $-(-\Delta)^{\alpha} u = f$, with $f(x) = \exp(-5x_1^2 - 10x_2^2)$ and $\alpha = 0.4$. We choose a simple 3-point stencil approximate laplacian on $\Omega_h = \{(x_1, x_2) \in \Omega : 1 \leq i \leq N_1, 1 \leq j \leq N_2\}$, where $N_1 = 40, N_2 = 20$ and $A \in \mathbb{R}^{n \times n}$, for $n = 800$. The eigenvalues $\lambda^{(A)}_{\text{min}}$ and $\lambda^{(A)}_{\text{max}}$ are again computed by a power/inverse-power method. We define the rectangle contour $\Gamma_A = \mathcal{G}(\lambda^{(A)}_{\text{min}} - \varepsilon, -\varepsilon, \lambda^{(A)}_{\text{max}} + \varepsilon, \varepsilon)$, with $\varepsilon = 10^{-1}$. The direct method is based on (6.13), with $z_{j+1} = \mathbf{h}_{j+1} + z_j$ such that $\mathbf{h}_j := \delta x$ or $\mathbf{h}_j := \delta y$, leading to $\ell^{(\Gamma_h)} = 2(\lambda^{(A)}_{\text{max}} - \lambda^{(A)}_{\text{min}} + 2\varepsilon)$, where $J_A$ is the number of points to approximate $\Gamma_A$. For the Jacobi preconditioner $M$, we have $\ell^{(\Gamma^{(MA)})} = 2(\lambda^{(MA)}_{\text{max}} - \lambda^{(MA)}_{\text{min}} + 2\varepsilon)$. We calculate one CROUT (row) ILU-factorization, setting the tolerance to $10^{-6}$ and the value of the restart parameter to 20. Moreover, $LU \approx \tilde{z} I - A$, with $\tilde{z} = \lambda^{(MA)}_{\text{min}}$.

In Fig. 13 (Middle), we plot in logscale i) the CPU-time (in seconds) for both the direct method (with $\Gamma_A$) and double-preconditioned
method (with ΓMA), and ii) \( \|A^{-\alpha}f_h - u_{\text{ref}}\|_{L^2(\Omega_h)} \). It is clear that the preconditioned method is convergent much more rapidly than the direct one.

**Experiment 9bis. 2d fractional Poisson equation.** For \( \Omega = [-2, 2]^2 \), we solve the fractional Poisson equation \(-(-\triangle)^{\alpha}u = f\), for \( f(x) = 1 \) and \( \alpha = 0.4 \). A 3-point stencil scheme is used for the laplacian on the square grid \( \Omega_h \), where \( N = 50 \), \( A \in \mathbb{R}^{n \times n} \), and \( n = 2500 \). The power and inverse-power method provides \( \lambda_{\text{min}}(A) \) and \( \lambda_{\text{max}}(A) \). We use the circular contour \( C_{C} \), with \( \varepsilon(A) = 10^{-2} \). The direct method makes use of (6.13), with \( z_j = z_c + r(A)e^{i\theta_j} \). We define the Jacobi preconditioner \( M \) and consider \( C_{MA} \), where \( \varepsilon = 5 \times 10^{-2} \). As in Experiment 9, one CROUT factorization is computed with the same parameters. We find \( r(A) \approx 8.34 \) and \( r(MA) \approx 1.6 \), corresponding to a gain factor equal to 5.2. In Fig. 13 (Middle), we provide in logscale i) the CPU-time (in seconds) for the direct method (with \( C_A \)) and double-preconditioned method (with \( C_{MA} \)), and ii) \( \|A^{-\alpha}f_h - u_{\text{ref}}\|_{L^2(\Omega_h)} \). The preconditioned method is definitively faster than the direct method, which is also more resources consuming.

**Fig. 13. CPU-time (in seconds) in logscale, and \( \|A^{-\alpha}f_h - u_{\text{ref}}\|_2 \) in logscale. (Left) Experiment 8. 1d Poisson. (Middle) Experiment 9. 2d Poisson. (Right) Experiment 9bis. 2d Poisson.**

**Experiment 10.** We finally propose a series of experiments for \((-\triangle + V + dW)^{\alpha}u = f\) on a bounded domain \([-10, 10] \) with null Dirichlet boundary conditions. The Cauchy integral is approximated by using \( J_{A,MA} = 128 \) quadrature nodes. For \(-\triangle\), we use a 5-point scheme. In the following tests, we report the residual history vs the GMRES iteration number (the tolerance is \( 10^{-15} \) and the restart parameter is set to 50 iterations). More specifically using circular contours, we compare the convergence i) without Cauchy integral preconditioning (No precond.), ii) Jacobi Cauchy integral
preconditioner (Jacobi precond.), iii) ILU Cauchy integral preconditioner (with scaling matrix for computing $M^\alpha x$, see Subsection 4.2) (ILU-precond.), iv) ILU factorization $M$ on $A$ and then $M^\alpha$ is used to precondition $A^\alpha$, v) and finally no Cauchy integral preconditioning, but ILU preconditioning of $A^\alpha$, assuming it is known (ILU-precond. on $A^\alpha$). The convergence graphs (residual history vs GMRES iteration number) are given in Fig. 14 for

- **Experiment 10a.** $V = 0$ and the brownian motion $dW$ is approximated by a symmetric random (uniform law) matrix of magnitude 0.12, and $\alpha = 0.75$.
- **Experiment 10b.** $V = 0$ and the brownian motion $dW$ is computed by an unsymmetric random (uniform law) matrix with magnitude 0.06, and $\alpha = 0.75$.
- **Experiment 10c.** $V = 0$ and the brownian motion $dW$ is approximated by a symmetric random (uniform law) matrix with magnitude 0.12, fixing $\alpha = 0.5$.
- **Experiment 10d.** $V = 100e^{-x^2}$ and the brownian motion $dW$ is approximated by a symmetric random (uniform law) matrix of magnitude 0.12, and $\alpha = 0.75$.

These tests illustrate the fact that the convergence of the GMRES solver is highly dependent on the presence of a potential and the value of $\alpha$. Overall, the ILU-Cauchy integral preconditioner allows for a faster (sometimes much faster) convergence than any other preconditioning approach.

### 7. Conclusion.
In this paper, we proposed an efficient method for computing the real power of a diagonalizable matrix $A$ and algorithms for solving fractional...
linear systems, using quadrature rules for Cauchy integrals and contours enclosing the spectrum of \( A \). Simple preconditioners are proposed for drastically reducing the computational complexity thanks to spectrum clustering. Some experiments are reported to illustrate the methodology. In particular, applications to (deterministic and stochastic) stationary fractional Poisson-like equations with Dirichlet boundary conditions are given. In a forthcoming paper, we will propose some realistic applications and comparisons with other methods such as the differential equation approach as defined in Subsection 4.4.
