*Dedicated*

To my parents who love me unconditionally  
to my supportive family and  
to my teachers

## **ACKNOWLEDGMENT**

I would like to thank my advisor Dr. Mohammed S. Ba-Shammakh for his continuous support, encouragement and valuable guidance throughout the Thesis project. My sincere gratitude to Dr. Mohammad M. Hossain (co-advisor) for his supports and trainings. His guidance not only helped me to complete this research successfully but also to become a better student and researcher. Special thanks to Dr. Sameer Al-Ghamdi for sharing his knowledge on the subject. His evening discussion was eye opening which makes this work even better. Many thanks to the other Thesis Committee Members, Dr. Shaikh A. Razzak and Dr. Abdallah A. Al-Shammari for their valuable comments and suggestions.

I would like to acknowledge the Department of Chemical Engineering and the Center for Research Excellence in Corrosion for all kind of supports pursuing my master study at KFUPM. I would also like to acknowledge King Abdul Aziz City for Science and Technology (KACST) for funding through project ARP-30-252. The cooperation of Center of Research Excellence in Nanotechnology, RI-KFUPM in catalyst characterization is highly appreciated.

Finally, I would like to deeply thank my family for everything including encouragements during my MS period. I would never forget my friends who were there for me any time I needed them.

## LIST OF SYMBOLES

$M_{WV}$  molecular weight of vanadium g/mol

$E_{des}$  energy of desorption, kJ/mol

$k_{d0}$  pre-exponential factor

$k_d$  adsorption constant

$T_m$  centering temperature K

$T$  desorption temperature, K

$r_{des}$  rate of desorption ml-NH<sub>3</sub>/g.s

$V_d$  volume of ammonia desorbed, ml/g

$V_m$  volume of ammonia adsorbed at saturation conditions, ml/g

$n$  order of the desorption rate

$R$  the universal gas constant J/k.mol or cm<sup>3</sup> atm K<sup>-1</sup> mol<sup>-1</sup>

$VO_x$  vanadium oxide surface species

### Greek letters

$\beta$  rate of temperature increase, °C/min

$\theta_{des}$  surface coverage of adsorbed species

$\nu$  stoichiometric number

## **Abbreviations**

ODH oxidative dehydrogenation

XRD X-ray diffraction

TPR temperature-programmed reduction

TPO temperature-programmed oxidation

TPD temperature-programmed desorption

## ABSTRACT

Full Name : [Abd Alwadood Hassan Elbadawi Babikir]

Thesis Title : [Fluidized-bed ODH of ethane to ethylene: optimization modeling and catalyst development]

Major Field : [Chemical Engineering]

Date of Degree : [November 2014]

Oxidative dehydrogenation (ODH) of ethane to ethylene is investigated in a fluidized-bed with a gas phase oxygen free environment over  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalysts. In catalyst formulation, both  $\text{ZrO}_2$  and  $\text{VO}_x$  loading are varied to obtain optimum catalytic performance. TPR/TPO results show that  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst is very reactive and stable in repeated reduction and oxidation cycles.  $\text{NH}_3$ -TPD analysis and desorption kinetics modeling indicate that the modification of  $\text{ZrO}_2$  gives an intermediate catalyst acidity and medium metal-support interaction. The estimated energy of ammonia desorption is found to be 75.4, 77.8 and 80.5 kJ/g for  $\text{Al}_2\text{O}_3/\text{ZrO}_2$  ratio of 2:1, 1:1 and 1:2, respectively. The increasing energy of desorption is due to the increased metal support interaction for the additional  $\text{ZrO}_2$  content. XRD, Raman and FTIR analysis indicate the presence of crystal phases and  $\text{VO}_x$  phases. The catalysts are evaluated in a fluidized CREC Riser Simulator in temperature range of 525-600 °C and 20-50 seconds contact time. The catalyst with  $\text{Al}_2\text{O}_3/\text{ZrO}_2$  ratio of 1:1 and 10 %  $\text{VO}_x$  loading displays highest ethylene selectivity (91.3%) and minimum  $\text{CO}_x$  formation (9.7 %). The kinetics of gas phase oxygen free ODH of ethane is established by using a modified Langmuir-Hinshelwood type model considering all the series-parallel reactions. The reducibility of the catalysts is also incorporated in kinetic models. It appears that the specific reaction rate constant for ethylene formation is almost 10 times higher than that of the formation of  $\text{CO}_x$  which is consistent to the product selectivity data. Finally, reaction conditions are optimized with GAMS using kinetic parameters and proposed reaction network. Optimum ethylene selectivity found to be 92 % at 5.6% ethane conversion and these two are slightly higher than what obtained by experiment. Theoretical optimum operating conditions found to be 600 °C using 0.2 g catalyst and reaction time of 20 seconds.

## ملخص الرسالة

الاسم الكامل: عبد الودود حسن البدوي بابكر

عنوان الرسالة: أكسدة غاز الايثان المتميعة الى الايثلين بانتزاع الأوكسجين : النمذجة الامثل وتطوير الحفاز

التخصص: الهندسة الكيميائية

تاريخ الدرجة العلمية: نوفمبر 2014

في هذه البحث تمت دراسة اكسدة غاز الايثان الى الايثلين بانتزاع الهيدروجين بانتزاع الهيدروجين باستخدام  $VO_x/\gamma-Al_2O_3-ZrO_2$  كحفاز في بيئة خالية من الاوكسجين، حيث تم تغيير نسب كل من  $ZrO_2$  و  $VO_x$  لتحديد نسب الحفاز التي تعطي افضل اداء. نتائج تحليل TPR/TPO اظهرت ان الحفاز  $VO_x/\gamma-Al_2O_3-ZrO_2$  نشط ومستقر اثناء دورات الاكسدة والاختزال. دراسة  $NH_3$ -TPD و تحليل حركيات التفاعل في هذه الاختبار اعطت مؤشر الى ان حموضة الحفاز منخفضة بالاضافة الى ان تفاعلا المعدن مع الداعم متوسط. تم حساب الطاقة اللازمة لامتناز الامونيا ووجد انها تعادل 75.4 ، 77.8 و 80.5 ك.جول للنسب الى  $ZrO_2$  الى  $Al_2O_3$  (2:1) ، (1:1) و (2:1) على التوالي. الزيادة في طاقة امتزاز الامونيا نسبة الى اضافة مركب اوكسيد الزركونيوم. ايضا تحليل الحفاز بواسطة XRD، Raman و FTIR اثبت وجود طور كريستالي من مركبات  $VO_x$ . تم اختبار الحفاز باستخدام مفاعل CREC Riser Simulator المتميع في درجة حرارة من 525 الى 600 درجة مئوية وزمن تفاعل من 20-50 ثانية. الحفاز المكون من نسبة (1:1)  $ZrO_2$  الى  $Al_2O_3$  والذي يحتوي على 10%  $VO_x$  اعطى افضل نتائج من حيث انتقائية الايثلين والتي تعادل 91% و اقل انتقائية لغازات اوكسيد الكربون والتي تعادل 9.7% . في هذا البحث ايضا تم دراسة حركيات التفاعل لأكسدة الايثان الى الايثلين في بيئة خالية من الاوكسجين باستخدام ميكانيكية Langmuir-Hinshelwood المعدلة اخذين في الاعتبار كل التفاعلات المتوازية والمتزامنة وكذلك درجة اختزال الحفاز. نتائج دراسة حركيات التفاعل اظهرت ان ثابت معدل تفاعل انتاج الايثلين 10 اضعاف ثابت معدل تفاعل انتاج  $CO_x$  وذلك يتوافق مع نتائج التفاعل التجريبية. وبالاضافة تم امثلة التفاعل باستخدام برنامج GAMS ونتائج دراسة حركيات التفاعل ووجد ان الانتقائية المثلى للايثلين 92% عند نسبة تحويل 5.6% للايثان. والظروف المثلى لتحقيق هذه النتائج النظرية هي 600 درجة مئوية و 0.2 جم من الحفاز ومدة تفاعل تقدر ب 20 ثانية.

# CHAPTER 1

## INTRODUCTION

### 1.1. Background

Ethylene is a valuable feed stock for the petrochemical industries. It is used as starting chemical to produce wide range of chemicals and products [1]. The major applications of ethylene include in (i) polymerization, (ii) oxidation, (iii) halogenation and hydrohalogenation, (iv) alkylation, (v) oxo reactions, (vi) hydration, (vii) dimerization to n-butenes and (viii) niche uses. Ethylene derivatives are used in the production of textiles, plastics, food packaging, antifreeze, and ethylene oxide glycol ether solvents. Ethylene is also used to produce polyethylene with linear higher olefins. These olefins are used to manufacture detergents, plasticizers, synthetic lubricants, additives, as co-monomers in the production of poly-ethylene. With rapid urbanization and increasing quality of human life, the global demand for ethylene is ever increasing. [Figures 1.1 and 1.2](#) show ethylene production and top producer countries. One can see that Asia, Europe and North America are the top ethylene producing regions. In Asia region, China and the Middle Eastern countries are major ethylene producer.

Steam cracking of petroleum hydrocarbons is the conventional source of ethylene. These steam cracking processes are energy intensive which contribute to the high ethylene production cost. The use of petroleum feed stocks, also the main source of energy, makes

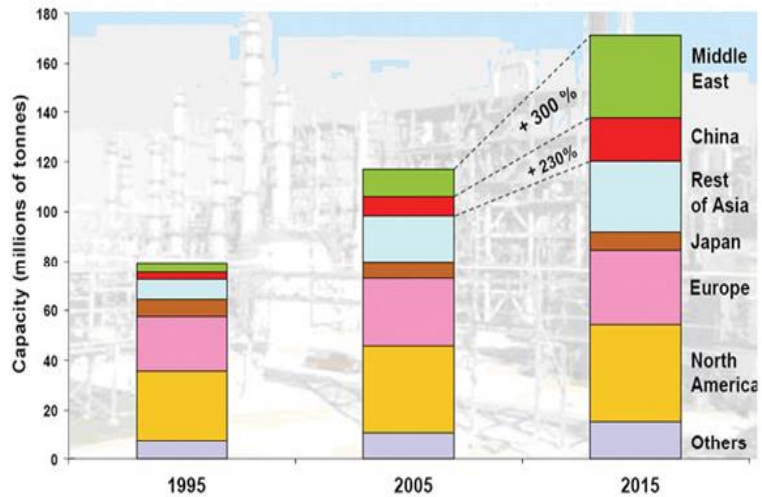

Figure 1.1. World production of ethylene [Parpinelli Tecnon]

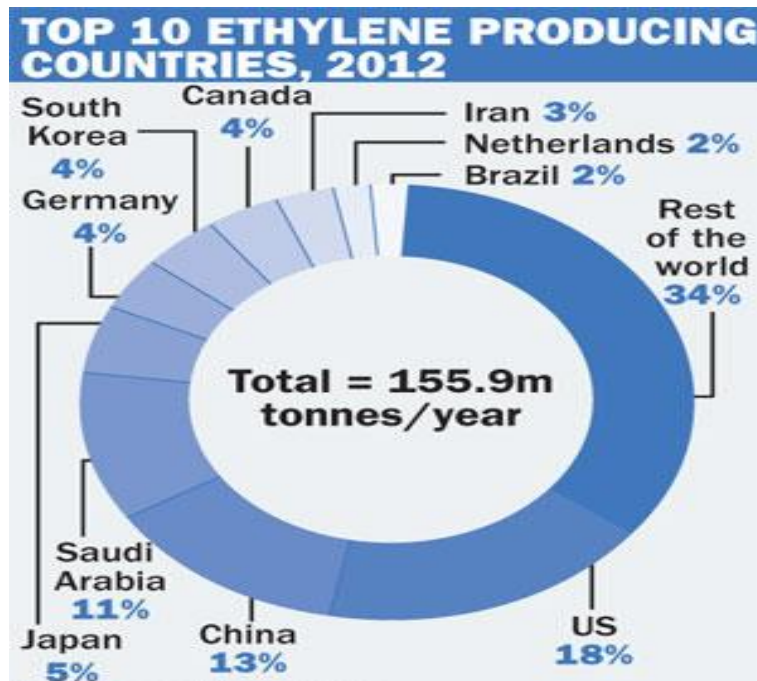

Figure 1.2. Top producing countries [OGJ and GPCA 2013]

the steam cracking approach further costly for producing ethylene. On the other hand, oxidative dehydrogenation (ODH) has a potential to produce ethylene from relatively cheaper gaseous feed stocks such as natural gas and refinery gas. The use of a suitable

catalyst can efficiently process the gaseous feeds to produce ethylene. Due to the fact, in recent years the ODH research has received great deal of attentions both in the industrial and academic settings.

## 1.2. ODH of ethane to ethylene

In oxidative dehydrogenation (ODH) process, both the feed ethane and oxidizing air streams are introduced to the reactor as shown in [Figure 1.3](#).

Figure 1.3. Schematic diagram of fixed bed ODH process

Ethylene is produced by a combination of simple dehydrogenation of ethane coupled with combustion of hydrogen to give water ([Equation 1.1](#)).

In this process, the presence of oxygen also favors the complete combustion of feed ethane and the product ethylene, which are undesired.

Therefore, the control of consecutive oxidation reactions leading to the formation of undesired by-products are the main challenge of ODH of ethane using gas phase oxygen. In this context, a gas phase oxygen free ODH in a circulating fluidized bed has been considered as a very promising alternative (Figure 1.4). This process consists of two interconnected fluidized bed reactors: (i) ODH reactor and (ii) catalyst regenerator and the solid catalysts is being circulated between the reactors. In this approach, ethane is dehydrogenated in the presence of a solid oxide catalyst which furnishes oxygen to the reactant and this is accompanied by simultaneous reduction of the catalyst. The reduced catalyst is then sent to a regenerator to be re-oxidized in contact with air and recycle back to the ODH reactor. In the overall process, the catalyst is continuously circulated between the ODH reactor and the regenerator. The major advantages of this process is the possibility of achieving higher ethylene selectivity by proper controlling of the reaction temperature given the two exothermic reactions are separated into two less exothermal steps. The remaining outstanding challenge for this process is the development of a fluidizable catalyst capable of satisfying wide variations in the normal metal oxidation state without suffering any structural failure.

Figure 1.4. Schematic diagram of fluidized bed ODH process

Keeping the above into consideration, the present research has been focused upon investigating  $ZrO_2$  modified fluidizable  $VO_x/\gamma-Al_2O_3-ZrO_2$  catalysts for ODH of ethane to ethylene under gas phase oxygen free environment. Following are the major contributions of this research:

- i. Developed highly active  $ZrO_2$  modified  $VO_x/\gamma-Al_2O_3-ZrO_2$  catalyst,
- ii. Investigated the effects of  $ZrO_2$  on the  $VO_x/\gamma-Al_2O_3-ZrO_2$ ,
- iii. Investigated the variation of  $VO_x$  loading on the  $VO_x/\gamma-Al_2O_3-ZrO_2$ ,
- iv. Evaluated the reactivity and stability of the synthesized fluidizable  $VO_x/\gamma-Al_2O_3-ZrO_2$  in a CREC Riser Simulator under the expected conditions of an industrial scale ODH reactor,

- v. Developed mechanism based (Langmuir-Hinshelwood) kinetic model taking into account of catalyst reduction kinetics model,
- vi. Optimized reaction conditions with GAMS using kinetic parameters and proposed reaction network. |

## CHAPTER 2

### LITERATURE REVIEW

The available articles in the open literature are been focused on different aspects of catalysis such as active metal phases, structure and morphology. These components are important for catalyst performance. Moreover, in ODH reaction catalyst selectivity is the most important parameter together with catalyst stability and other parameters. Kinetic modeling as well is a major tool to understand reaction mechanisms. The understanding reaction mechanism can also help to increase ethylene selectivity. In addition these models can be useful to optimize the reaction conditions to maximize the desired product yields. Literature review in this chapter covers catalyst composition, ODH kinetic modeling and optimization.

#### 2.1. ODH Catalyst structure

##### 2.1.1. Catalyst support

Like other conventional heterogeneous catalytic reactions, both the support and the active metal components play important roles in ODH reactions. The most commonly studied metals are V and Cr, using different type of support materials [2]. For example, the phosphate supported V catalysts are more active and provides better ethylene selectivity than that is reported for  $(VO)_2P_2O_7$  [3]. For a Cr containing catalyst, it was shown that at equivalent conversion level, ethylene selectivity varies according to different supports  $(VO)_2P_2O_7 > CrPO_4 > Cr/\alpha-ZrP > Cr/\beta-ZrP$ . Iron phosphate phases such as  $FePO_4$ ,  $Fe_2P_2O_7$ ,  $\alpha-Fe_3(P_2O_7)$  and  $\beta-Fe_3(P_2O_7)$ , and nonstoichiometric (mixed) iron phosphate phases with

P:Fe ratios of 1.2:1 and 2:1 have been also reported to be active for ODH reactions [4]. The nickel based Ni–Co/Al<sub>2</sub>O<sub>3</sub> catalysts are active but shows low ethylene selectivity (less than 30 % ) [5].

There are some studies investigated different acidic SAPO-34 support materials such as AlPO-34, SAPO-34, NaAPSO-34 and LaAPSO-34 in ODH catalysts [6]. It was demonstrated that the cracking reactions were inhibited with SAPO-34 catalysts. The deactivation effects were practically absent even in a longer period of operation in a laboratory scale reactor. Upon introduction of an active metals such as V, Co, Mg and Mn, the ALPO-5 supported catalysts showed improved activity. However, the ethylene selectivity did not exceed 65% [6]. There are some studies dealt with the acidic and basic Y zeolites supported transition metal (Ni, Cu, and Fe) catalysts in ODH reactions [7]. Among these catalysts, the nickel based catalyst shows better activity and selectivity. Based on the catalyst activity and ethylene selectivity, these metal-loaded Y zeolites samples were ranked as Ni/Y-zeolite > Cu/Y-zeolite > Fe/Y-zeolite [8]. In order to improve the activity and selectivity sometimes Li, Mg, Al, Ga, Ti, Nb and Ta have been used as promoter [9, 10] .

### **2.1.2. Catalyst active phase**

Mo and V are the most commonly used metals for ODH of lighter hydrocarbons. In some cases a third metal has been employed as promoter. The phosphorous promoted bimetallic catalysts were found to be effective, especially when both V and phosphorous were added together [11]. Vanadium with Ti, Sn or Zr pyrophosphates support were studied in ODH reaction [12]. Catalyst exhibited a good conversion with selectivity up to 90%. Cr containing oxide pillared zirconium phosphate materials was synthesized using

the fluoro-complex method which enhanced catalyst activity [13]. A multi component  $\text{BaCl}_2\text{-TiO}_2\text{-SnO}_2$  showed high selectivity of ethylene and low  $\text{CO}_x$  selectivity [14]. It was believed that the presence of  $\text{Cl}^-$  ions in the catalyst play vital and positive roles in ODH reaction. Although, this catalyst displayed promising result (92.6% ethylene selectivity), the deactivated rate was very high. The catalyst activity was sharply declined during the initial time on stream. The other types of metals tested are La, Nd, Sm and Gd. In catalyst synthesis modified sol-gel method were employed [15]. Among, the synthesized catalysts, Gd-NiO showed the best catalytic performance for ODH reaction, with 56% ethane conversion and 51% ethylene selectivity at 375 °C. Cobalt-titania (anatase) catalysts was also investigated alone and with the addition of Phosphorous [16].

It was shown that the addition of vanadium and phosphorous can enhance the ethane conversion, ethylene selectivity and catalyst stability although Mo is more effective in the same aspects[17]. NiO-CeO<sub>2</sub> mixed oxides were also investigated. The addition of cerium oxide to NiO also improve the catalytic performance [13]. V<sub>2</sub>O<sub>5</sub>/Nb<sub>2</sub>O<sub>5</sub> catalysts with various V<sub>2</sub>O<sub>5</sub> contents was studied [18], it gave 38% selectivity and 28 % yield although pure Nb<sub>2</sub>O<sub>5</sub> has very little activity by itself.

It is important to mention here that all the above studies conducted in fixed reactors using air as oxidizing source, which contribute to the  $\text{CO}_x$  formation due to complete oxidation of feed ethane and product ethylene. Consequently, the ethylene selectivity is low. The other drawback of the fixed bed ODH are the separation of product form  $\text{CO}_x$  and nitrogen associated with oxidizing air.

Combustion reactions can be controlled by controlling the availability of gas phase oxygen. One of the possible alternative is the gas phase oxygen free ODH in a circulating fluidized bed reactor system as proposed by the present research group [19, 20]. In this approach, the oxidized form of the catalyst will be the source of lattice oxygen. The oxygen depleted catalyst can be re-oxidized by circulating them to a regenerator maintaining a continuous air flow and suitable temperature. It was showed that up to 84.5% ethylene selectivity can be obtained in the range of 550–600 °C. The selectivity of the VO<sub>x</sub> based catalyst can be further improved with MoO<sub>x</sub> modification [20]. MoO<sub>x</sub> enhanced the reducibility of VO<sub>x</sub> therefore ethane conversion was increased. Despite some interesting results both the VO<sub>x</sub> and VO<sub>x</sub>-MoO<sub>x</sub> catalyst shows decreased ethylene selectivity at higher temperature and conversion levels which was due to the consecutive oxidation of product ethylene.

### **2.1.3. Reactor type**

In literature mainly fixed bed reactors are employed for oxidative dehydrogenation of lighter hydrocarbons to produce olefins. There are also few studies considered fluidized bed and fluidized bed membrane reactors. Fluidized bed membrane reactor (FLBMR) was studied experimentally in comparison to the conventional operation as a fluidized bed reactor (FLBR) for the catalytic oxidative dehydrogenation of ethane using a  $\gamma$ -alumina supported vanadium oxide catalyst. For both reactor configurations, the influence of process parameters such as temperature and contact time was investigated. Further, the experimental data obtained were compared to previous experiments with a fixed-bed reactor (FBR) and a packed-bed membrane reactor (PBMR) operated with a similar catalyst. For identical overall feed rates, the distributed oxidant feeding in the FLBMR

improves the selectivity to ethylene significantly. The beneficial effect of oxidant dosing over the membrane is most pronounced at high temperatures and long contact times. Under limiting oxidant supply the FLBMR and the PBMR show a similar performance, but under moderate oxygen excess the FLBMR outperforms the PBMR significantly. The maximum ethylene yield observed in the FLBMR was 37% compared to 35% for the PBMR. Beside a high productivity, for the FLBMR a broader favorable operation range with respect to the oxygen–hydrocarbon ratio was observed, what indicates a lower sensitivity against oscillations and disturbances in the reactant feed, corresponding to a higher operational safety. Due to excellent heat transfer characteristics, the fluidized bed membrane reactor concept is very promising for maximizing the yield of the desired intermediates also in large-scale plants, especially for strongly exothermic reactions [26].

Oxidative dehydrogenation of ethane to ethylene in a large-scale multi-tubular reactor has been analyzed. The results suggest that the reactor operation would be feasible, provided that high heat transfer areas per unit volume and low to moderate oxygen partial pressures are maintained. Egg-shell-type catalysts lead to a feasible operation through the moderation of the heat generation rate. Although operation with spherical catalyst pellets is realistic, the introduction of catalyst geometries providing higher bed void fractions (e.g., hollow cylinders) would lead to a minimization of the pressure drop and would allow the processing of higher gas flow-rates, leading consequently to increased ethylene production rates. Low operation pressures, a few bars over atmospheric, should be selected resulting from a compromise between an increase in gas density to satisfy both pressure drop and productivity constraints and the drop of selectivity with the increase in pressure. The oxygen distribution along the reactor axial coordinate has a positive impact on the reactor

performance due to an improvement in the selectivity based on the operation with lower oxygen partial pressures. A membrane reactor for the continuous axial feed of oxygen is currently under study for the ODH of ethane to ethylene over Ni-based mixed oxide catalysts [27].

## 2.2. Kinetics modeling

Short-chain olefin have been produced from several reactions such as cracking and oxidative dehydrogenation (ODH). Kinetics of these reactions were investigated in literature to determine the reaction networks and reaction mechanisms. For example, propane on  $\text{VO}_x/\text{ZrO}_2$  catalysts kinetic were studied using isotopic tracer, and elementary reaction steps were successfully determinate [28]. A similar study used the same techniques to study elementary steps and their reversibility in the oxidative dehydrogenation of propane over  $\text{ZrO}_2$ -supported  $\text{MoO}_x$  catalysts [29]. Study showed that propane is the major product and  $\text{CO}_x$  gases were produced by secondary combustion of propane.  $\text{C}_4$  hydrocarbons ODH reaction over  $\text{VMgO}$  catalyst investigated and its kinetics were studied, using intermediate products reaction network proposed. Catalyst showed significant activity in absence of oxygen[30]. Kinetic and isotopic tracer and exchange measurements were used to determine elementary steps of ethane ODH over vanadium oxide catalyst. The study suggested that oxygen, OH groups, and oxygen vacancies are the most reactive species during ethane ODH. Furthermore ethane ODH over  $\text{MoO}_3/\text{Al}_2\text{O}_3$  kinetics studied using in-situ FTIR to determine role of the support as well as selective and unselective pathways of the ODH [31]. Mars-Van Krevelen mechanism and Langmuir-Hinshelwood equations were used to investigate reaction networks of ethane ODH over  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3$  catalyst [32]. Eley-Rideal steady-state mechanism was applied to ODH reaction of ethane

and propane over vanadia-silica catalyst doped by potassium. It was shown that taking into account water adsorption on catalyst surface makes the increases model accuracy [33]. Ethane ODH kinetics over Ni–Nb–O mixed oxides kinetics were studied [34]. Study considered Mars–Van Krevelen mechanism and the kinetic model was able to successfully predict the catalytic performance. Temperature-programmed reaction (TP-reaction) was used to study reaction pathways of oxidative and non-oxidative dehydrogenation of ethane over  $\text{MoO}_3/\gamma\text{-Al}_2\text{O}_3$  [35]. It was found  $\text{Al}_2\text{O}_3$  enhance the unselective oxidation of ethane to carbon oxides, and  $\text{MoO}_3$  phase is involved in the selective oxidative dehydrogenation (ODH) of ethane to ethylene and over-oxidation of ethylene to  $\text{CO}_x$ . Vanadium oxide supported on silica (SBA-15) was used for a kinetic study of the ODH of propane in a fixed bed reactor[36]. Moreover, partial oxidation of ethane to ethylene and acetic acid over MoV investigated using two-site Eley-Rideal-Redox (ERR) model which predicted experimental data with good accuracy [37].

Only a few studies investigated ODH reaction in oxygen-free environment. It was reported that ODH reactions can occurs in oxygen-free environment and oxygen could be provided by the catalyst lattice[38]. Furthermore a kinetic model that can be applied using oxygen and oxygen-free environment presented to describe partial oxidation of n-butane to maleic anhydride [39,40]. The proposed kinetic model assumes that there are three sources of oxygen; adsorbed oxygen, surface lattice oxygen and subsurface lattice oxygen. Moreover the degree of catalyst oxidation was taken into account. It was found that lattice oxygen has the major effect on selective oxidation and adsorbed oxygen lead to non-selective oxidation. Propane ODH in oxygen-free environment investigated [41,42],

however there are no reported studies on kinetic of propane ODH in oxygen free environment.

There are several studies on ODH catalysts, there are a few studied that deal with light olefin ODH in dense fluidized beds, using riser or downer reactors. Moreover the majority of these studies in “dense fluidized beds” have been limited to butane ODH [43,44].

The motivation to use the fluidized-bed conditions that it is close to isothermal conditions, in contrast with Fixed-bed reactor which operates at non-isothermal conditions and that may damage the catalyst. Additionally, catalyst has better performance in fluidized conditions in ODH reaction of short-chain hydrocarbons and that bring us to investigate ODH reaction kinetics in such conditions especially ethane ODH to ethylene. The kinetic study of ethane ODH reaction over  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3$  catalyst is reported [45], using CREC-riser simulator in absence of oxygen feed. Langmuir-Hinshelwood rate expression was used and degree of catalyst oxidation also considered. Model gives good results which in agreement with experimental data.

### **2.3. Optimization of ethane ODH reaction**

Catalyst properties and reaction mechanism are used in the area of reaction conditions modeling and optimization. A representative model should be developed describing what is actually happening during the reaction under study as well as the reactor. Some of these reactors as well as reaction conditions are modeled and optimized in literature, for examples fixed-bed multi-tubular reactor system for ODH of ethane is modeled by examining a variety of parameters affecting reactor performance [46]. Multi-

tubular reactor system which is being used to model ODH reaction of ethane in an industrial-scale reactor for ethylene production was modeled to test a variety of parameters affecting reactor performance. The model showed that a double-bed multi-tubular reactor with intermediate air injection scheme was better than a single-bed design. That is because of the increased ethylene selectivity while operating under lower oxygen partial pressures. The optimized reactor length for 100% oxygen conversion was theoretically determined for both reactor designs. Distributed oxygen feed with a limited number of injection points showed an important improvement on the reactor performance in terms of ethane conversion and ethylene selectivity. This concept also enhances the reactor runaway temperature problem, and enabled operations over a wider range of conditions to obtain enhanced ethylene production.

Another modeling work done considering fluidized bed reactor for the oxidative dehydrogenation of ethylbenzene to styrene[47]. A dynamical model is proposed for a fluidized bed catalytic reactor for the production of styrene by oxidative dehydrogenation of ethylbenzene. The static and dynamic bifurcation of the reactor model conducted, it showed that the reactor is to be operated in a multiplicity region in order to yield a maximum production rate of styrene. Ethylene yield also optimized in oxidative coupling of methane over Li/MgO catalyst [48], the central composite design and the response surface method was effective to estimate the optimum C<sub>2</sub>H<sub>4</sub> yield for OCM over Li/MgO (Li/Mg = 0.1). A second order polynomial equation models were developed to estimate the values of C<sub>2</sub>H<sub>4</sub> yield, C<sub>2</sub>H<sub>4</sub> selectivity and CH<sub>4</sub> conversion by utilizing the experimental data. Neural network modeling method used to model the effect of oxygenate additives on the performance Pt-Sn/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalyst in propane dehydrogenation[49]. The

dehydrogenation reaction carried out in fixed bed quartz reactor, steady reports modeling were performed in three different levels of oxygenate additives, and the results gave the optimum amounts of water and ethanol for the reaction.

Regarding oxidative dehydrogenation of ethane to ethylene in fluidized bed reactor, literature review revealed that there are only few studies were focused on the fluidized bed systems. It is required to investigate this case study and to model the reaction to optimize ethylene yield. On the other hand in this study a mathematical model is developed based on temperature programmed reduction characterization technique. The objective is to correlate catalyst properties (metal loading, oxygen carrying capacity) to its performance during oxidation reaction. The model explicitly is a function of temperature and implicitly is a function of metal loading and other catalyst properties.

## **2.4. Conclusion of literature review**

ODH of ethane is a very promising alternative technology for ethylene production. The exothermic nature of the ODH reactions requires less energy as compared to the cracking process. It is economically attractive given it uses comparatively cheaper natural/refinery gas as feed stock. There are significant number of articles available in the open literature dealing with various aspects of ODH of ethane. Followings are the main observations based on the literature review as presented in this Chapter 2:

- Developing a suitable catalyst still a challenge for commercial scale application of ODH of ethane to ethylene. Only few catalysts reported in the open literature show good ethylene selectivity which drastically decreases with increasing ethane

conversion. Complete oxidation of ethane/ethylene to  $\text{CO}_x$  is mainly responsible for decreasing ethylene selectivity.

- Most of the catalysts are mixed metal oxides with low metal dispersion. The metal-support interaction plays a major role in ethylene selectivity.
- The present research group investigated the novel gas phase oxygen free ODH of ethane to ethylene using a fluidized bed system. This process shows encouraging ethylene selectivity at high ethane conversion. The complete oxidation is significantly decreased due to the unavailability of oxygen in the gas phase.
- There are only a few reported studies presented phenomenological kinetic modeling ODH of ethane, especially in the fluidized bed conditions.
- Only few studies reported the optimization of the ODH process.

Table 2.1. Summary of literature review

Topic	Author	Selectivity ,yield and conversion %	Notes
Ferrous and its oxides	Miller et al 2002	S=65% c=56%	A mixture of $\text{FePO}_4$ and $\text{Fe}_2\text{P}_2\text{O}_7$
Mo and oxides + (zr, v ,ti) promoter phosphorous support	I. Lisi et al 2005 and haddad et al 2007	S= 90% c= 20%	At 560°C when vanadium added as promoter
$\text{MoO}_x$	haddad et al , 2009	S=less than in mo based catalyst	Vanadium and phosphorous added to enhance the performance
$\text{VO}_x/ \gamma\text{-Al}_2\text{O}_3$	Sameer et al 2012	27.6% conversion and 57.6–84.5% selectivity	Metal–support interactions and as a result, a well dispersed $\text{VO}_x$ ,500-600°C
Ni-o +(la ,nd and gd )	Qin et al 2013	S =51% c=56 %	375°C using sol-gel method
$\text{VO}_x\text{-MoO}_x/ \gamma\text{-Al}_2\text{O}_3$	Bakare et al 2014	S=80% c=24 %	$\text{MoO}_x$ improved $\text{VO}_x$ isolation

Optimization of propane dehydrogenation over $\text{Pt-Sn}/\gamma\text{-Al}_2\text{O}_3$	Mitra et al 2006	-	Neural network modeling method used

## CHAPTER 3

### OBJECTIVES

#### 3.1 Major objectives

- I. Development of a highly active fluidizable VO<sub>x</sub>-based catalyst suitable for oxidative dehydrogenation (ODH) of ethane to ethylene in a gas phase oxygen free reaction conditions. In this regard a ZrO<sub>2</sub> modified  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> is used as support.
- II. Establishment of phenomenological based kinetics model to describe the kinetics of ODH ethane using the developed VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst.
- III. Optimization ODH of ethane reaction conditions to maximize ethylene selectivity and to minimize CO<sub>2</sub> formation.

#### 3.2 Specific objectives

- i. To investigate the effects of ZrO<sub>2</sub> modification on the activity and stability of VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts at various  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> ratios and constant VO<sub>x</sub> loading.
- ii. To optimize the VO<sub>x</sub> loading on ZrO<sub>2</sub> modified  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> supports.
- iii. To characterize the catalysts using different techniques such as XRD, N<sub>2</sub> adsorption, FTIR, Raman, NH<sub>3</sub>-TPD and TPR/TPO to understand the physiochemical properties of the catalysts and their stability.

- iv. To evaluate the performances (ODH of ethane to ethylene) of the  $\text{VO}_x/\gamma\text{Al}_2\text{O}_3\text{-ZrO}_2$  catalysts in a fluidized CREC Riser Simulator under different reaction conditions as expected in a large scale ODH unit.
- v. To construct the reaction network based on experimental data, to develop the reaction mechanisms and to formulate phenomenological based kinetic model for the fluidized ODH of ethane to ethylene using  $\text{VO}_x/\gamma\text{Al}_2\text{O}_3\text{-ZrO}_2$ .
- vi. To optimize the reaction conditions based on ODH of ethane data in the CREC Riser Simulator, kinetic model and reduction model. The objective functions are formulated using GAMS software and evaluated by utilizing nonlinear programs solver CONOPT.

## CHAPTER 4

### EXPERIMENTAL METHODS

#### 4.1. Catalyst synthesis

Impregnation by soaking (excess of solvent) technique was used to prepare catalyst samples [40]. Before metal loading, the support alumina was calcinated under pure N<sub>2</sub> flow at 500 °C for 4 hours to remove moisture and volatile compounds. The calcined sample was placed in a beaker and toluene was added. Zirconium tetra-chloride was then added to the beaker and the mixture was left under stirring for 12 h. The sample was filtered from the solvent and dried under ambient conditions. After complete drying, the sample was calcinated again at 500°C for 5 hours also to remove the solvent. Three support samples prepared with different  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> to ZrO<sub>2</sub> weight ratios (2:1, 1:1 and 1:2).

Two sets of sample were prepared using impregnation. In the first set of samples, V loading was kept at 15 wt% on the above three ZrO<sub>2</sub> modified samples. The second set of samples were prepared by successive impregnation to load 5%, 10% and 15% on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> = 1:1. Vanadyl acetylacetonate V(AcAc)<sub>3</sub> (Aldrich, 97%) was used as vanadium precursor. The V loading was also accomplished by the same approach as Zr loading. The Zr modified Al<sub>2</sub>O<sub>3</sub> support and ZrCl<sub>2</sub> was added to a beaker containing toluene. The mixture was stirred for 24 hours to obtain homogenous mixture which facilitate better metal dispersion. The solid sample was separated by vacuum filtration and dried at ambient temperature. The dried sample was then reduced by hydrogen (10% H<sub>2</sub>

and 90% Ar) at 500 °C in a fluidized bed reactor. Finally, the reduced sample was calcined under air at 500 °C for 4h the oxide form of the catalyst was obtained. After this treatment catalyst color became yellow indicating the presence of V<sub>2</sub>O<sub>5</sub> on support surface.

## **4.2. Catalyst characterization**

### **4.2.1. X-Ray Fluorescence (XRF)**

XRF analysis was used to determine elements and compounds ratios in each sample. A Bruker Tornado M4 micro-ed XRF analyzer, equipped with a single high performance XFlash detector and 25 µm diameter spot size, employed for XRF analysis.

### **4.2.2. BET surface area**

The nitrogen adsorption and BET surface area of the VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst samples was determined in a Quantachrome ASIQwin. The nitrogen adsorption was carried out at 77 K. For each experiment, 0.4–0.50 g of catalyst sample degassed at 350 °C for 2h. The adsorption isotherms were measured in the 0.04 to 1 relative pressure range.

### **4.2.3. X-ray diffraction (XRD)**

X-ray diffraction (XRD) analysis was conducted to identify the crystallographic structure of catalyst samples. XRD patterns of all catalysts reported in this study were recorded on a Rigaku MiniFlex Diffractometer with monochromatic Cu K $\alpha$  radiation ( $\lambda$  = 0.15406 nm, 30 kV, 15 mA) using the normal scan rate of 4°/min. X-rays were collected using a 1.25° divergent scattering slit, and a 0.13 mm receiving slit. Samples were scanned within the 2 $\theta$  range of 20–80° with a step size of 0.005°.

#### **4.2.4. Temperature programmed reduction-oxidation (TPR/TPO)**

(TPR/TPO) experiment were conducted using AutoChemII ASAP 2920 analyzer as shown in Figure 4.1. The purposes of TPR/TPO cycles are to determine catalyst activity temperature ranges, maximum activity temperature and catalyst stability during reduction-oxidation cycles. Its reported that during reduction/oxidation at high temperature vanadium dispersion changes[23] and that changes VO<sub>x</sub> phases on support surface [24] , and that affects the catalyst activity[25].

At the beginning of the experiment Argon (99.9%) introduced at rate of 50 ml/min while temperature increased to 300 °C for period of 3 hours. temperature cooled to ambient and H<sub>2</sub> Argon gas mixture (10% H<sub>2</sub> ) circulated to reduce the sample at rete of 50 ml/min and temperature elevated to 750 °C at heating rate of 10 °C/min, meanwhile H<sub>2</sub> concentration measured using thermal conductivity detector (TCD) and the signal later calibrated to volume of H<sub>2</sub> consumed cc/g catalyst . Plot of H<sub>2</sub> volume versus time and temperature obtained and total H<sub>2</sub> volume consumed obtained by numerical integration.

#### **4.2.5. Temperature programmed desorption (TPD)**

The purposes of NH<sub>3</sub>-TPD test was to determine catalyst total acidity. The metal–support interactions were also evaluated by TPD kinetics analysis. Furthermore, NH<sub>3</sub>-TPD was utilized to determine the quantity and strength of acid sites available on the surface of the prepared catalyst samples. NH<sub>3</sub>-TPD experiments were conducted using a Micromeritics AutoChem II 2029 analyzer. The catalyst sample (0.15-0.20 g) was placed in a U-shaped quartz container and degassed for 2 h at 300 °C in a flow of helium at 30 ml/min. The samples were then cooled to 120 °C and brought to saturation with ammonia using a NH<sub>3</sub>/He gas mixture (5% NH<sub>3</sub>/He) for one hour at

a rate of 50 ml/min. After that, the ammonia flow was stopped, and replaced by a He purge gas, fed at the rate of 50 ml/min. This was done for 1 h at 120 °C to remove the physically adsorbed ammonia. Following this step, the temperature was raised up to 500 °C at different heating rates (10, 20 and 30 °C/min). As the temperature was increased, ammonia desorbed as it gained enough energy to overcome the activation energy barrier.

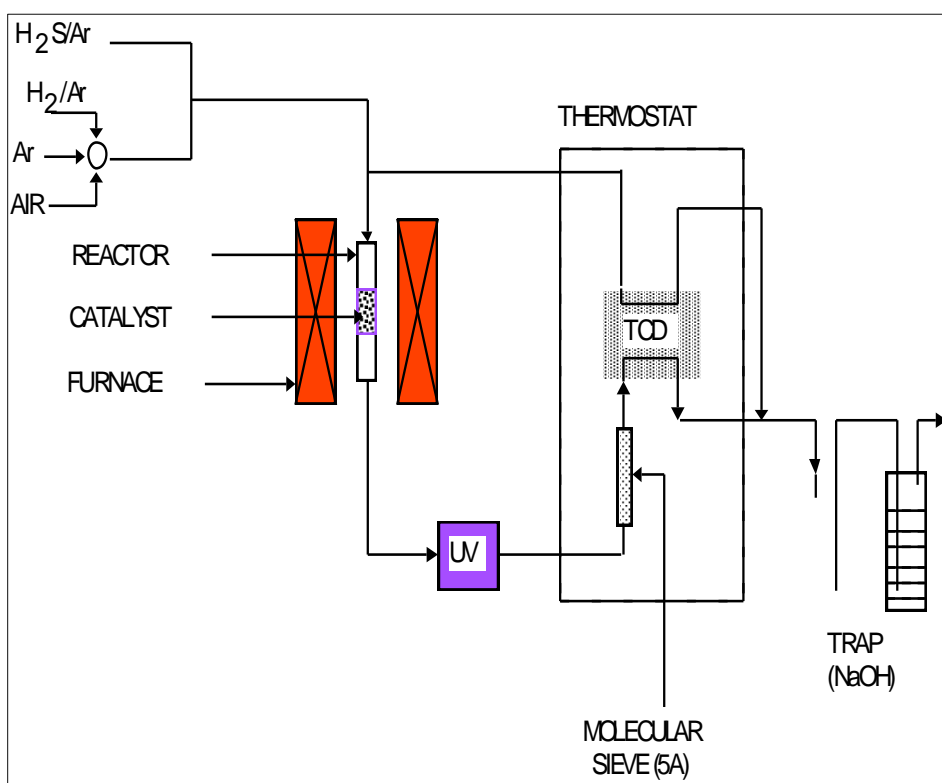

Figure 4.1. Schematic diagram of AutoChemII ASAP 2920 analyzer for TPR test

#### **4.2.6. Scanning electron microscopy (SEM)**

Shape and morphology of the active metals phases were examined by SEM (Tescan Lyra-3) with high performance focused ion beam (FIB) at various magnifications (up to 500 kx) using 20 kv voltage. For SEM analysis the samples were prepared by 5 nm Au coating.

#### **4.2.7. Raman spectroscopy**

The Raman spectra were collected using Yvon Jobin equipment with a cooled iHR320 Horiba spectrometer with CCD detector that removes the elastic laser scattering, laser source is green type at 532 nm and laser intensity of 50%, with 96 slit width and 50 to 2500 spectrum window. The samples were maintained in powder form to minimize mass transfer limitations and ensure that all catalytic material in the cell is exposed to the flowing gases.

#### **4.2.8. Fourier transform infrared spectroscopy (FTIR)**

FTIR spectroscopy of prepared samples was recorded using Nicolet 6700 Thermo Fischer Scientific instrument. For each experiment 3 mg of powdered samples were mixed thoroughly with 400 mg KBr. Thereafter, infrared spectra of pelletized samples were collected in the range  $400\text{ cm}^{-1}$  to  $4000\text{ cm}^{-1}$ .

### **4.3. Catalyst evaluation in fluidized CREC riser simulator**

#### **4.3.1. Reactor set-up**

The reactivity and the stability of the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst samples were tested using the CREC riser simulator [Figure 4.2a](#) [19]. The batch reactor with a capacity of  $53\text{ cm}^3$ , has been designed for catalyst evaluation and kinetic studies under fluidized bed

reactor conditions. The major components of the CREC riser simulator is shown in [Figure 4.2a](#) which includes a vacuum box, series of sampling valves, a timer, two pressure transducers and three temperature controllers. The product gas was analyzed by gas chromatography (GC) with thermal conductivity detector (TCD) and a flame ionization detector (FID).

#### **4.3.2. Fluidized bed ODH of ethane experimental runs**

The ODH of ethane to ethylene experiments were conducted at various temperatures and contact times. The selected temperature should be consistent to the reduction temperature of the catalysts as observed in the TPR analysis. In a typical run, 0.4 g of oxidized catalyst sample was loaded in the reactor basket and leak test was conducted. Following the leak test, the system was purged by flowing argon. The temperature program was started to heat the reactor to the desired temperature. The argon flow was maintained to keep the reactor from any interference of gas phase oxygen. Once the reactor temperature reached to the desired temperature, the argon flow was discontinued. The reactor isolation valve was closed when it reached the desired pressure level.

The vacuum pump was started to evacuate the vacuum box until it reached 20.7 kPa (3.75 psi). The catalyst was fluidized by rotating the impeller. At this point, feed ethane was injected into the reactor by using preloaded gas tight syringe. The reaction continues for a pre-specified time. At termination point, the isolation valve between the

Figure 4.2. (a) Schematic diagram of the CREC riser simulator experimental set-up (b) Overview of the CREC riser simulator reactor body.

reactor and vacuum box opened automatically and transferred all the reactant and products into the vacuum box. The gas samples in the vacuum bottle were analyzed using an Agilent 7890A GC equipped with both a TCD and a FID detector. For each catalytic run, the product samples were analyzed three times to ensure the accuracy of the analysis. Finally, the product analysis data were used to calculate conversion and selectivity of

various products. The following definitions were used in calculating the conversion and selectivity, respectively:

$$\text{Conversion of ethane} = \frac{\text{Moles of ethane converted}}{\text{Moles of ethane fed}} \times 100 \% \quad (4.1)$$

$$\text{Selectivity of product i} = \frac{\text{Moles of product i}}{\text{Total moles of products} - \text{Moles of i}} \times 100 \% \quad (4.2)$$

## CHAPTER 5

### RESULTS AND DISCUSSION - EFFECTS OF ZrO<sub>2</sub>

This chapter presents the effects of ZrO<sub>2</sub> modification on VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts. The support γ-Al<sub>2</sub>O<sub>3</sub> was modified using different amount of ZrO<sub>2</sub>. The VO<sub>x</sub> was then dispersed on the ZrO<sub>2</sub> modified γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> supports. It is hypothesized that the addition of ZrO<sub>2</sub> alters the surface acidity and the metal-support interaction which has significant influence on the ethylene selectivity [12]. The effects of ZrO<sub>2</sub> modification was assessed by different characterization techniques such as XRF, XRD TPR/TPO, TPD and Raman. The metal support interaction was demonstrated by NH<sub>3</sub> desorption kinetics analysis. The catalysts were evaluated in a fluidized CREC riser simulator at various reaction conditions as expected in a large scale ODH reactors using ethane as a feed.

#### 5.1. Catalyst characterization

##### 5.1.1. XRF and nitrogen adsorption/desorption analysis

XRF analysis was used to quantify sample compositions after synthesis. XRF results are shown in [Table 5.1](#) which indicates compound percentages are equal to what was targeted with slight deviation. The nitrogen isotherm analysis was conducted to understand the adsorption/desorption characteristics of the catalyst sample. The isotherm data was further processed to determine the BET surface of ZrO<sub>2</sub> modified VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> sample. [Figure 5.1](#) shows the adsorption/desorption isotherms of a ZrO<sub>2</sub> modified VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> sample synthesized for this study. The sample shows a Type-V

isotherm indicating narrow size mesoporosity [22]. The calculated BET surface area and monolayer volume are presented in Table 5.1. The BET surface area of the ZrO<sub>2</sub> modified sample is lower than the surface of the bare  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> support (141 m<sup>2</sup>/g). The dispersed ZrO<sub>2</sub> and the vanadium species occupied the support pores, which contributed to the decrease of the surface area. The monolayer volume of the adsorbed nitrogen can be calculated by Equation 5.1

$$n_m = \frac{S_{BET}}{A_m \times N} \quad (5.1)$$

Figure 5.1. N<sub>2</sub> adsorption/desorption isotherms of 15% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) catalyst sample

where,  $S_{BET}$  is the BET surface area m<sup>2</sup>,  $N$  represents Avogadro's constant and molecule/mol,  $A_m$  stands for the volume occupied by one N<sub>2</sub> gas molecule (0.162 m<sup>2</sup>), and  $n_m$  denotes the monolayer volume per gram catalyst. The monolayer coverage occurs after 0.75 relative pressure indicates good dispersion of active sites and their availability for

adsorption. This was expected as the catalyst was synthesized by soaking impregnation which provided good metal dispersion and thus, a satisfactory monolayer volume.

Table 5.1. XRF<sup>a</sup> and BET surface area characterization results

Sample	VO <sub>x</sub> %	Al <sub>2</sub> O <sub>3</sub> %	ZrO <sub>2</sub> %	BET surface area (m <sup>2</sup> /g.cat)	Monolayer volume (cm <sup>3</sup> /g)
15% VO <sub>x</sub> /Al <sub>2</sub> O <sub>3</sub> -ZrO <sub>2</sub> (2:1)	14.4	57.2	28.4	24.17	2.47 × 10 <sup>-4</sup>

<sup>a</sup> Catalyst elements percentages are within ±2% accuracy

### 5.1.2. X-ray diffraction (XRD)

Figure 5.2 shows the XRD patterns of the various  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> containing support samples and the VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst after VO<sub>x</sub> loading. The V<sub>2</sub>O<sub>5</sub> was detected in the range of 2 $\theta$  from 10 to 40° are relevant to V<sub>2</sub>O<sub>5</sub>[26]. T-ZrO<sub>2</sub> peaks can also be found at 2 $\theta$  of 30°, 48° and 65° while  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> peaks appeared at 2 $\theta$  of 45° and 60°. One can see in Figure 5.3 that the V<sub>2</sub>O<sub>5</sub> peak intensity was sharply decreased with decreasing the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> to ZrO<sub>2</sub> ratios (increasing in ZrO<sub>2</sub> contents). Only VO<sub>2</sub> was obtained on the support surface, which resulted in lower oxygen-carrying capacity and therefore lower catalyst activity. Furthermore, ZrO<sub>2</sub> introduced a crystal phase to the catalyst, in comparison with the catalyst sample without ZrO<sub>2</sub> [19].

Increasing ZrO<sub>2</sub> contents reduced V<sub>2</sub>O<sub>5</sub> peaks sharpness in samples with (2:1) and (1:1)  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> to ZrO<sub>2</sub> weight ratio, and further increasing ZrO<sub>2</sub> content in Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:2) sample only VO<sub>2</sub> was obtained on support surface which results in lower oxygen carrying capacity and therefore catalyst activity. Furthermore ZrO<sub>2</sub> introduced crystal phase to the catalyst in comparison with catalyst sample without ZrO<sub>2</sub> [19], this crystal phase is not

Figure 5.2. XRD patterns of Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> with various ZrO<sub>2</sub> ratios and 15% VO<sub>x</sub>/ Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1)

detected by XRD and may reduce oxygen carrying capacity and catalyst activity by enhancing active site agglomeration.

### 5.1.3. Reducibility and oxygen carrying capacity

TPR/TPO characterization is an important technique for oxygen free ODH because it simulates the actual ODH reaction as compared in [Equation 5.2 and 5.3](#).

Reduction of catalyst during TPR,

Reduction of catalyst during gas phase oxygen free ODH of ethane

One can easily see that both in the ODH of ethane and in the TPR with hydrogen, the gaseous reactant reduces the  $V_2O_5$  into  $V_2O_3$ . Consequently, the TPR evaluation of the catalyst sample clearly indicates the activity (reactivity) of the catalyst at various temperature ranges. The TPR/TPO test also determines the oxygen-carrying capacity and the redox properties of the catalysts. The oxygen-carrying capacity eventually determines the circulation rate of the catalyst between the ODH reactor and the catalyst regenerator.

Figure 5.3 a and b shows the TPR profiles and  $H_2$  consumption for different  $ZrO_2$  containing catalyst samples. In all catalysts, the V loading maintained at 15 wt% of the catalyst. Presence of 3 peaks indicates that the reduction proceeds in several steps [49,53]. Introduction of  $ZrO_2$  reduced support surface acidity and that enhance the formation of isolated mono-vanadate species on support surface [54,55]. During vanadium oxide reduction, oxygen vacancies are formed at the surface. As the reduction proceeds, the concentration of these vacancies gradually decreases. They aggregate and part of vanadium oxide edges may shear producing a new structure (non-isolated species). This may also occur, as a result of increasing the vanadium loading [51].

TPR results may also point to the catalyst oxygen-carrying capacity and the oxygen releasing rate. This is the case, since the oxygen-carrying capacity of the catalyst can be determined according to Equation 5.1 (two moles of hydrogen reduce one mole of oxygen). Figure 5.3b shows the histogram plots of hydrogen consumption at different  $Al_2O_3$  to  $ZrO_2$  ratios with same 15%  $VO_x$ . It appears that the hydrogen consumptions were comparable between the catalyst samples containing  $\gamma-Al_2O_3/ZrO_2$  ratios of 2 to 1 and 1 to 1. The catalyst reducibility was significantly decreased with 1:2  $\gamma-Al_2O_3/ZrO_2$ : 1:2 ratio (Figure 5.3 a and b).

Figure 5.3. (a)TPR profile for catalyst  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  with various  $\text{ZrO}_2$  loading (b)  $\text{H}_2$  consumption versus  $\text{ZrO}_2$  ratio

The repeated TPR/TPO experiments were conducted to confirm catalyst reducibility and reoxidation ability in the multiple cycles. This also indicates any possibility of thermal sintering in the high temperature redox cycles. The  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (2:1) sample was selected due to its high oxygen-carrying capacity as revealed in

hydrogen consumption analysis. [Figure 5.4](#) shows the TPR profiles of the VO<sub>x</sub>/ γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) sample under repeated TPR/TPO cycles. One can see that the TPR profiles remained almost unchanged after first cycle. The decomposition of the residual metal precursors possibly contributed to the first cycle. Once they were removed, the hydrogen consumption of the sample became stable over the repeated TPR/TPO cycles. Calcination temperature directly affected redox properties, since in this scenario, all samples were calcinated at same temperature. Only composition of ZrO<sub>2</sub> affected the reduction and oxidation ability, as well as new surface species such as polyvanadate. It can be formed during the reduction cycle, when oxygen vacancies are created [51]. In reduced sample, γ-Al<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub> remain in their original phases after reduction and that can be interpreted as good thermal stability[24]. Reduced vanadium over redox cycles was calculated as in [Equation 5.4](#).

$$\text{fraction reduced (f)\%} = \frac{M_{w_v} \times V_{H_2}}{v \times V_g \times W_o} \times 100\% \quad (5.4)$$

where, W<sub>v</sub> is the amount of reduced vanadium (g), M<sub>w<sub>v</sub></sub> is the molecular weight of vanadium (g/mol), V<sub>H<sub>2</sub></sub> is the volume of reacted hydrogen (cm<sup>3</sup> at STP), V<sub>g</sub> is the molar volume of gas (mol/cm<sup>3</sup> at STP), W<sub>o</sub> is initial weigh of vanadium and v is the stoichiometric number of hydrogen based on the following reaction stoichiometry. Assuming that V<sub>2</sub>O<sub>5</sub> is the initial reducible catalyst species present on the support [19], V<sub>2</sub>O<sub>5</sub> reduction percentages was found to be 59% for first cycle and 57.7% for the following cycles remain almost constant. In reduced sample, γ-Al<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub> remain in their original phases after reduction and that can be interpreted as good thermal stability[24]. Reduced vanadium over redox cycles was calculated as in [Equation 5.5](#).

$$\text{Fraction reduced (f)\%} = \frac{M_{w_v} \times V_{H_2}}{v \times V_g \times W_o} \times 100\% \quad (5.5)$$

where,  $W_v$  is the amount of reduced vanadium (g),  $M_{w_v}$  represents the molecular weight of vanadium (g/mol),  $V_{H_2}$  stands for the volume of reacted hydrogen ( $\text{cm}^3$  at STP),  $V_g$  denotes the molar volume of gas ( $\text{mol}/\text{cm}^3$  at STP),  $W_o$  is initial weight of vanadium and  $v$  represents the stoichiometric number of hydrogen of the  $\text{VO}_x$  reduction reaction ( $\text{H}_2 + \text{VO}_x = \text{H}_2\text{O} + \text{V}_2\text{O}_3$ ). Assuming that  $\text{V}_2\text{O}_5$  is the initial reducible catalyst species present on the support [19],  $\text{V}_2\text{O}_5$  reduction percentages was found to be 59% for first cycle and 57.7% for the following cycles remain almost constant.

Figure 5.4. TPR /TPO cycles of 15%  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  (2:1) catalyst

#### 5.1.4. Scanning electron microscopy (SEM)

SEM characterization was conducted to investigate the size and the shape of the metal crystals of the catalyst before and after reduction in TPR. Figure 5.5a shows SEM images with magnification of 50 kx of fresh samples of  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  (2:1) catalyst which calcinated at 500 °C. The images reveals that impregnation of vanadium oxide resulted in non-uniform size and shape particles. The pH of the impregnation solution and

support surface affects the nature of vanadium oxide on the support,  $\text{Al}_2\text{O}_3$  has Surface pH of 8.9 which will results in polyvanadate formation (V-O-V bond ) but thermal treatment converts polyvnadate into monovanadate[54]. Therefore, the fresh sample has isolated and bulk phase  $\text{VO}_x$  as indicated by XRD peaks. This observation is consistant to the literature for  $\text{VO}_x$  species to by pure isoladed, peaks in XRD pattern will disappear[19]. [Figure 5.5b](#) shows SEM images for the reduced samples of  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (2:1), which reduced at 500 °C under  $\text{H}_2$  flow. Since there are many form of  $\text{VO}_x$  can appear on support surface , such as  $\text{V}_2\text{O}_5$  and  $\text{VO}_2$ , these reduced oxides are mostly present in crystalline and agglomorated form due to lake of oxygen and will be oxidized again in regeneration process.

Reduction of samples at 500 °C did not affect alumina and zirconia phases, however slight weight loss migh occure,  $\gamma$ -alumina tends to transfer into  $\theta$ -alumina when temperature rises to 700 °C and that will results in loss of surface area. Therefore the support can be considered stable similar results were concluded in literature [57]. The major change happens after reduction on the support surface and it is reversable .

Figure 5.5. SEM images of 15% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) (a) Fresh sample (b) Reduced sample

### 5.1.5. Acidity and metal-support interaction

NH<sub>3</sub>-TPD was conducted to determine the catalyst acidity and its strength. Catalyst acidity affects metal-support interactions. Ammonia was used in TPD analysis due to its strong basicity and small molecular size. Furthermore, ammonia allows to determine the total acidity and strength of acid sites, for wide range of temperatures. For all samples, ammonia was firstly adsorbed at 120 °C and desorbed in a temperature range from 120 to 500 °C. Following this, the sample was heated at a heating rate of 10 °C/min and the desorbed concentration of ammonia was recorded using a TCD detector. [Figure 5.6](#) shows the NH<sub>3</sub>-TPD profiles of catalyst samples with various Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> ratios. ZrO<sub>2</sub> affect metal-support interaction specially at low and intermediate metal loading[55]. One can see from [Figure 5.6](#) that desorption profiles of the samples have not significantly changed after the ZrO<sub>2</sub> modification.

Total acidity was calculated by calibrating TCD signal to volume of NH<sub>3</sub> desorbed and the area under the curve calculated using numerical integration. Heating rate of 10 °C/min was used and samples weight during TPD test which in all samples was 0.2 g, Equation 5.6 was used to calculate samples total acidity calculations.

$$\text{Total acidity (ml NH}_3\text{/g)} = \frac{a}{w\beta} \quad (5.6)$$

Figure 5.6. NH<sub>3</sub>-TPD profiles of VO<sub>x</sub>/γAl<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> samples various amount of ZrO<sub>2</sub> loading (constant 15 wt% VO<sub>x</sub> loading)

where, (1) a is the area under the curve after TCD signal calibration (ml NH<sub>3</sub> °C/min), (2) w is sample weight and β is the heating rate °C/min. Samples total acidity was found to be in the range between 2 and 6 (mlNH<sub>3</sub>/g.cat). The total acidity was decreased with decreasing the Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> ratios (increasing the ZrO<sub>2</sub> content). Zirconia and metal loading reduces samples acidity by blocking acid sites[57], however samples acidity is almost

constant when metal loading is further increased. This observation indicates that ZrO<sub>2</sub> enhances vanadia species isolation on the surface which created more active sites, since ZrO<sub>2</sub> as mentioned before has lower acidity than alumina[19].

The NH<sub>3</sub>-TPD data was further treated to estimate the desorption kinetics parameters such as desorption energy  $E_{des}$  and frequency factors  $k_{des,0}$ . These kinetic parameters are very important to assess the metal-support interaction. The NH<sub>3</sub>-TPD data can be modeled as described in [37] used to estimate these parameters under the following assumptions;

- i- Homogeneous catalyst surface,  $k_d = (-E_{des}/RT)$ .
- ii- Ammonia doesn't re-adsorb during experiment.
- iii- Uniform adsorbate concentration in the gas flow.
- iv- First order adsorption rate in surface coverage.

A high gas flow rate maintained together with appropriate conditions to satisfy the previous assumptions, and by performing species balances on desorbing NH<sub>3</sub> as and following same steps mention in [24],  $E_{des}$  and  $k_{des,0}$  can be obtained ;

$$r_{des} = -V_m \left( \frac{d\theta_{des}}{dt} \right) = k_{d,0} \theta_{des} \exp \left[ \frac{-E_{des}}{R} \left( \frac{1}{T} - \frac{1}{T_m} \right) \right] \quad (5.6)$$

where,  $\theta_{des}$  is the surface coverage,  $K_d$ ,  $k_d$  are the desorption constant and pre-exponential factor, respectively,  $T_m$  is centering temperature, and by rising the temperature gradually with a constant value  $\beta$  the following equation applies:

$$T = T_o + \beta t \quad (5.7)$$

$$\frac{dT}{dt} = \beta \quad (5.8)$$

$$\left(\frac{d\theta_{des}}{dt}\right) = \left(\frac{d\theta_{des}}{dT}\right) \left(\frac{dT}{dt}\right) = \beta \left(\frac{d\theta_{des}}{dT}\right) \quad (5.9)$$

Equations 5.6 and 5.7 give:

$$\left(\frac{d\theta_{des}}{dt}\right) = \frac{k_{des,0}}{V_m \times \beta} \theta_{des} \exp \left[ \frac{-E_{des}}{R} \left( \frac{1}{T} - \frac{1}{T_m} \right) \right] \quad (5.10)$$

where,

$$\theta_{des} = 1 - \frac{V_{des}}{V_m} \quad (5.11)$$

Combining Equations 5.10 and 5.11 results in

$$\left(\frac{dV_{des}}{dT}\right) = \frac{k_{des,0}}{\beta} \left(1 - \frac{V_{des}}{V_m}\right) \exp \left[ \frac{-E_{des}}{R} \left( \frac{1}{T} - \frac{1}{T_m} \right) \right] \quad (5.12)$$

Equation 5.12 was fitted to experimental data using Mathematica NonlinearModelFit built-in function at heating rate of 10 °C/min for all samples. Ammonia pre-adsorbed at 120 °C and samples weigh was 0.2 g, parameters obtained are shown in Table 5.2.

Table 5.2. Estimated<sup>b</sup> TPD model parameters for catalyst samples at 10 °C/min heating rate

Sample	$K_{des,0}$ (cm <sup>3</sup> /min)	$E_{des}$ kJ/mol	$R^2$	AIC	$V_{des}$ (ml NH <sub>3</sub> /g.cat)
15% VO <sub>x</sub> Al <sub>2</sub> O <sub>3</sub> -ZrO <sub>2</sub> (2:1)	3.9×10 <sup>-6</sup>	75.44±3.5	0.99	-64252	5.87
15% VO <sub>x</sub> Al <sub>2</sub> O <sub>3</sub> -ZrO <sub>2</sub> (1:1)	5.6×10 <sup>-6</sup>	77.88±3.8	0.99	-64055	3.4
15% VO <sub>x</sub> /Al <sub>2</sub> O <sub>3</sub> -ZrO <sub>2</sub> (1:2)	14.9×10 <sup>-6</sup>	80.52±4	0.99	-51751	2.75

<sup>b</sup> Confidence interval was set to be 95%

Coefficient of determination  $R^2$  found to be above 0.99 in all cases which indicates a good regression. Akaike information criterion (AIC) was also used as a measure of the relative

quality of a statistical model to data set, the large negative AIC values indicate goodness of the fitting as can be seen in [Table 5.2](#).

One can see from [Table 5.2](#) activation energies for some samples are higher than bare  $\text{Al}_2\text{O}_3$  and  $\text{VO}_x/\text{Al}_2\text{O}_3$  which indicates stronger interaction between vanadium species and the support [19] which confirm the presence of isolated vanadium oxide species, on the other hand vanadium species interaction may results in formation of  $\text{VO}_2$  [60] which will lead to lowering catalyst  $\text{O}_2$  carrying capacity. On the whole, the intermediate interaction between active sites and supports is favorable. TPD kinetics show increased metal-support interaction, indicated by high desorption energy due to the introduction of  $\text{ZrO}_2$ . Higher metal-support interaction decreases the  $\text{VO}_x$  reducibility. Thus, catalyst activity is consistent with TPR results. Furthermore, decreased catalyst activity can reduce conversion of ethane. However, it is expected to increase ethylene selectivity by controlling  $\text{O}_2$  release.

## **5.2. ODH of ethane in a fluidized CREC Riser Simulator**

The fluidized ODH of ethane experiments were conducted in a CREC-Riser Simulator using pure ethane feed (99.95% ethane). For comparison, all three catalysts ( $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$ ) with different  $\gamma\text{-Al}_2\text{O}_3/\text{ZrO}_2$  ratios (constant 15 %  $\text{VO}_x$  loading) were evaluated under same experimental conditions. The catalyst activity and product selectivity was evaluated using 0.4 g of oxidized catalysts and 2 ml of ethane injection. The product analysis of the preliminary experiments shows that  $\text{C}_2\text{H}_6$ ,  $\text{C}_2\text{H}_4$ ,  $\text{CO}_2$  and  $\text{CO}$  are the major products of the gas phase oxygen free ODH of ethane reaction. Based on this product analysis, one can consider the following possible reactions to be involved under the studied reaction conditions:

**Desired reaction:****Undesired reactions:**

Therefore, the reaction between the catalyst and the feed ethane has to be developed at the reaction conditions maximizing the desired ethylene product selectivity and minimizing complete combustion of  $\text{CO}_x$ . Keeping the above in mind, the temperature during the experiments were varied from 525 to 600 °C, while the contact time was adjusted between 20 and 50 sec. After each ODH run, the catalyst was regenerated by supplied air at 550 °C for 10 min.

In order to demonstrate the effects of  $\text{ZrO}_2$  the conversion and product data are presented as per gram of  $\text{VO}_x$  loading on the  $\text{Al}_2\text{O}_3$ - $\text{ZrO}_2$  support. [Figure 5.7](#) displays the product selectivity at various  $\text{Al}_2\text{O}_3/\text{ZrO}_2$  ratios. All the catalyst samples gives good selectivity to ethylene although the ethane conversion is relatively low. This low conversion was due to the low catalyst/feed ratio used for the evaluation. The ethane conversion further decreased with the increase of the  $\text{ZrO}_2$  content (decreasing  $\gamma$ - $\text{Al}_2\text{O}_3/\text{ZrO}_2$  ratio). This was expected after the TPR analysis of the samples which showed that the oxygen carrying capacity of the samples decreased with the increase of the  $\text{ZrO}_2$  content on the support. Interestingly, ethane selectivity slightly increased between when the  $\gamma$ - $\text{Al}_2\text{O}_3/\text{ZrO}_2$  ratio was decreased form 2:1 to 1:1. At this level up to 90% ethylene selectivity was achieved 600 °C reaction temperature. Further increment of  $\text{ZrO}_2$  decreased

the ethylene selectivity was sharply decreased which is directly related to the scarcity of oxygen in the high ZrO<sub>2</sub> containing sample ( $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> 1:2 to 1:1).

Overall, both the ethane conversion and ethylene selectivity were increased by augmenting the ZrO<sub>2</sub>. This is due to enhanced catalyst activity via the formation of reducible polyvanadates [42, 54]. This agrees with the TPR results. However, at high ZrO<sub>2</sub> content, crystalline VO<sub>x</sub> species are also formed. This results in a decreasing ethane conversion and ethylene selectivity. TPD kinetics also show an increased metal-support interaction due to high desorption energies. This high desorption energies were likely caused by an increased surface heterogeneity, which can favour catalyst ethylene selectivity by controlling the lattice O<sub>2</sub> released [64].

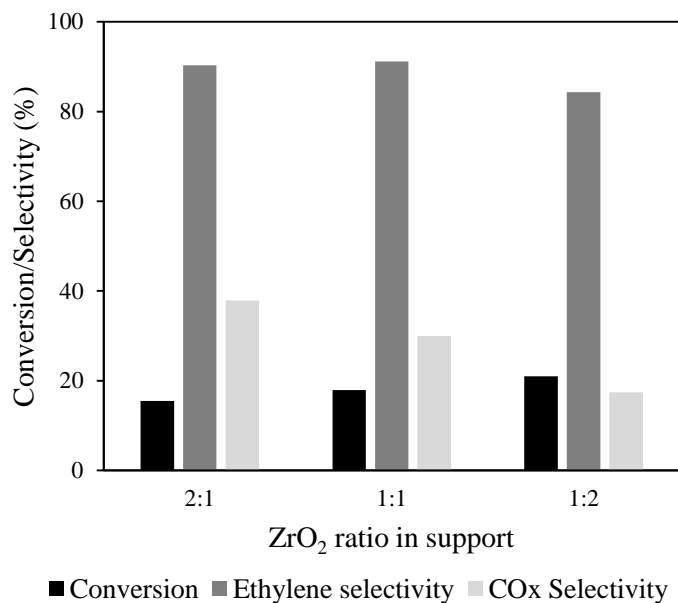

Figure 5.7. Effect of ZrO<sub>2</sub> on C<sub>2</sub>H<sub>6</sub> conversion and product selectivity (per gram of VO<sub>x</sub>, t=40 sec, T=600°C, W=0.4, feed= 1 ml)

Figure 5.8 shows ethane conversion and ethylene selectivity over 3 reduction and oxidation cycles for VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) catalyst sample. Stable performance was

obtained which indicates sample thermal stability and ability to be regenerated. Ethane conversion is shown in Figure 5.9 which becomes high at catalyst activity temperature range and lower outside this region. Sample without  $ZrO_2$  gives higher ethane conversion and the addition of  $ZrO_2$  lowered catalyst conversion by decreasing  $VO_x$  reducibility. Figure 5.9 displays the relationship between ethane conversion and ethylene selectivity with reaction temperature.

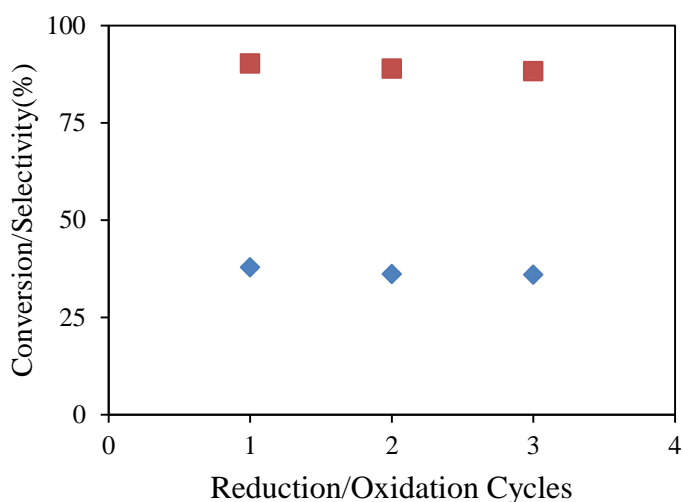

Figure 5.8. Conversion and selectivity over redox cycles for  $VO_x/Al_2O_3-ZrO_2$  (2:1)  
 ■ Ethylene selectivity, ♦ Conversion (per gram  $VO_x$ ,  $t=40$  sec  $T=600$  °C, feed= 1 ml)

It can be seen that as the reaction temperature increases, with the unprompted  $VO_x/\gamma-Al_2O_3$  catalyst the conversion of ethane increased from 13.75 % at 550 °C to 18.80 % at 600 °C. On the contrary, with the  $VO_x/\gamma-Al_2O_3-ZrO_2$ , the ethane conversion was slightly decreased from 13.75 % at 550 °C to 11.45 % at 600 °C.

Figure 5.9. Effect of temperature on C<sub>2</sub>H<sub>6</sub> conversion per gram VO<sub>x</sub> (t=45 sec, feed= 1 ml, ■ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1), ◆Al<sub>2</sub>O<sub>3</sub>)

Figure 5.10 Effect of temperature on product selectivity per gram VO<sub>x</sub> (t=40 sec, feed= 1 ml, ■ethylene  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1), ◆ethylene Al<sub>2</sub>O<sub>3</sub>, x CO<sub>x</sub>  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1), ▲CO<sub>x</sub> Al<sub>2</sub>O<sub>3</sub> (2:1)

Figure 5.10 shows products selectivity per gram VO<sub>x</sub> for VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> and VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) catalyst samples. Ethylene selectivity reaches 90.3 % for VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) catalyst sample and only 42% for VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> sample. This can be attributed to

ZrO<sub>2</sub> effect which enhances metal support interaction as mentioned earlier. Lower V reducibility decrease O<sub>2</sub> availability for combustion reactions which lead to production of CO<sub>2</sub> and CO gases.

Catalyst selectivity to CO<sub>x</sub> gases versus temperature is shown in [Figure 5.10](#). Highest CO<sub>2</sub> selectivity obtained was 44.2% for VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) sample and 15.5% for sample without ZrO<sub>2</sub>. Furthermore, in the sample containing ZrO<sub>2</sub> formation of CO<sub>x</sub> is decreasing with temperature indicating ZrO<sub>2</sub> enhanced catalyst activity and selectivity at high temperature of 600 °C. This agrees with TPR results in [Figure 5.3a](#). On the other hand, VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> sample produces more CO<sub>x</sub> at high temperature due to combustion of produced ethylene.

The time effect is shown in [Figure 5.11](#) for VO<sub>x</sub> on γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:2) and Al<sub>2</sub>O<sub>3</sub> at fixed reaction temperature of 550 °C. For sample without ZrO<sub>2</sub>, combustion effect appears as CO<sub>x</sub> production which is increasing over time. However ZrO<sub>2</sub> addition results in stable reactivity with temperature and time as shown. Combustion reaction leads to CO<sub>x</sub> production, and CO<sub>2</sub> selectivity reaches 50%. In fact also increasing ZrO<sub>2</sub> contents in the support decrease catalyst reducibility which will result in lower conversion.

In general, the introduction of ZrO<sub>2</sub> to the support, enhanced ethylene selectivity and stability. ZrO<sub>2</sub> lowers support total acidity and also reduces Lewis acidity which leads to cracking reactions and CO<sub>x</sub> production as shown in NH<sub>3</sub>-TPD analysis. Similar results were obtained when the SAPO-34 catalyst was used in the ethane ODH reaction, where CH<sub>4</sub> traces were detected, as a result of cracking reactions [6].

Figure 5.11. Effect of time on products selectivity per gram VO<sub>x</sub> loaded on (a) Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (2:1) (b) Al<sub>2</sub>O<sub>3</sub> (t=40 sec, feed= 1 ml, ♦Conversion ■, Ethylene selectivity, ▲CO<sub>x</sub> selectivity)

**Following are the conclusions of the effects of ZrO<sub>2</sub> study:**

- i. Metal loading and stirring for long period reduced the specific surface area due to blockage of support pores.
- ii. XRD indicates the presence of V<sub>2</sub>O<sub>5</sub> and ZrO<sub>2</sub> in the VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts. XRD pattern of VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> showed that VO<sub>x</sub> are present in crystalline phase, this phase introduced by ZrO<sub>2</sub>. VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> sample shows only the amorphous phase.
- iii. The TPR results show good catalyst activity, also reduction of V<sub>2</sub>O<sub>5</sub> which occurs in two steps at low ZrO<sub>2</sub> contents. Increasing ZrO<sub>2</sub> contents decreased metal reduction. Also, TPR/TPO cycles shows excellent catalyst stability in repeated reduction and re-oxidation process.

- iv.  $\text{NH}_3$ -TPD measurement indicates the presence of weak acid sites on the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$ . The desorption kinetics analysis suggests a medium interaction between  $\text{VO}_x$  and support which enhances the metal reducibility as seen in TPR.
- v. The gas phase oxygen free ODH ethane in presence of  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  shows ethylene, CO and  $\text{CO}_2$  are the major products. The high temperature and longer contact time favor the  $\text{CO}_x$  formation due to consecutive oxidation of ethane to ethylene and finally to  $\text{CO}_x$ .
- vi.  $\text{ZrO}_2$  additions enhanced catalyst performance by enhancement of metal support interaction. Higher ethylene selectivity even after ten repeated reduction runs.

## CHAPTER 6

### RESULTS AND DISCUSSION - EFFECTS OF VO<sub>x</sub>

This chapter deals with the effects of the variation of vanadium loading on a ZrO<sub>2</sub> modified  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> support. In this regards, the vanadium loading was varied between 5 to 15 wt% while  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> ratio was kept at 1:1. The prepared samples were characterized using XRF, nitrogen adsorption, temperature programmed reduction/oxidation, XRD, FTIR, and Raman analysis. The reduction kinetics of the catalyst samples were established using a nucleation and nuclei growth model. The reducibility of the catalysts were further correlated with the ODH of ethane to ethylene performance of the VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts.

#### 6.1. Catalyst characterization

##### 6.1.1. XRF and N<sub>2</sub> adsorption/desorption

The compositions of the various component of the VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts are measured by XRF analysis and are presented in [Table 6.1](#). The XRF analysis shows that the percentages of different species are closed to targeted values with slight deviation.

[Figure 6.1](#) shows the adsorption/desorption isotherms of three different catalysts with various VO<sub>x</sub> loading. One can see that all the samples follow type (v) isotherm indicating narrow size meso-porosity[51]. The monolayer coverage occurs after 0.75 relative pressures which indicates a good dispersion of active site and availability for adsorption.

Table 6.1. XRF and BET surface area characterization results<sup>a</sup>

Sample	V%	O <sub>2</sub> %	Al%	Zr%	BET surface area m <sup>2</sup> /g.cat
5% VO <sub>x</sub> /γ-Al <sub>2</sub> O <sub>3</sub> - ZrO <sub>2</sub> (2:1)	4.6	48.81	27.2	7	24.17
10% VO <sub>x</sub> /γ-Al <sub>2</sub> O <sub>3</sub> - ZrO <sub>2</sub> (1:1)	9.3	40.4	27.2	7	16.5
15% VO <sub>x</sub> /γ-Al <sub>2</sub> O <sub>3</sub> - ZrO <sub>2</sub> (1:2)	14.46	22.94	27.2	7	11.24

<sup>a</sup> samples composition is within ± 2% error

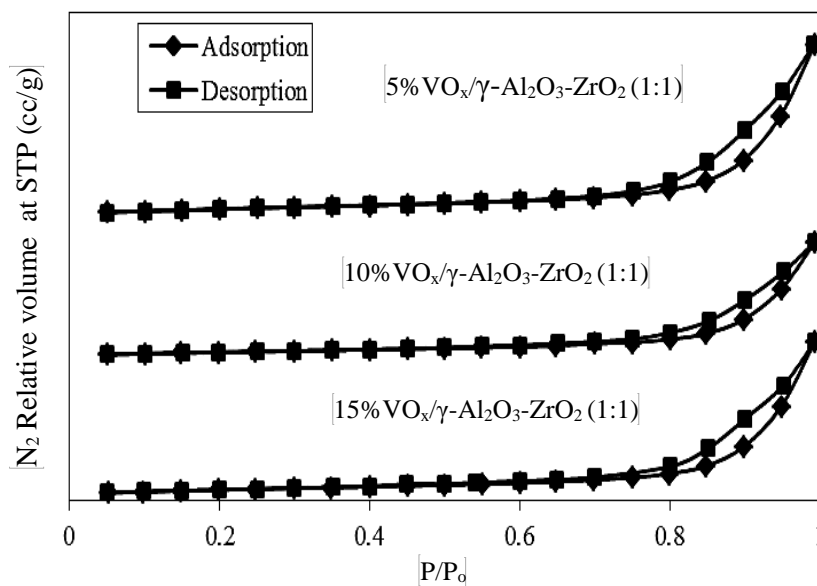

Figure 6.1. N<sub>2</sub> adsorption/desorption isotherms of catalyst samples

BET surface area was determined from N<sub>2</sub> adsorption desorption/desorption isotherms. Table 6.1 also shows the BET surface area and monolayer volume. As expected, the surface area of the catalyst samples were decreased with the increase of VO<sub>x</sub> loading. The pore blockage by the increased amount of VO<sub>x</sub> is mainly responsible for the decreased

surface area. Previous studies also showed that catalyst synthesis using impregnation by soaking reduces surface area although it gives good metal dispersion.

### 6.1.2. X-ray diffraction (XRD)

XRD analysis was conducted to identify the crystallographic structure of catalyst samples. Figure 6.2 shows XRD patterns of  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1) catalyst with different  $\text{VO}_x$  loading together with the support.  $\text{VO}_x$  species were obtained after oxidation and reduction peaks in the range of  $2\theta$  from  $10$  to  $40^\circ$  are relevant to  $\text{V}_2\text{O}_5$ [18]. The  $t\text{-ZrO}_2$  peaks can also be found at  $2\theta$  of  $30^\circ, 48^\circ$  and  $65^\circ$ ,  $\gamma\text{-Al}_2\text{O}_3$  peaks appears at  $2\theta$  of  $45^\circ$  and  $60^\circ$ . Amorphous phase is present and it has been changed toward crystallinity by increasing metal loading and the repeated thermal treatment at  $500^\circ\text{C}$ .  $\gamma\text{-Al}_2\text{O}_3$  and  $\text{ZrO}_2$  peaks appear in the support in contrast with pure  $\gamma\text{-Al}_2\text{O}_3$  and  $\text{ZrO}_2$ , support crystallinity as shown in Figure 6.2.

Figure 6.2. XRD patterns of  $\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1) with various  $\text{VO}_x$  loading

At low VO<sub>x</sub> loading of 5% only amorphous phase of VO<sub>x</sub> species was formed [18] while at higher loadings of 10% and 15% crystal phase detected indicating formation of poly vanadate and crystalline VO<sub>x</sub>. In all samples,  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub> phases enhances catalyst thermal stability [52]. Moreover, ZrO<sub>2</sub> contents introduced crystal phase to the catalyst in comparison with catalyst sample without ZrO<sub>2</sub> [19], this crystal phase is not detected by XRD and may reduce oxygen carrying capacity and catalyst activity by enhancing metal crystal agglomeration.

### 6.1.3. Raman spectroscopy

Nature of vanadium oxide on support surface further investigated by using Raman spectroscopy. The Raman spectra of catalyst samples are shown in [Figure 6.3](#). Sharp peaks at 132 cm<sup>-1</sup> are arise due to vibration of V<sub>6</sub>O<sub>13</sub> [53], while peaks in the range of 200 to 600 cm<sup>-1</sup> are from vibration of crystalline V<sub>2</sub>O<sub>5</sub>. These crystalline V<sub>2</sub>O<sub>5</sub> species are formed as a result of V-O-V bond, and peaks at 995 cm<sup>-1</sup> are due to V=O bond. It can be clearly seen that sample with 15% VO<sub>x</sub> loading ([Figure 6.3a](#)) the sample exhibits sharp peaks in the range of crystalline V<sub>2</sub>O<sub>5</sub>. Increasing metal loading to certain level leads to poly-vanadate species. On the contrary, the poly-vanadate peaks almost disappeared in samples with 5 and 10% VO<sub>x</sub> loading ([Figure 6.3b and c](#)). These findings are in line with the TPR results, where sample (c) gives the lowest H<sub>2</sub> consumption and activity relative to the others in (a and b).

It is reported in literature that vanadium loading forms monolayer on support surface [54]. This monolayer consists mainly from V-O and V=O bonds which are responsible from isolated vanadium species formation on support surface. ZrO<sub>2</sub> addition has little impact on metal support interaction especially at low vanadium loading.

Increasing ZrO<sub>2</sub> contents in the support can result in monolayer coverage at higher vanadium loading levels that can enhance vanadium species isolation on support surface [55-61]. This can be attributed to the stronger V-O-Al bonds than V-O-Zr bonds [54]. Surface vanadium oxide layer on oxide supports is more likely to form than crystalline V<sub>2</sub>O<sub>5</sub> due to surface mobility of vanadium oxide and the lower surface free energy of crystalline V<sub>2</sub>O<sub>5</sub> ( $8-9 \times 10^{-6} \text{ J cm}^{-2}$ ) relative to supports (Al<sub>2</sub>O<sub>3</sub>  $\sim 68-70 \times 10^{-6} \text{ J cm}^{-2}$ ; ZrO<sub>2</sub>  $\sim 59-80 \times 10^{-6} \text{ J cm}^{-2}$ ; TiO<sub>2</sub>  $\sim 28-38 \times 10^{-6} \text{ J cm}^{-2}$ )[62].

Figure 6.3. Raman spectroscopy of catalyst samples (a) 15% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) (b) 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) (c) 5% V<sub>2</sub>O<sub>5</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1)

#### 6.1.4. FTIR spectroscopy

Figure 6.4 shows FTIR spectra of the different VO<sub>x</sub> containing VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) catalyst samples. Vanadium related species vibrations appear between 750 to 1400 cm<sup>-1</sup>, and the band at 934 cm<sup>-1</sup> can be attributed to Al-O-V vibrations and due to

significant interaction between  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and vanadium [66, 51]. The band at 1052 cm<sup>-1</sup> is relative to the V=O stretching mode and the vibration at 754 cm<sup>-1</sup> can be attributed to the V–O–V stretch [58]. This observation is also consistent to the Raman analysis which confirms the presence of isolated and polymeric VO<sub>x</sub> on catalyst surface. On the other hand, Zr-O related vibrations recorded before 640 cm<sup>-1</sup> wavenumber. Comparison of the FTIR spectra of VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst with bulk V<sub>2</sub>O<sub>5</sub> spectra shows that the absorptions at 980 and 1010 cm<sup>-1</sup> can be attributed to V<sub>2</sub>O<sub>5</sub> crystallites [49]. Therefore as mentioned earlier, the FTIR and Raman confirm the presence of isolated and poly vanadate species with crystalline phase.

Figure 6.4. FTIR spectra of catalyst samples (a) 15% VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) (b) 10% VO<sub>x</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) (c) 5% V<sub>2</sub>O<sub>5</sub>/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1)

### 6.1.5. Catalyst acidity

The NH<sub>3</sub>-TPD experiments were conducted to determine the total acidity and acid strength of the prepared catalysts. Ammonia was used for acidity measurement of the catalyst samples due to its strong basicity and small molecular size. Furthermore, ammonia allow to determine the total acidity and strength of acid sites for wide range of temperatures [19]. The acidity of the VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst significantly affects metal support interaction which also determines the reducibility of the VO<sub>x</sub> species. Generally, higher the reducibility of ODH the catalyst facilitates the ethane conversion but lowers ethylene selectivity due to uncontrolled O<sub>2</sub> release. For all the experiments, samples were saturated with ammonia at 120 °C. The ammonia desorptions were conducted in the temperature range of 120-500 °C with a heating rate of 10 °C/min under argon flow. [Figure 6.5](#) shows the ammonia desorption profiles on different VO<sub>x</sub> containing VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub>(1:1) catalysts. One can easily see in this [Figure 6.5](#), ZrO<sub>2</sub> affect metal-support interaction specially at low and intermediate metal loading[53]. Introduction of zirconia to alumina as created additional weak acid sites indicated by new peaks at higher temperature of 270 °C ([Figure 6.5](#)). The multiples peaks indicates second order adsorption[38].

It can be noticed that increasing VO<sub>x</sub> loading also decrease sample acidity but further increasing the percentage 15% acidity increased again. This can be attributed to acidic properties of agglomerated VO<sub>x</sub> species at high loading. Total acidity of the catalysts were calculated by calibrating TCD signal to volume of NH<sub>3</sub> desorbed. Data was collected using 0.2 g for all samples during TPD test. The area under the curve calculated using numerical integration to be used in total acidity calculations. [Equation 6.1](#) shows samples total acidity calculations.

$$\text{total acidity (ml NH}_3\text{/g)} = \frac{a}{w\beta} \quad (6.1)$$

where, (1) a is the area under the curve (ml NH<sub>3</sub> °C/min), (2) w is sample weight and (3) β is the heating rate °C/min. Total acidity was found to be 5.73, 5.5 and 4.78 for 5%, 10% and 15% VO<sub>x</sub> containing catalysts, respectively. As mentioned earlier, increasing metal loading reduces samples acidity by blocking acid sites[56]. However, introduction of ZrO<sub>2</sub> also decreased total acidity but in the same time samples acidity is almost constant when metal loading is increased.

Figure 6.5. NH<sub>3</sub>-TPD profile of VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) catalyst

### 6.1.6. Reducibility and oxygen carrying capacity

TPR characterization is an important technique for oxygen free ODH given TPR simulates the actual ODH reaction as shown in [Equations 6.2](#) and [6.3](#).

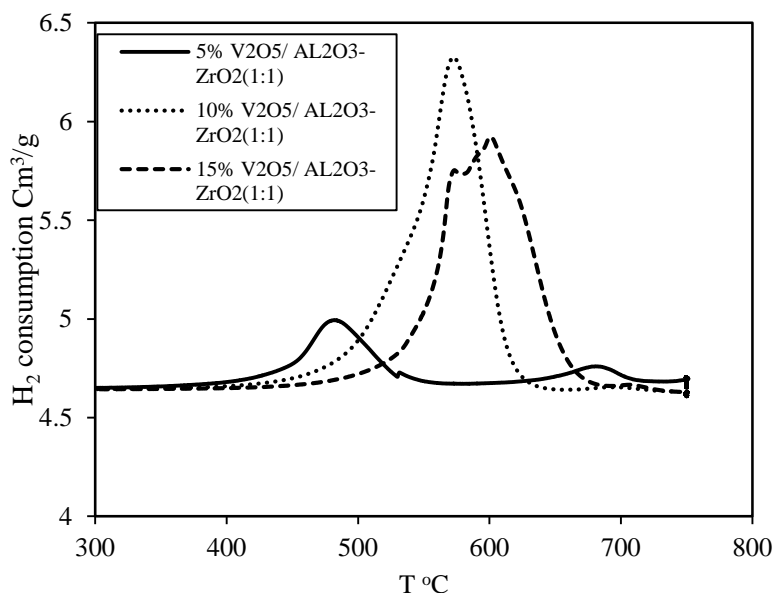

Figure 6.6. TPR profile for catalyst  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1) with various  $\text{VO}_x$  loading

TPR provides indication of catalyst activity and the temperature range of this activity. Additionally, TPR can be utilized to estimate  $\text{O}_2$  carrying capacity and redox properties of the catalysts. TPR results are shown in Figure 6.6 in which plots of  $\text{H}_2$  consumption versus temperature for catalysts with 5%, 10% and 15%  $\text{VO}_x$  loading on the support. All the samples give a major single peak which indicate that the reduction proceed by a single step [66,53]. The 5%  $\text{VO}_x$  sample shows lowest oxygen consumption. The sample with 10%  $\text{VO}_x$  loading gives the highest  $\text{H}_2$  consumptions per gram of catalyst. Sample with 15%  $\text{VO}_x$  gives lower  $\text{H}_2$  consumption due to formation of crystal phase of  $\text{VO}_x$  as reported in XRD patterns. It can be seen that increasing  $\text{VO}_x$  contents shifted the

reduction temperature toward right direction. This can be attributed to formation of crystalline  $\text{VO}_x$  species which are difficult to reduce at low temperature. Introduction of  $\text{ZrO}_2$  reduced support surface acidity and that enhance the formation of isolated mono-vanadate species on support surface [53].  $\text{ZrO}_2$  also affects metal support interaction specially at high  $\text{VO}_x$  loading [52]. During vanadium oxide reduction, oxygen vacancies are formed at the surface, as the reduction proceeds concentration of these vacancies surpasses a certain value, they aggregate and part of vanadium oxide may shear edges producing new structure (non-isolated species). This may also occur as a result of increasing vanadium loading[54]. TPR results can give indication of catalyst oxygen carrying capacity and oxygen releasing rate since oxygen carrying capacity of the catalyst can be determined according to Equations 6.2, 6.3 and 6.4 that is two moles of hydrogen reduce one mole of oxygen, and oxygen released during the reduction can be calculated.

Reduction/oxidation cycles can confirm catalyst ability to be regenerated and also its thermal stability. Reduction/oxidation properties of catalyst samples were examined by repeating TPR cycles. Figure 6.7 shows repeated cycles for the sample with the highest activity (10%  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1)), same trend obtained in all samples although  $\text{H}_2$  consumption slightly decreased at cycles number 3, 4 and 5 and then become constant.

Calcination temperature directly affect reduction/oxidation properties, and since in the present study all samples were calcinated at the same temperature, only composition effect considered to analyze catalyst reduction and oxidation ability.

Figure 6.7. TPR/TPO cycles of 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) catalyst

$$\text{Metal reduced (f)\%} = \frac{M_{w_v} \times V_{H_2}}{v \times V_g \times W_o} \times 100\% \quad (6.5)$$

where, (1)W<sub>v</sub> is the amount of reduced vanadium (g),(2) MW<sub>v</sub> is the molecular weight of vanadium (g/mol), (3)V<sub>H<sub>2</sub></sub> is the volume of reacted hydrogen (cm<sup>3</sup> at STP), (4)V<sub>g</sub> is the molar volume of gas(mol/cm<sup>3</sup> at STP), (5) W<sub>o</sub> is initial weigh of vanadium and (6) v is the stoichiometric number of hydrogen based on the following reaction stoichiometry.

Figure 6.8 shows the percentage of vanadium reduces over TPR reduction/oxidation cycles, reacted hydrogen is calculated by calculating the TPR peak. The reduced vanadium is calculated as in Equation 6.5. Calculations were based on the assumption of V<sub>2</sub>O<sub>5</sub> is the initial reducible catalyst species present on the support [19]. As can be seen from Figure 6.8 stable behavior and medium H<sub>2</sub> consumption was obtained and sample gives good stability in term of metal reduction.

Figure 6.8. Percentage of vanadium reduction during TPT/TPO cycles

### 6.1.7. TPR kinetics modeling

During the TPR, the metal oxide reduction usually involves several steps. The overall reduction rate depends on one or combination of diffusion of reducing agent ( $H_2/C_2H_6$ ), adsorption, surface reaction and desorption of the gaseous product ( $H_2O/CO_x$ ). Depending on the nature of the reducible species, one of the above steps or their combination can control the overall reaction. Since the TPR experiments were carried out in conditions similar to what in [65], the external transport limitation can be assumed to be negligible because concentration variation of the gas phase reactant in the bulk phase and the oxygen carrier surface is negligible. Intraparticle diffusion was considered negligible due to small particle size of the samples. Therefore, the intrinsic TPR kinetics can be formulated considering an overall reaction rate being a function of the solid material reduction  $f(\alpha)$  [36] and the compositions of the gas phase:

$$\frac{d\alpha}{dt} = K(T)f(\alpha)f(P_{H_2}, P_{H_2O}) \quad (6.6)$$

where,  $\alpha$  is the progress of the reaction which can be expressed in many forms. In this study, the degree of reduction and oxidation of the catalyst sample is defined using the hydrogen and oxygen consumption data, for the reactions. Based on TPR profile analysis, the transient solid conversion ( $\alpha$ ) during each solid-state reaction can be written as:

$$\alpha(t) = \frac{\Delta n_t}{\Delta n_{total}} \quad (6.7)$$

where, (1)  $\Delta n_t$  is the moles of H<sub>2</sub> or O<sub>2</sub> consumed at time t (min), (2)  $\Delta n_{total}$  is the total moles of H<sub>2</sub> or O<sub>2</sub> consumed in the whole reduction or oxidation cycle. The function  $f(P_{H_2}, P_{H_2O})$  can be considered as constant if all the TPR experiments were carried out at same feed flow rate, hydrogen partial pressure, hydrogen essentially free of water, and differential conversion.

In this case Equation 6.6 can be written as:

$$\frac{d\alpha}{dt} = K(T)f(\alpha) \quad (6.8)$$

and the rate constant can be defined by Arrhenius Equation:

$$k(T) = k_o \text{Exp} \left[ \frac{-E_{app}}{R} \left( \frac{1}{T} - \frac{1}{T_m} \right) \right] \quad (6.9)$$

where, (1)  $E_{app}$  is the activation energy, (2)  $k_o$  is the pre-exponential factor and (3)  $T_m$  the centering temperature to minimize cross-correlation between parameters. The function of the degree of conversion  $f(\alpha)$  depends on the model applied in the determination of the kinetics.

The accessibility of the metal oxide grains in TPR experiments depends on support material properties. Thus, shape, size, and pore size distribution are all factors affecting

reducibility of oxide sites. Regarding metal support-interaction, there is a preferred orientation of the active component, which mainly depends on the chemical nature of the support material. In this study function  $f(\alpha)$  assumed to take account for catalyst material properties.

Avrami-Erofeev model (see [Table 6.2](#)) describes the function  $f(\alpha)$  in reduction and oxidation of supported oxides proceeds via nucleation and crystal growth as follow:

$$f(\alpha) = n(1 - \alpha)(-\ln[1 - \alpha])^{\frac{n-1}{n}} \quad (6.10)$$

where,  $n$  is the Avrami exponent indicative of reduction mechanism of crystal dimensions growth. The value of  $n$  may vary depending on the mechanism of the reduction of the metal species [65], each value has certain meaning. In the present study  $n$  equals to 1 gives the best fit indicating random nucleation. Substituting [Equations 6.9 and 6.10 in 6.8](#) then the final model equation cab be written as:

$$\frac{d(\alpha)}{dt} = nk_o \text{Exp} \left[ \frac{-E_{app}}{R} \left( \frac{1}{T_o + \beta t} - \frac{1}{T_m} \right) \right] (1 - \alpha) \quad (6.11)$$

where, (1)  $T_o$  the initial temperature, (2)  $\beta$  is the heating rate °C/min.

Table 6.2. Avrami-Erofeev models

Value of n	Mechanism	Model formulation
n	Avrami-Erofeev model	$f(\alpha) = n(1 - \alpha)(-\ln[1 - \alpha])^{\frac{n-1}{n}}$
1	Random nucleation	$f(\alpha) = (1 - \alpha)$
2	2-dimensional nuclei growth (2D Avrami-Erofeev model)	$f(\alpha) = 2(1 - \alpha)(-\ln[1 - \alpha])^{\frac{1}{2}}$
3	3-dimensional nuclei growth (3D Avrami-Erofeev model)	$f(\alpha) = 3(1 - \alpha)(-\ln[1 - \alpha])^{\frac{2}{3}}$

Kinetic parameters in Equation 6.11 was evaluated using Mathematica parametric NDSolve and FindFit functions. Regression achieved using 150 data points from TPR experiment collected every 2 seconds starting from room temperature up to 750 °C and heating rate ( $\beta$ ) of 10 °C/min with 147 degree of freedom. A good regression results were obtained as can be seen in Figure 6.9. Table 6.3 shows kinetic parameters values.

Table 6.3. Estimated kinetic parameters within 95% confidence interval

Sample	$k_0$	E (kJ/mol)	$R^2$	Cor	AIC
5% VO <sub>x</sub>	$12 \times 10^{-4}$	124±6.2	0.99	0.56	-23034
10% VO <sub>x</sub>	$9.3 \times 10^{-4}$	162±8.1	0.99	0.78	-29034
15% VO <sub>x</sub>	$3.6 \times 10^{-4}$	181±9	0.99	0.81	-31678

Activation energies obtained with good regression as indicated by  $R^2$  and AIC statistics. The AIC is used as a measure of the relative quality of a statistical model to data set. Large negative AIC indicates good fitting as can be seen from Figure 6.9. Moreover activation energy is affected by nucleation and crystal growth processes. In fact activation energy being a difference between activation energy for nucleation and activation energy for particle growth. As discussed earlier, activation energy depends on metal type and support materials and in this occasion VO<sub>x</sub> species has high interaction with the support and requires more energy to be reduced [65-69]. Furthermore, in comparison with catalysts activation energy for TPR reaction reported in [65], these values are higher which indicates VO<sub>x</sub> on the Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> are more difficult to be reduced. VO<sub>x</sub> species on the support can be presented in many forms such as isolated VO<sub>x</sub>, poly vanadate and crystalline form. Increasing vanadium loading can affect formation of these species and therefore activation

energy varies with  $\text{VO}_x$  percentage. Reducibility of  $\text{VO}_x$  species varies depending on the type and therefore reaction or reduction rate [32]. Thus activation energy depends on the reducibility. For this catalyst, activation energy is higher than other supported metal oxides [65]. Activation energy for Ni reported to be 54.5 kJ/mol when alumina was used as support keeping in mind Ni is more active than V. Furthermore, crystalline  $\text{VO}_x$  formed during synthesis shifted the reduction temperature to higher range (see Figure 6.6) which explain increased activation energy for reduction [67].

Figure 6.9. Predicted degree of reduction versus experimental values for (a) 5%  $\text{VO}_x$  (2) 10%  $\text{VO}_x$  (3) 15%  $\text{VO}_x$  supported on  $\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1)

## 6.2. ODH of ethane in a fluidized CREC Riser Simulator

The fluidized ODH of ethane experiments carried out in a CREC Riser Simulator using pure ethane (99.95% purity) as feed. All the experiments were conducted at atmospheric pressure and constant catalyst to feed ratio of 0.2 g cat/ml feed. The temperature was varied between 525 and 600 °C while reaction time was adjusted from 20 to 50 seconds. After each run the catalysts were regeneration by circulating air for 10 minutes.

Figures 6.10 and 6.11 display the ethane conversion and product selectivity of ODH of ethane using the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst samples. Figure 6.10 shows ethane conversion for  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  (1:1) catalyst sample at 45 seconds and 575 °C. The highest conversion was obtained 5.7% at 10%  $\text{VO}_x$  consisting with TPR data which gives highest  $\text{H}_2$  consumption at temperature from 500 to 650 °C. Sample with 5%  $\text{VO}_x$  gives lowest conversion due to low  $\text{VO}_x$  contents and 15% has lower activity due to crystalline  $\text{VO}_x$  phase as mention earlier.

Furthermore, ethylene selectivity is shown in Figure 6.11. 5%  $\text{VO}_x$  containing sample only active in temperature range from 450 to 530 °C and that explains low selectivity and conversion. Intermediate  $\text{VO}_x$  contents of 10% has a controlled oxygen release and thus minimum combustion of the feed and ethylene occurs. Consequently, the ethylene selectivity with this catalyst shows is highest (88.4%) and the lower  $\text{CO}_x$  selectivity is lowest as shown in Figure 6.11.

Figure 6.10. Ethan conversion at various VO<sub>x</sub> supported on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1)

(feed=2ml, T=575 °C, t=45 sec w=0.4 g)

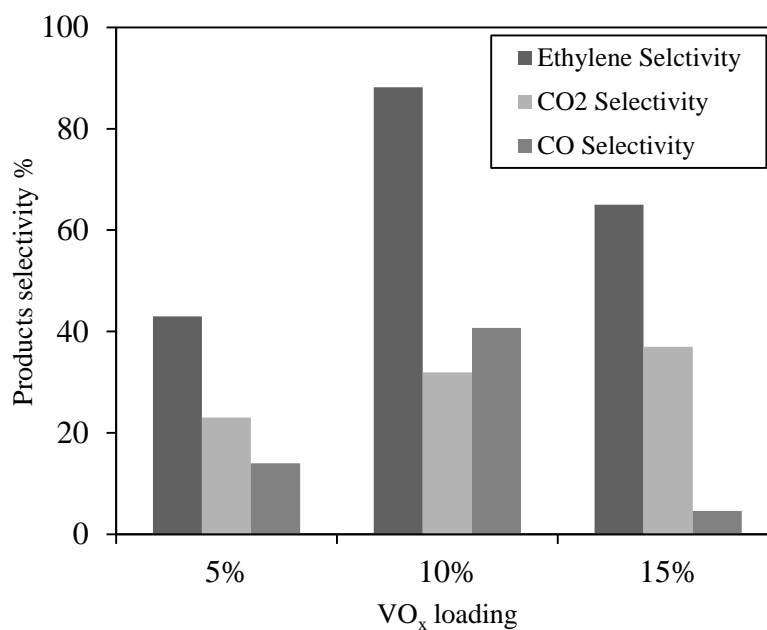

Figure 6.11. Products selectivity at various VO<sub>x</sub> supported on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1)

(feed=2ml, T=575 °C, t=45 sec w=0.4 g)

Figure 6.12 shows the effects of temperature on conversion and selectivity for 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) catalysts. ZrO<sub>2</sub> contents in 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) also contributed into increasing ethylene selectivity up to at 575°C reaction temperature and lowering conversion. However ethylene selectivity decreases by increasing VO<sub>x</sub> content.

Figure 6.12. Effect of temperature on C<sub>2</sub>H<sub>6</sub> conversion and C<sub>2</sub>H<sub>4</sub> selectivity for 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1), ◆Ethane conversion, ■ Ethylene selectivity×CO<sub>2</sub> selectivity, ▲ CO selectivity (t=45 sec, w=0.4, feed= 2 ml)

CO<sub>x</sub> selectivity for 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) is shown in Figure 6.12. Highest CO<sub>2</sub> selectivity obtained was 50.7% at 525°C and for CO highest selectivity was 31.5% at 550°C, but in general ethylene selectivity slightly increased by increasing reaction temperature. Catalyst activity mainly depends on surface VO<sub>x</sub> species nature which affects both activity and selectivity. Figure 6.12 shows conversion increases and decreases during ODH reaction, which can be related to reaction conditions and catalyst surface active sites. As mentioned earlier, it is required to optimize the types of VO<sub>x</sub> species on the support

surface. This severely affects catalyst activity and selectivity During ODH reaction as can be seen from [Figure 6.13](#), which is a schematic representation of the reaction. Isolated  $\text{VO}_x$  species which contains  $\text{V}=\text{O}$  bond can be converted into polymeric phase with  $\text{V}-\text{O}-\text{V}$  bond. Literature reported that there are two main reason to convert isolated  $\text{VO}_x$  into polymeric. Either during synthesis low pH level or by thermal treatment [54]. The other cause of polymerization of isolated  $\text{VO}_x$  species is reduction during ODH reaction when feed consume  $\text{O}_2$  from catalyst surface. These vacancies lead to formation  $\text{V}-\text{O}-\text{V}$  bond instead which will results in polymerizing vanadium species on the surface [54].

Figure 6.13. Ethane ODH over supported  $\text{V}_2\text{O}_5$

Time effect also is shown in [Figure 6.14](#) at constant reaction temperature. Increasing ethylene selectivity up to 90.8% at 50 seconds reaction time. Highest  $\text{CO}_2$  selectivity obtained was 40.8% at 20 sec reaction time and for  $\text{CO}$  highest selectivity was 14.9% at 50 sec, but in general again ethylene selectivity slightly increased by increasing reaction time. [Figure 6.15](#) show catalyst stability over reaction/regeneration cycles. Catalyst stability can be attributed to the thermal stability of  $\text{Al}_2\text{O}_3\text{-ZrO}_2$  support and also  $\text{VO}_x$  stability on the surface [18, 53].  $\text{VO}_x$  thermal stability was also confirmed by TPR

Figure 6.14. Effect of time on C<sub>2</sub>H<sub>6</sub> conversion and product selectivity for 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:1) (T=575 °C, w=0.4, feed= 2 ml)

Figure 6.15. Conversion and selectivity over reaction/regeneration cycles for 10% VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> (1:2) (t=45 sec T=575 °C w=0.4 feed= 2 ml)

reduction/oxidation cycles (Figure 6.7), in which consistent peaks was obtained over 3 cycles.

Metal reduction directly affects feed conversion [32,44]. By decreasing acidity vanadium reducibility decreased which explains the low conversion of ethane. However ZrO<sub>2</sub> enhanced metal support interaction which leads to good selectivity to ethylene by the dehydrogenation process. Furthermore ZrO<sub>2</sub> affected V<sub>2</sub>O<sub>5</sub> reduction as can be seen from XRD and TPR profile. This can also affect the nature of VO<sub>x</sub> species on support surface and types of bond between these species. However a qualitative measure is required to specify the percentage of VO<sub>x</sub> in the samples (i.e. % V<sup>5+</sup>, % V<sup>4+</sup>, etc.).

V-Support interaction and V loading determine type of the bonds and thus what type of VO<sub>x</sub> species exist on support surface[52]. There are several types of VO<sub>x</sub> species such as isolated vanadium oxide species, dimeric vanadium oxide species, two-dimensional vanadium oxide chains and V<sub>2</sub>O<sub>5</sub> crystals. Samples of VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> contain isolated, dimeric and crystalline V<sub>2</sub>O<sub>5</sub> as shown in Raman analysis before. These VO<sub>x</sub> species contain V=O terminal bond with V-O-V and V-O-support bond, V-O-V bond is associated with polymeric VO<sub>x</sub> species and previous studies showed V-O-V has no effect in ODH reaction[69].

**The following are the conclusions of this Chapter 6:**

- i. XRF confirms catalyst compositions of the targeted VO<sub>x</sub> loading. The increasing of VO<sub>x</sub> loading shows slight decrease of the surface area of the catalysts.
- ii. XRD and Raman analysis indicate the presence of V<sub>2</sub>O<sub>5</sub> and ZrO<sub>2</sub> in the VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalysts. XRD pattern of VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> showed that VO<sub>x</sub> are present in crystalline phase due to the ZrO<sub>2</sub> modification. Raman spectra confirmed

the existence of isolated and polyvanadate species.  $\text{NH}_3$ -TPD measurement indicates weak acid sites on the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$ .

- iii. The TPR results showed two peaks due to reduction of  $\text{V}_2\text{O}_5$  which occurs in two steps at low  $\text{ZrO}_2$  contents. Increasing  $\text{ZrO}_2$  contents decreased metal reduction. Also TPR/TPO cycles shows catalyst stability.
- iv. Activation energy from TPR kinetics indicated lower reducibility at high  $\text{VO}_x$  loading with random nucleation mechanism.
- v. The fluidized bed conditions enhanced the conversion of the ethane due to intense gas-solid mixing. The  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  shows a good performance in terms of ethylene selectivity even after ten repeated reduction runs.  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst gives good ethylene selectivity at 10%  $\text{VO}_x$  loading. Ethylene selectivity stable in reaction temperature range.

## CHAPTER 7

### KINETICS MODELING

This chapter presents the phenomenological kinetics modeling of the fluidized bed ODH of ethane to ethylene in gas phase oxygen free conditions. In this regard, the best performing catalyst (10 wt% VO<sub>x</sub> on Al<sub>2</sub>O<sub>3</sub>/ZrO<sub>2</sub> = 1:1) was selected for the kinetics experiments in the CREC Riser Simulator. The Langmuir-Hinshelwood type kinetics models were developed considering all the series-parallel reactions. The reducibility of the catalysts is also incorporated in kinetic models in order to take into account of the depletion of the oxygen concentration due to the gas (ethane)-solid (catalyst) reaction.

#### 7.1. The reaction network

The network of ethane ODH reaction consists both desired and undesired reactions. According to open literature, following are the major reactions in a gas phase ODH of ethane [28, 29]:

Desired reaction

Undesired reaction

In oxygen-free environment, the ODH reaction proceeds by a gas (ethane)-solid(metal oxide) reaction, as expressed in [Equation 7.4](#), producing ethylene as desired product.

However, the feed ethane and desired product ethylene may further react with solid phase oxygen to give carbon oxides ( $\text{CO}_x$ ). Therefore, the overall reaction network should contain all the series-parallel reactions (Figure 7.1) [29].

Figure 7.1. ODH of ethane reaction network

The reaction network represent three reactions (1) ethane selective oxidation to ethylene, (2) ethane non-selective oxidation (combustion) to  $\text{CO}_x$  and (3) ethylene combustion to  $\text{CO}_x$ . In the context of the present study, the product analysis of ODH of ethane in a CREC riser simulator using  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalysts also shows ethylene,  $\text{CO}_2$ , CO and  $\text{H}_2\text{O}$  as major products which further support the above reaction network.

### 7.1.1. Rate equations

In literature, there are kinetic studies of ODH of ethane reactions and only a few these studies which considered the Eley-Rideal and Langmuir–Hinshelwood models for ethane ODH to ethylene [3,18,22]. According to these studies hydrocarbon feed reacts with lattice oxygen from the catalyst to produce alkene and water. The reduced catalyst is then re-oxidized with molecular oxygen to recover oxygen consumed by the feed.

In catalytic ODH reaction, it is assumed that there are three types of oxygen one can consider: adsorbed, surface lattice and subsurface lattice oxygen. Kinetic model should take into account for these types of oxygen as in Langmuir–Hinshelwood mechanism. In Langmuir–Hinshelwood mechanism, both of the reactants adsorbed on the catalyst surface as shown in [Figure 7.2](#) [39]. The other reactant in the gas-phase may react directly in one step (Eley-Rideal) or may sample several surface sites before reacting(L-H) [23,24]. [Equations 7.5, 7.6 and 7.7](#) show a simple representation of Langmuir–Hinshelwood rate expression.

Figure 7.2. Steps of Langmuir–Hinshelwood mechanism (a) reactants adsorption (b) Surface reaction (c) products desorption

In the context of present study, rate of formation of all product species in ethane ODH reaction over 10 wt %  $VO_x/\gamma-Al_2O_3-ZrO_2$  catalyst is described using Langmuir–Hinshelwood rate expression. The model takes into account the adsorption on the catalyst surface and the reactions with the lattice oxygen of the catalyst to form the products. The generalized model can be expressed as follows:

$$r_i = \frac{k_i^k K_i^A P_i}{1 + \sum_j^n K_j^A P_j} \quad (7.8)$$

where,  $r_i$  is the rate of reaction of component  $i$  (mol/(g<sub>cat</sub>.min)),  $k_i^k$  the kinetic constant for component  $i$  ( mol/(g<sub>cat</sub>.min),  $K_i^A$  the adsorption constant for component  $i$  (in units of atm<sup>-1</sup>), and  $P$  the partial pressure of component  $i$  ( atm) and  $n$  is the total number of chemical species.

The rate Equation 7.8 is valid if the catalyst is reduced completely and all the oxygen carried by the catalyst is consumed at reaction temperature. However, it is important to consider the variation of oxygen content of the catalyst with time during the reaction. Such variation of oxygen content can be expressed in terms of degree of reduction of the catalysts. In several studies, the degree of reduction of the catalyst is modeled as activity decay [42]. In the context of present study, TPR data is modeled using activity decay function ( $\alpha$ ).

We assumed reaction of C<sub>2</sub>H<sub>6</sub> with adsorbed oxygen is the one responsible of producing ethylene as in Equation 7.6 and free released oxygen leads to combustion of C<sub>2</sub>H<sub>6</sub> and C<sub>2</sub>H<sub>4</sub> Equations 7.2 and 7.3. During the ODH experiments in CREC Riser Simulator, the products concentration was much less than ethane concentration, or in other words ethane concentration at any time is greater than products concentration. Therefore, it can be assumed that no product re-adsorption occurs. A similar conclusion was given in [43]. Therefore, Equation 7.8 can be written for each component as:

$$r_1 = \frac{k_{C_2H_6}^k K_{C_2H_6}^A P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.9)$$

$$r_2 = \frac{k_2^* K_{C_2H_6}^A P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.10)$$

$$r_3 = \frac{k_3^* K_{C_2H_4}^A P_{C_2H_4}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.11)$$

where,

$$k_2^* = k_2^{CO_2} + k_2^{CO} \quad (7.12)$$

$$k_3^* = k_3^{CO_2} + k_3^{CO} \quad (7.13)$$

In addition, adsorption constants and kinetic constants are lumped together and [Equations 7.10, 7.11 and 7.12](#) become:

$$r_1 = \frac{k_1' P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.14)$$

$$r_2 = \frac{k_2' P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.15)$$

$$r_3 = \frac{k_3' P_{C_2H_4}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (7.16)$$

where,

$$k_1' = k_{C_2H_6}^k \times K_{C_2H_6}^A \quad (7.17)$$

$$k_2' = k_2^* \times K_{C_2H_6}^A \quad (7.18)$$

$$k_3' = k_3^* \times K_{C_2H_4}^A \quad (7.19)$$

## 7.2. TPR model development

During the ODH of ethane reaction, the catalyst starts reacting with the reducing agent (hydrogen/ethane/ethylene) at certain temperature and the rate increases with temperature until a maximum value. The catalyst reduction during ODH reactions can be modeled using the TPR data given the same reduction steps occurs in TPR except it uses hydrogen as reducing agent. During TPR, hydrogen is consumed and the consumption of hydrogen is measured within certain temperature range. Catalyst reaction (consumption) with hydrogen makes a specific curve represents catalyst finger print according to catalyst properties. A single or a multiple peak curve can be obtained depending on the nature of metal oxide on catalyst surface [19,20]. The model is mainly a modified standard normal distribution function in Equation 7.20 representing the H<sub>2</sub> consumption in the temperature range which catalyst is active as can be seen in Figure 7.3.

$$\phi(x) = \frac{\exp\left[\frac{-(x-\mu)^2}{2\sigma^2}\right]}{2\sqrt{\pi}} \quad (7.20)$$

where,  $\sigma$  is the variance and  $\mu$  is the mean, this equation represents the rate of oxygen release by a specific catalyst and by simple modification it can fit the case as follow:

$$V_{H_2} = a_1 + b_1 \times \exp\left[\frac{-(T-T_m)^2}{2c_1^2}\right] \quad (7.21)$$

where, (1)  $V_{H_2}$  is H<sub>2</sub> consumption cm<sup>3</sup>/min, (2)  $a_1$  is the initial amount of H<sub>2</sub> consumption at low temperature, (3)  $b_1$  equal the highest consumption minus  $a_1$  (4)  $c_1$  is a constant °K (5)  $T_m$  Temperature of the maximum consumption. This model is also valid for all catalysts with TPR profile similar to vanadium oxide supported catalysts, except these parameters mentioned that are unique for the specific catalyst. For multiple peaks, study suggests that

there is more than one metal oxide phases working as active site. Therefore, data must be de-convoluted before fitting the model. The ratio of the accumulated oxygen released by the catalyst to the total oxygen capacity of the catalyst could be released at very high temperature, and ( $\alpha$ ) can be written as;

$$\alpha = \frac{\int_0^T a_1 + b_1 \exp\left[\frac{-(T-T_m)^2}{2c_1^2}\right] dT}{\int_0^{1000} a_1 + b_1 \exp\left[\frac{-(T-T_m)^2}{2c_1^2}\right] dT} \quad (7.22)$$

Figure 7.3. TPR model parameters graphical representation

## 7.3. Mathematical model development

### 7.3.1. Assessment of mass transfer limitations

Overall reaction rate of ethane disappearance and formation of produces involves diffusion, adsorption and intrinsic reaction steps. Depending on the nature of the reducible species, one of the above steps or their combination can control the overall reaction. The external mass transfer can be assessed from Sherwood number and Froessling's

dimensionless correlations[44]. External mass transfer effect can be negligible if the following condition is satisfied:

$$W_{C_2H_6g} \gg r'_{A(obs)} \quad (7.23)$$

$$W_{C_2H_6g} = k_g(C_{C_2H_6g} - C_{C_2H_6s}) \quad (7.24)$$

$$Sh = 2 + 1.1Sc^{0.33}Re^{0.5} \quad (7.25)$$

$$k_g = \frac{Sh \times D_{AB}}{d_p} \quad (7.26)$$

$$r_i = \frac{v}{W} \frac{d\left(\frac{P_i}{RT}\right)}{dt} \quad (7.26)$$

where, (1)  $W_{C_2H_6,g}$  is radial flux of ethane (mol/s.cm<sup>2</sup>) (2)  $Sh$ ,  $Sc$ , and  $Re$  are Sherwood, Schmidt, and Reynolds numbers, respectively, (3)  $k_g$  is the external mass transfer coefficient (cm/s), (4)  $r'_{A(obs)}$  is the observed reaction rate (mol/g solid. s), (5)  $C_{C_2H_6,g}$  is the bulk concentration of ethane, (6)  $C_{As}$  is the surface concentration of ethane (mol/L), (7)  $D_{AB}$  diffusivity cm<sup>2</sup>/s. Values of these parameters are shown in [Table 7.1](#).

Reaction rate  $r'_{A(obs)}$  was calculated at higher conversion of ethane using [Equation 7.26](#) and found to be  $1.3 \times 10^{-5}$  (mol/g solid. s).  $W_{C_2H_6,g}$  was found equal to 0.00123 mol/s.cm<sup>2</sup> and according to this values  $W_{C_2H_6,g} \gg r'_{A(obs)}$  and thus condition in [Equation 7.23](#) is satisfied and the external mass transfer can be considered negligible.

Intraparticle diffusion was assessed using the Weisz-Prater criterion [44] :

$$C_{wp} = \frac{r'_{A(obs)} \rho_p R_p^2}{D_{eff} C_{As}} < 1 \quad (7.27)$$

where, (1)  $r'_{A(\text{obs})}$  is the observed reaction rate (mol/g solid. s), (2)  $\rho_p$  is the particle density (g/cc), (3)  $R_p$  is the particle radius(cm), (4)  $D_{\text{eff}}$  is the effective diffusivity (cm<sup>2</sup>/s), (5)  $C_{AS}$  is the concentration of gaseous reactant at the surface of solid particles (mol/L). Values also can be found in Table 7.1.  $C_{wp}$  also found to be 0.0000688 mmol/cm<sup>3</sup> and the value is much less than 1, therefore intraparticle mass transfer also is negligible for this reaction.

Table 7.1. Parameters used to evaluate mass transfer limitations

Parameter	Value	Remarks
$r'_{A(\text{obs})}$ (mol/g solid. s)	$1.3 \times 10^{-5}$	Calculated at highest conversion
$D_{AB}$ (cm <sup>2</sup> /s)	0.00027	from Fuller's correlation [45]
$C_{C_2H_6,s}$ (mol/cm <sup>3</sup> )	0.0	
$C_{C_2H_6,g}$ (mol/cm <sup>3</sup> )	0.0137	
Sh	2	the lowest value of Sh equals 2, which occurs at stagnant fluid conditions around the solid particle
$R_p^2$ cm	0.006 cm	Estimated from pulse chemisorption using AutoChem II Analyzer
$\rho_p$ (g/cm <sup>3</sup> )	0.545	
$D_{\text{eff}}$ (cm <sup>2</sup> /s)	0.1 $D_{AB}$	

### 7.3.2. Kinetic model formulation

CREC riser simulator is considered mixed batch reactor as reported in [46]. Thus reaction rate can be expressed as:

$$\eta r_i = \frac{V}{W} \frac{d\left(\frac{P_i}{RT}\right)}{dt} \quad (7.28)$$

where, (1)  $V$  is the reactor volume ( $\text{cm}^3$ ), (2)  $W$  is the catalyst (g), (3)  $p_i$  the partial pressure of species  $i$ , (4)  $R$  the gas constant in ( $\text{cm}^3 \cdot \text{atm} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ ), (5)  $T$  the reactor temperature (K), and (6)  $t$  is the time (seconds). Moreover, from assessment of mass transfer limitation in [Section 7.3.1](#),  $\eta$  is the effectiveness factor which will be taken as 1. Then the rate equation can be expressed as:

$$\frac{dP_i}{dt} = \frac{WRT}{V} r_i \quad (7.29)$$

$$\frac{dP_i}{dt} = \frac{WRT}{V} r_i \alpha \quad (7.30)$$

At this stage reaction network in [Figure 7.1](#) can be written in term of ordinary differential equations (ODEs). This set of ODEs represent the change in partial pressure of reactant and products inside the reactor as a function of time and this set should be solved simultaneously using experimental initial conditions.

$$\frac{dP_{\text{C}_2\text{H}_6}}{dt} = -\frac{WRT}{V} (r_1 + r_2) \quad (7.31)$$

$$\frac{dP_{\text{C}_2\text{H}_4}}{dt} = \frac{WRT}{V} (r_1 - r_3) \quad (7.32)$$

$$\frac{dP_{\text{C}_2\text{H}_6}}{dt} = \frac{4WRT}{V} (r_2 + r_3) \quad (7.33)$$

Temperature effect was included in reaction constants and expressed according to Arrhenius relationship given in [Equation 7.34](#). This allowed us to evaluate activation energies  $E_i'$  and pre-exponential factors  $k_o'$  which are the actual  $E_i$  and  $k_o$  multiplied by adsorption constant  $K_i^A$ .

$$k'_i = k'_o \text{Exp} \left[ \frac{-E'_i}{R} \left( \frac{1}{T} - \frac{1}{T_m} \right) \right] \quad (7.34)$$

where,  $T_m$  is the average reaction temperature [42], which in this case equals to 562 °C. Subsisting [Equations 7.28-7.30 and 7.34](#) in [7.31-7.33](#)  $E_i'$   $k_o'$  can be obtained using Mathematica “FindFit” fit built-in function after solving the ODE’s set in [Equations 26-28](#) using Parametric parametric “NDSolve”.

### 7.3.3. Estimation of TPR model parameters

The model given in [Equation 7.22](#) was fitted to TPR experimental data in [Figure 7.4](#) using Mathematica built-in function “FindFit”. Parameters values are shown in [Table 7.2](#) together with the model statistical analysis using coefficient of determination ( $R^2$ ) and Akaike information criterion (AIC).

Coefficient of determination  $R^2$  was found to be 0.961 which indicates a good regression as seen in [Figure7.5](#). Akaike information criterion (AIC) also was used as a measure of the relative quality of a statistical model to data set. According to literature, the large negative value of AIC indicates goodness of fitting. [Table 7.2](#) reports the  $R^2$  and AIC value of the TPR model fitting. One can see that the  $R^2$  is high and large negative values of AIC, indicating excellent fitting of the TPR model [Equation 7.22](#).

### 7.3.4. Estimation of kinetic parameters

The kinetics parameter were evaluated by a nonlinear regressions analysis using ODH of ethane experimental form as developed in CREC Riser Simulator and implemented in Mathematica. The set of ODEs in [Equations 7.31-7.33](#) representing the kinetic models was solved simultaneously using “NDSolve” before it was fitted to experimental data. Upon solving ODEs the partial pressure of each species becomes a function of time.

Figure 7.4. Model predicted H<sub>2</sub> consumed and experimental data at various temperature

Table 7.2. Fitted model parameters using equation with confidence interval of 95%

Parameter	a	b	c	AIC	R <sup>2</sup>
Value	4.65	1.44	38	-286	0.999

Figure 7.5. Plot of model predicted H<sub>2</sub> consumed and experimental data

Temperature effect appears when reaction data was collected at several reaction temperatures (525, 550, 575 and 600 °C). Using Arrhenius relation components, activation energies ‘ $E_i$ ’ and pre-exponential factors “ $k_o$ ” were estimated. Furthermore, catalyst weight “ $w$ ” was taken as 0.4 g with reactor volume “ $v$ ” of 53 cm<sup>3</sup>.

Activity function ( $\alpha$ ) in Equation 7.22 was estimated at each temperature. The value of  $\alpha$  was varied from 0 to 1 in a way that if all O<sub>2</sub> carried by the catalyst is consumed during reaction that means  $\alpha$  is 1 and all metal reduced by 100%. However, in the real case as shown in TPR result for the same catalyst, metal reduction is always less than 100% therefore  $\alpha$  is always less than 1. Table 7.3 shows kinetic parameters estimation with statistical adjusted R<sup>2</sup>.

Table 7.4 shows that activation energies  $E_i$ ’ and pre-exponential factors  $k_o$  were estimated by plotting reaction constants at each temperature as shown in Figure 7.6. However, as mentioned before these activation energies and pre-exponential factors are multiplied by adsorption constant. Since  $K^A_{C_2H_6}$  was estimated already, Equation 7.17 used again to calculate the observed  $k_{C_2H_6}$  and the corresponding activation energy and pre-exponential factor as shown in Figure 7.6.

Table 7.3. Estimated kinetic model parameters with 95% confidence interval

Parameter	T=525 °C	T=550 °C	T=575 °C	T=600 °C
$k'_1$ (mol/g <sub>cat</sub> .s.atm)	0.162	0.1811	0.2114	0.2147

Figure 7.6. Plot of reaction constants versus temperature inverse

Activation energy is defined as the energy barrier required accomplishing a certain reaction. Thus by comparing the values of activation energies given in Table 7.4, it can be seen that the activation energy for the formation of CO<sub>x</sub> from ethane (reaction 2 in Figure 7.1) is lower than that required for the formation of ethylene and that is why it is difficult to control the selectivity to ethylene. On the other hand, activation energy in reaction 3 in Figure 7.1 is relatively high thus this reaction is difficult to occur. Furthermore, when actual activation energy for ODH (reaction 1 in Figure 7.1) to produce ethylene was calculated, it was found that this energy is less than the activation energy for the same reaction over 10% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst [29] and this can explain the improved catalyst selectivity when compared to the un-modified version of the catalyst.

Figure 7.7 shows component partial pressure at various temperatures during ODH reaction in CREC riser simulator reactor together with the model predicted values. As can be seen in Figure 7.7, the model is in good agreement with experimental data. It is obvious

that Langmuir-Hinshelwood mechanism successfully represented ethane ODH reaction over 10% wt  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$ . However, there is a slight deviation from experimental data at some points and this can be attributed to Langmuir-Hinshelwood nature which account mainly for adsorption and surface reaction. In contrast in some studies [18], it is reported that the participation of catalyst oxygen in both the selective and unselective steps of the reaction sequence indicating that ethane reduces the catalytic surface and creates oxygen vacancies, readily replenished by gaseous di-oxygen. Such fact should be considered by the proposed model together with the metal support interaction and redox properties. [Figure 7.8](#) also shows overall plot of predicted components partial pressures versus experimental data. [Figure 7.9](#) shows plot of model predicted product selectivity versus conversion at different reaction temperatures. Trend of data is consistent with the proposed reaction network.

One may be interested in making a comparison between estimated kinetic parameters in this study and those in the literature. However there is only a few studies that reported fluidized bed ODH of ethane to ethylene kinetics. Therefore similar studies are used to compare the kinetic parameters as reported in [Table 7.6](#). The dissimilarity between reported kinetic parameters and the values reported in the present study can be attributed to several reasons including different experimental set-up, different catalysts, reaction mechanism and the proposed network. It is reasonable to compare kinetic parameters in the present study to those were reported in Sameer et.al [19] because fluidized conditions was used, however catalyst is modified by ZrO<sub>2</sub>. As can be seen in [Table 7.6](#), activation energy of C<sub>2</sub>H<sub>4</sub> formation is 88 kJ/mol, which is much higher than the calculated value in the present study (28.4 kJ/mol). This can be attributed to different

Table 7.6. Reported activation energy C<sub>2</sub>H<sub>4</sub> of ethylene formation in ethane ODH

Catalyst	Activation energy of		
	C <sub>2</sub> H <sub>4</sub> formation kJ/mol	Reference	Notes

10 wt% VO <sub>x</sub> /c-Al <sub>2</sub> O <sub>3</sub>	88	12	Fluidized bed ,oxygen free environment
1.4 wt % VO <sub>x</sub> /γ-Al <sub>2</sub> O <sub>3</sub>	94	16	Fixed bed reactor using O <sub>2</sub> supply
28.4 wt % VO <sub>x</sub> /SiO <sub>2</sub>	86	17	Fixed bed reactor using O <sub>2</sub> supply

catalyst compositions and properties which can be seen from XRD, TPR results. Furthermore, although both studies adopted Langmuir-Hinshelwood mechanism to express reaction rate, in the present study the L-H rate equation was modified assuming product partial pressure is very low in comparison with ethane partial pressure. Ethane ODH kinetic over  $\text{VO}_x$  based catalyst also investigated at fixed bed reactor and activation energy of  $\text{C}_2\text{H}_4$  formation was found to be 94 kJ/mol as reported in [Table 7.6](#) [46]. However, a different reaction network was proposed, by considering  $\text{CO}_x$  gases are only produced from ethane. Additionally, Mars-Van Krevelen mechanism was used to describe the reaction.

**Following are the conclusions of kinetics modeling:**

- i. The gas phase oxygen free ODH of ethane in fluidized bed proceeds with series-parallel reaction network forming ethylene, water and carbon oxides as major products. A Langmuir-Hinshelwood type model together with catalyst activity decay model (oxygen depletion) based on TPR results described the reaction rates adequately.
- ii. The model was found to be in a good agreement with experimental data. Reactants and products partial pressure during ODH reaction were predicted satisfactory.
- iii. The formation of ethylene requires least amount of activation energy of 28.4 kJ/mol which is consistent to the experimental data (more selective product).

## CHAPTER 8

### OPTIMIZATION

Optimization and mathematical modeling are powerful tools to solve different problems which arise in chemical engineering. Problems as designing a plant, determining the number of units for a specific task, assigning raw materials to different production processes and deciding the production planning or production targets are some of the issues that can be solved through mathematical modeling. In other words, the mathematical formulations are used to make decisions at different levels, from the synthesis and design of the process up to its operation and scheduling. In the present study the objective is to optimize the operating conditions in CREC riser reactor, which is in this case study can be considered a batch unit. A batch unit operates in a non-continuous manner, receiving feed at certain times and after a processing time, producing products or intermediates. Semi-continuous units are characterized by a processing rate for each product; they are operated continuously with periodic startups and shutdowns.

The aim of this section is to optimize ODH of ethane to ethylene in fluidized bed reactor over 10% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst to determine the optimum conditions to achieve higher ethylene yield. As mentioned before literature review revealed that there are no much studies conducted. It is required to investigate this case study and to model the reaction to optimize ethylene yield. Kinetic model was utilized in optimization of ethane ODH reaction over 10% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst. In kinetic model in chapter 6 reaction network was assumed in the way that consider all possible reactions and the rate equation

as well established using Langmuir-Hinshelwood kinetics rate expression. Furthermore catalyst decaying performance was taken into account via modeling TPR experimental data for 10% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> catalyst in order to consider as much catalytic properties.

On the other hand in this study a mathematical model is developed based on temperature programmed reduction characterization technique. The objective is to correlate catalyst properties (metal loading, oxygen carrying capacity) to its performance during oxidation reaction. The model explicitly is a function of temperature and implicitly is a function of metal loading and other catalyst properties.

Oxygen releasing consumes hydrogen, this consumption of hydrogen measured with in certain temperature range. Catalyst reaction (consumption) with hydrogen makes a specific curve represents catalyst finger print according to catalyst properties. A single or a multiple peak curve can be obtained depending on the nature of metal oxide on catalyst surface [25,26]. The model is manly a modified standard normal distribution function

## **8.1. Optimization model development**

There are a general steps in solving an optimization problems:

1. Analyze the process itself so that the process variables and specific characteristics of interest are defined; that is, make a list of all of the variables.
2. Determine the criterion for optimization, and specify the objective function in terms of the variables defined in step 1 together with coefficients. This step provides the performance model.
3. Using mathematical expressions, develop a valid process or equipment model that relates the input-output variables of the process and associated coefficients.

4. If the problem formulation is too large in scope: (a) break it up into manageable parts or (b) simplify the objective function and model.
5. Applying a suitable optimization technique to the mathematical statement of the problem.

### **8.1.1. Formulation of optimization program**

Hypothesis:

- i. Reaction pathways are irreversible as shown in [Figure 7.1](#) in [chapter 7](#).
- ii. Rate of production of ethylene follows Langmuir-Hinshelwood kinetics.
- iii. Catalyst composition controlling the O<sub>2</sub> release.
- iv. Catalyst restore its performance after regeneration.
- v. Catalyst properties represented by TPR mathematical model.

The objective function represents such factors as profit, cost, energy, and yield in terms of the key variables of the process being analyzed. The process model and constraints describe the interrelationships of the key variables [70]. In this study the objective function is ethylene partial pressure inside the reactor. The explicit decision variables are Temperature, time and catalyst weight with the implicit catalyst characteristics.

This section deals with development of the optimization model for ethane ODH reaction over VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst. Optimization strategy is to quantify the best solution to a problem within constraints. The optimization models consist of:

- i. Variables: all types may be present.
- ii. Parameters: the parameters are fixed to values.
- iii. Constraints: the limitation on the variables value.

- iv. Mathematical relationships or equations: the mathematical expressions can include equalities, inequalities and logical conditions. In general the model equalities are usually include mass balances, energy balances, equilibrium relations and engineering relations. The model inequalities often consists of allowable operating limits, specification, performance requirement and bounds on availability's.

The general form of such an optimization model is:

$$\max f(x, y, p)$$

such that,

$$h(x, y, p) = 0$$

$$g(x, y, p) \leq 0$$

$$x \in X \subseteq \mathbb{R}^n \quad (x \text{ is a vector of continuous variables})$$

$$y \in Y = \{0, 1\} \quad (y \text{ is a vector of binary variables})$$

$$p \quad (p \text{ is a vector of parameters})$$

- Variables

The continuous variables,  $x$ , are real numbers that may represent time, temperature, pressure and catalyst weight

- Objective Function

In this work the objective for the model is to maximize ethylene partial pressure

- Constraints

$h(x, y, p)$  are the equality constraints which correspond to reaction rates, reaction constants and partial pressure of each components

$g(x,y) \leq 0$  are the inequality constraints which correspond to limitation on time, temperature and catalyst weight

The model for ethane ODH reaction optimization is as follow:

Max

$$\frac{dP_{C_2H_6}}{dt} = -\frac{WRT}{V}(r_1 + r_2) \quad (8.1)$$

s.t

$$\frac{dP_{C_2H_4}}{dt} = \frac{WRT}{V}(r_1 - r_3) \quad (8.2)$$

$$\frac{dP_{C_2H_6}}{dt} = \frac{4WRT}{V}(r_2 + r_3) \quad (8.3)$$

$$r_1 = \frac{k'_1 P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (8.4)$$

$$r_2 = \frac{k'_2 P_{C_2H_6}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (8.5)$$

$$r_3 = \frac{k'_3 P_{C_2H_4}}{1 + K_{C_2H_6}^A P_{C_2H_6}} \alpha \quad (8.6)$$

$$\alpha = \frac{\int_0^T a + b \times \text{Exp}\left[\frac{-(T-T_m)^2}{2 \cdot c^2}\right]}{\int_0^{1000} a + b \times \text{Exp}\left[\frac{-(T-T_m)^2}{2 \cdot c^2}\right]} \quad (8.7)$$

$$K_i = k_{i,0} \text{Exp}\left[\frac{-E_i}{R} \times \left(\frac{1}{T} - \frac{1}{T_m}\right)\right] \quad (8.8)$$

$$525 < T < 600 \quad (8.9)$$

$$20 < t < 120 \quad (8.10)$$

$$0 < W < 1 \quad (8.11)$$

Model established in form of non-linear program NLP with inequality constraints. Model non-linearity appears from the rate [Equations 8.4, 8.5 and 8.6](#) where components partial pressure appears in both numerator and the denominator. And as mentioned earlier; model can be considered as a function of reaction temperature T and time t with catalyst weight. However catalyst properties (metal loading, oxygen carrying capacity) included also with in the term  $\alpha$ . GAMS software was used to optimize the objective function using CONOPT solver.

### **8.1.2. Reaction and kinetic parameters**

Reaction conditions as presented in chapter 4 where temperature varied between 525-600 °C , reaction time 20-50 seconds and catalyst weight in ODH reaction experiment was fixed at 0.4g. However these conditions reflected in the constraints with slight differences in order to explore wider range of conditions in optimization process. Kinetic parameters  $k_0$  and  $E_i$  values can be found in chapter 6 where kinetic model regression achieved and these values estimated. Similarly TPR model  $\alpha$  associated parameters also can be found in chapter 6.

### **8.1.3. Undergoing optimization using GAMS**

Nonlinear models created with GAMS must be solved with a nonlinear programming (NLP) algorithm. Currently, there is a large number of different solvers available and the number is growing. The most important distinction between the solvers is whether they attempt to find a local or a global solution. Solvers that attempt to find a global solution (so called Global Solvers) can usually not solve very large models. As a contrast most local solvers can work with much larger models. In the present study

CONOPT solver was used. The algorithm used in GAMS/CONOPT is based on the GRG algorithm first suggested by Abadie and Carpentier (1969).

## 8.2. Results and discussion

Reactor conditions optimized using GAMS software. Nonlinear solver used in order to maximize ethylene production and thus to minimize CO<sub>x</sub>, also to production and to specify reactor conditions that achieve this objective under number of constraints. Solution using GAMS gives zero errors, NONOPT and bounds. [Table 8.1](#) shows the model parameters value, ethane conversion and ethylene selectivity calculated using [Equations 8.12 and 8.13](#). Moreover new reaction network appears according to optimum solution where there is no CO<sub>x</sub> gases produced directly from ethane as shown in [Figure 8.1](#).

Table 8.1. Optimized kinetics parameters using GAMS software

Parameter	Value
P <sub>C<sub>2</sub>H<sub>6</sub></sub> (atm)	0.602
P <sub>C<sub>2</sub>H<sub>4</sub></sub> (atm)	0.836
P <sub>CO<sub>x</sub></sub> (atm)	0.103
r <sub>1</sub> (mol/gcat.s.atm)	0.172
r <sub>2</sub> (mol/gcat.s.atm)	0
r <sub>3</sub> (mol/gcat.s.atm)	0.043
W (g)	0.2
T (°C)	600
t (sec)	20
α	0.569

Figure 8.1. Optimized reaction network

Equations 8.12 and 8.13 used to calculate ethane conversion and product selectivity:

$$\text{Conversion of ethane} = \frac{\text{Moles of ethane converted}}{\text{Moles of ethane fed}} \times 100 \% \quad (8.12)$$

$$\text{Selectivity of product } i = \frac{\text{Moles of product } i}{\text{Mof ethane}} \times 100 \% \quad (8.13)$$

Optimized ethylene selectivity found to be 92% at 5.9 % ethane conversion ant the optimum conditions found to be 600 °C reaction temperature, 20 seconds reaction period and 0.2 g catalyst weight.

Figure 8.2. Plot of optimum partial pressure in time domain

These results consist with the observed conversion and selectivity trend during ODH reaction at various temperature where ethylene selectivity decreases with time and temperature due to CO<sub>x</sub> formation temperature as can be seen in figure. In literature using different types of catalyst high selectivity to ethylene only achieved at low conversion. In other words selectivity decreases when conversion increased, this low selectivity can be attributed to thermodynamics limitation and selectivity control due to CO<sub>x</sub> gases production [71]. Also these results eliminate reaction in [Equation 7.2](#) in which ethane converted to CO<sub>x</sub> by direct combustion. This is somehow is reasonable because combustion of ethane requires electrophilic oxygen O<sub>2</sub><sup>-</sup>, on the other hand catalyst release nucleophilic oxygen (O<sup>2-</sup> and O<sup>-</sup>) to selectively oxidize the feed [72].

## CHAPTER 9

### CONCLUSIONS AND RECOMMENDATIONS

A series of  $\text{VO}_x/\gamma\text{Al}_2\text{O}_3\text{-ZrO}_2$  catalysts were synthesized, characterized and evaluated in a fluidized CREC Riser Simulator for ODH of ethane to ethylene in gas phase oxygen free reaction conditions. The phenomenological kinetics model was developed using Langmuir-Hinshelwood type rate expression. The optimum reaction conditions were determined using GAMS software and the reaction kinetics data obtained from the CREC Riser Simulator. Following are the conclusion of this research:

#### 9.1. Effect of $\text{ZrO}_2$

- i. XRD analysis show the presence of both  $\text{V}_2\text{O}_5$  and  $\text{ZrO}_2$  species on the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalysts. XRD patterns also indicate that  $\text{VO}_x$  is present in the prepared catalyst in a crystalline phase, with the formation of this crystalline phase being promoted by the  $\text{ZrO}_2$ . Sample of  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3$  catalyst display an amorphous phase only.
- ii. TPR results show good  $\text{V}_2\text{O}_5$  reduction activity at low  $\text{ZrO}_2$  content (2;1 ratios). TPR/TPO oxidation-reduction cycles show good catalyst stability. Increasing  $\text{ZrO}_2$  content decreases the percent of metal reduction.
- iii.  $\text{NH}_3\text{-TPD}$  measurements show the existence of weak acid sites on the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$ . The desorption kinetics suggests a medium range of interaction energies

involved between  $\text{VO}_x$ , and the support, with this likely enhancing metal reducibility.

- iv. ODH of ethane in the presence of  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  and under free oxygen atmosphere shows that ethylene, CO and  $\text{CO}_2$  are the major products.
- v. Among the three samples, the catalyst with  $\gamma\text{-Al}_2\text{O}_3\text{:ZrO}_2 = 2\text{:}1$  ratio gives the highest ethane conversion (37.9%). This result agrees with TPR analysis which shows best reducibility (highest  $\text{H}_2$  consumption).
- vi. The  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst ( $\gamma\text{-Al}_2\text{O}_3\text{:ZrO}_2 = 2\text{:}1$ ) gives ethylene selectivity up to 90 % (at 600 °C) while the unmodified  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3$  catalyst gives 42 % ethylene selectivity under same reaction conditions.
- vii.  $\text{ZrO}_2$  addition alters the acidity and structure of the support which influences the formation of  $\text{VO}_x$  (mono or poly). The  $\text{ZrO}_2$  also affects the metal support interaction and plays a vital role in lowering  $\text{VO}_x$  reducibility, therefore ethylene selectivity was increased due to controlled  $\text{O}_2$  release.

## 9.2. Effect of $\text{VO}_x$ reducibility

- i.  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  catalyst gives good ethylene selectivity at 10%  $\text{VO}_x$  loading. This ethylene selectivity was stable in reaction temperature range.
- ii. XRF techniques was used to confirm catalyst composition and BET surface area was used to measure the surface area.
- iii. XRD and Raman analysis indicates the presence of  $\text{V}_2\text{O}_5$  and  $\text{ZrO}_2$  in the  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  catalyst. XRD pattern of  $\text{VO}_x/\text{Al}_2\text{O}_3\text{-ZrO}_2$  showed that  $\text{VO}_x$  are present in crystalline phase, this phase introduced by  $\text{ZrO}_2$ . Raman spectra

confirmed the existence of isolated and polyvanadate species.  $\text{NH}_3$ -TPD measurement indicates weak acid sites on the  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$ .

- iv. The TPR results showed two peaks due to reduction of  $\text{V}_2\text{O}_5$  which occurs in two steps at low  $\text{ZrO}_2$  contents.
- v. Activation energy from TPR kinetics indicated lower reducibility at high  $\text{VO}_x$  loading with random nucleation mechanism.

### **9.3. ODH Kinetic modeling**

- i. The gas phase oxygen free ODH of ethane in fluidized bed proceeds with series-parallel reaction network forming ethylene, water and carbon oxides as major products. A Langmuir-Hinshelwood type model together with catalyst activity decay model based on TPR results described the reaction rates adequately.
- ii. The model was found to be in a good agreement with experimental data. Reactants and products partial pressure during ODH reaction were predicted satisfactory.
- iii. The formation of ethylene requires least amount of activation energy of 28.4 kJ/mol which is consistent to the experimental data (more selective product).

### **9.4. Optimization of ethane ODH reaction**

- i. Based on kinetic studies of ODH of ethane to ethylene reaction in CREC-riser over  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst, an optimization model developed and TPR mathematical model utilized to describe catalyst activity behavior and properties such as metal loading percentage and type of materials. The optimization model also consistence with reaction data extracted from CREC- riser reactor.

- ii. ODH reaction conditions of ethane to ethylene reaction in CREC-riser over  $\text{VO}_x/\gamma\text{-Al}_2\text{O}_3\text{-ZrO}_2$  catalyst were optimized using the developed optimization model in GAMS software and higher Selectivity and conversion obtained using less amount of catalyst and higher reaction temperature for short period of time.

## 9.5. Recommendations

- i. Further investigation of  $\text{VO}_x$  and  $\text{ZrO}_2$  content and catalyst surface science to increase conversion.
- ii. Different methods of synthesis.
- iii. Different catalyst to feed ratios and fluidization speed.
- iv. Development of reaction rate expression after determination of adsorption constant experimentally.
- v. Development of optimization model to optimize different types of catalysts

## Vitae

Name	: Abd Alwadood Hassan Elbadawi
Nationality	: Sudanese
Date of Birth	: 3/11/1990
Email	: abdulwadoodhassan@gmail.com
Address	: King Fahd University of Petroleum & Minerals, Dhahran
Academic Background	: B.Sc. Chemical Engineering – University of Khartoum

Abd Alwadood H. Elbadawi is a M.S student at department of chemical engineering at King Fahd University of Petroleum and Minerals and research assistant at the research institute center of research excellence in corrosion. He went to University of Khartoum where he was awarded Bachelor of Science in chemical engineering. Currently is a member of research project in chemical engineering department funded by KACST on ethane conversion into ethylene. He also presented research papers in international conferences and presented a poster in the 23<sup>rd</sup> ISCRE & 7<sup>th</sup> APCRE , Bangkok , Thailand , September 2014.

## Research Outcomes

### Journal Papers (in progress):

1- **AbdAlwadood H. Elbadawi**, Mohammed S.Ba-Shammakh, Sameer Al-Ghamdi, Shaikh A. Razzak, Mohammad M. Hossain, Hugo I. de Lasa, “Fluidizable VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> Catalysts for ODH of Ethane to Ethylene in a Gas Phase Oxygen Free Environment”.

2- **AbdAlwadood H. Elbadawi**, Mohammed S.Ba-Shammakh, Sameer Al-Ghamdi, Shaikh A. Razzak, Mohammad M. Hossain, Hugo I. de Lasa, “Fluidized-bed ODH of Ethane to Ethylene over VO<sub>x</sub>/γ-Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> Catalyst: Effect of VO<sub>x</sub> Reducibility on Catalyst Activity”.

3- **AbdAlwadood H. Elbadawi**, Sameer A. Al-Ghamdi, Mohammad M. Hossain.” Kinetic Modeling of Ethane Oxidative Dehydrogenation over 10% VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub>-ZrO<sub>2</sub> Catalyst in a Fluidized-Bed Riser Simulator”.

4- **AbdAlwadood H. Elbadawi**, Mohammed S.Ba-Shammakh, Sameer Al-Ghamdi, Mohammad M. Hossain,” An Optimization Model for ODH of Ethane to Ethylene on VO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst in a fluidized bed CREC Riser Simulator”.

### Conferences Contribution:

1- **AbdAlWadood H.E**, Mogahid Osman, Sameer Al-Ghamdi, Mohammed Ba-Shammakh, Shaikh A.Razzak, , Hugo I. de Lasa, Hossain, M.M. (2014), Fluidized-bed ODH of ethane to ethylene over V<sub>2</sub>O<sub>5</sub>-Nb/La-Al<sub>2</sub>O<sub>3</sub> catalysts, 23rd Canadian symposium on catalysis, Edmonton, Alberta, Canada, May- 2014.

2- **AbdAlWadood Elbadawi**, Mogahid Osman, Mohammed Ba-Shammakh, Shaikh A. Razzak, Hossain, M.M. Hugo I. de Lasa (2014), Oxidative dehydrogenation of ethane to ethylene over V<sub>2</sub>O<sub>5</sub>/La-Al<sub>2</sub>O<sub>3</sub> catalysts, 64th Canadian Chemical Engineering Conference, October 19-22, 2014, Niagra Falls, Ontario, Canada.

3- Idris A. Bakare, **AbdAlwadood H. Elbadawi**, Shaikh A. Razzak, Sameer Al-Ghamdi, Hugo I. de Lasa, Mohammad M. Hossain ,” Fluidized bed ODH of ethane to ethylene over  $\text{VO}_x\text{-MoO}_x/\gamma\text{-Al}_2\text{O}_3$  catalyst: Desorption kinetics and catalytic activity “, 23<sup>rd</sup> ISCRE & 7<sup>th</sup> APCRE , Bangkok , Thailand , September 2014.

4- **AbdAlWadood Elbadawi**, Mogahid Osman, Mohammed Ba-Shammakh, Shaikh A. Razzak, Hossain, M.M. Hugo I. de Lasa (2014), Oxidative dehydrogenation of ethane to ethylene over  $\text{V}_2\text{O}_5/\text{La-Al}_2\text{O}_3$  catalysts, AIChE Annual Meeting, November 16-21, 2014, Hilton Atlanta, GA, USA.
