DEDICATION

This dissertation is dedicated to my family. Thank you for being my pillar of support, and for all your love, patience and guidance.

ACKNOWLEDGEMENTS

I would like to express my sincerest gratitude to the following people and institutions for their unwavering support:

- My supervisors, Dr Gareth Kilian and Mr Yakub Kadernani, thank you for your guidance, advice, input and patience.
- My parents, Alexis and Leah for all your love, sacrifice and patience.
- My sisters Nancy, Shimwe and Phoebe, thank you for being my biggest supporters. Your love and encouragement kept me going.
- My partner Hyacinthe, thank you for being a voice of reason and for your endless motivation.
- My friend, Nancy, thank you for walking alongside me on what seemed like a never-ending journey.
- My support system, Marcellah, Jaret and all my other friends. Thank you for the prayers and late night motivation.
- My fellow postgraduate students for the unforgettable times in the laboratory, constant motivation and advice.
- The staff members of the Department of Pharmacy, especially Mrs Jean van Jaarsveld and Mrs Arista van Jaarsveld for assisting me in the laboratory and ensuring that my environment was conducive for working.
- Mr Lukhanyo Bolo from the Department of Chemistry, for sharing your knowledge and expertise.
- The Nelson Mandela University Centre for High Resolution Transmission Electron Microscopy, for the assistance with microscopy work.
- The National Research Foundation, Dorhmel Cunningham Scholarship and the Nelson Mandela University Postgraduate Research Scholarship for their steadfast financial support.
- To the Almighty, it is by your love and strength that this work was achieved.

ABSTRACT

Purpose: Vulvovaginal candidiasis (VVC) is the second most common cause of vaginitis, affecting 75% of women of sexual maturity. The prescribed first line treatment involves the use of locally-acting imidazole creams. These conventional dosage forms possess limitations, such as leakage, messiness and low residence time at the site of application; all which promote poor patient adherence to pharmacotherapy. Poor adherence is then attributed to increased incidence of VVC reoccurrence and the emergence of *Candida* strains. It was, therefore, speculated that through the use of novel drug delivery systems (NDDS), the pharmacokinetic and antimicrobial characteristics of a model antifungal drug (miconazole nitrate [MNZ]) could be improved.

Primary aim: To develop, optimise and characterise a mucoadhesive hydrogel incorporated with MNZ loaded solid lipid nanoparticles (MNZ-SLNs) for the intended treatment of VVC.

Methodology: This study was conducted in three phases, *viz.* pre-formulation studies, development, optimisation and characterisation of MNZ-SLNs, and the development and characterisation of MNZ-SLN-loaded thermoresponsive hydrogel.

Results: An alternative method for the quantification of MNZ was developed through the use of an octyl stationary phase. The method was deemed suitable for its intended use with a linear equation of $y = 811214x + 67958$ and a respective limit of quantitation (LoQ) and detection of 0.015 mg/ml and 0.052 mg/ml. Differential scanning calorimetry (DSC) studies suggested that cholesterol showed great promise of facilitating high drug entrapment efficiency (EE). MNZ-SLNs were prepared by means of a novel melt-emulsification sonication and low temperature solidification method and optimised statistically by a 13-run-two-factor central composite rotatable design (CCRD). The predicted optimisation parameters were 4% m/v lipid concentration and 260.94 sonication time. Optimal MNZ-SLN formulations were prepared and characterised by means of photon correlation spectroscopy (PCS), transmission electron microscopy (TEM) and centrifugation. PCS revealed uniform particles with a narrow polydispersity index (PDI) and a mean hydrodynamic diameter (z-avg.) of 73.03 nm and zeta potential (ZP) of

38.43 mV. Percent EE was calculated via an indirect method as 75.24%. Furthermore, the MNZ -SLNs were incorporated into a mucoadhesive thermo-responsive hydrogel with a sol-gel transition temperature of 33.33 ± 2.82 °C. *In vitro* drug release testing (IVDRT) was undertaken with the aid of a Franz diffusion vertical cell (FDVC) apparatus. A % cumulative drug release of 27.94% and 15.87% was obtained for MNZ- SLNs and MNZ-SLN hydrogels, respectively, after eight hours. The resultant data was fitted into various kinetic models with the aid of DDSolver™ (Microsoft Excel® add-ins, 2016) to evaluate which model attained the highest correlation co-efficient (r^2). Both formulations attained high r^2 of 0.9941 and 0.9945, respectively, with the Korsmeyer- Peppas mathematical model. A high diffusional exponent (n) of >1 was observed, suggesting a super case II drug release mechanism. Finally, a modified Kirby-Bauer disc diffusion assay was used for ascertaining *Candida albicans* susceptibility to the developed formulations. Controls in the form of unloaded preparations and a commercially available cream were used. MNZ-SLNs and MNZ-hydrogel demonstrated superior antifungal activity to the commercially available cream.

Conclusion: These results indicate that the developed MNZ-SLNloaded hydrogel formulation with localised thermo-responsive effect may be a promising carrier for intravaginal delivery of MNZ in the treatment of VVC.

Keywords: Vulvovaginal Candidiasis (VVC), Solid lipid nanoparticles (SLN), Miconazole nitrate (MNZ), Mucoadhesive hydrogel, Controlled drug release, Thermoresponsive polymers, High performance liquid chromatography (HPLC), Central composite rotatable design (CCRD).

CHAPTER 1

INTRODUCTION

1.1 BACKGROUND

Vulvovaginal candidiasis (VVC), commonly known as vaginal thrush, is an infection characterised by the overgrowth of *Candida* species on the vaginal mucosa (White and Vanthuyne, 2006). It is the second most common cause of vaginitis, following bacterial vaginosis. VVC affects approximately 70 to 75% of women of child-bearing age, half of which will experience multiple episodes of infection in their lifetime (Emeribe *et al.*, 2015; Nelson *et al.*, 2013). The highest prevalence of VVC is observed in women of sexual maturity between the ages of 20 to 40 years (Rathod *et al.*, 2012). Despite extensive research into the prevalence, aetiology and treatment of VVC, a global rise in the frequency of opportunistic infections has been observed in the past decade. Most notably, the growing trend in azole-resistant candidiasis and the alteration of pathogenic fungi, both of which exacerbate the VVC pandemic (Singh, 2001). Furthermore, *Candida* species account for 96% of all opportunistic mycoses (Bondaryk *et al.*, 2013). Due to *Candida* species being a vital cause of morbidity, superficial candidiasis of the mucosa is a major source of pain, irritation and disruption that, consequently, lowers a patient's quality of life (Adolfsson *et al.*, 2016). This serves as a strong motivation for the development of better treatment options.

Imidazole antifungals are a pharmacological class of antimycotic agents that have been formulated into locally-acting dosage forms. The World Health Organisation (WHO) (2017) and the South African National Department of Health (SANDoH) (2017) have approved the use of intravaginal imidazole creams, alone, as standard first line treatment regimens for VVC. When used correctly, imidazole creams demonstrate sufficient efficacy for the treatment of VVC. However, shortcomings, such as brief residence time at the site of infection and frequent need for application, render them impractical. Moreover, the lengthy treatment period of VVC accompanied with impractical pharmacotherapy promote a decline in patients' treatment adherence (Powell, 2010).

To mitigate such shortcomings and adherence failure, two key parameters for improvement could be to better the absorption of the active pharmaceutical ingredient

(API) at the site of infection and prolong drug release, thereby improving pharmacotherapy and subsequent treatment adherence. The availability of a mucosal formulation that combines controlled drug release and mucoadhesive characteristics is desirable (Nalungwe and Kilian, 2016).

Drug absorption is an important pharmacokinetic parameter that is guided by the physicochemical properties of the drug in question, the route of administration and the biological environment of the target site. For efficient drug delivery, the API must be absorbed at the site of application (Chillistone and Hardman, 2017). For systemically-acting dosage forms, the drug should ideally be absorbed consistently and completely at the site of application. In contrast, drugs intended for localised activity (i.e. the imidazole creams) should have minimal systemic absorption in order to prevent unwanted systemic exposure and adverse effects (Gerk *et al.*, 2016). Similar to other mucosal delivery routes, drug permeation across the vaginal membrane occurs through various mechanisms, such as (a) cell diffusion guided by a concentration gradient, (b) receptor-mediated transport and (c) diffusion across a tight junction of cells (Mirza *et al.*, 2016). This varied delivery is due to the vaginal epithelium, which is about 200 to 300 μm thick and is protected by a thin fluid film made up mixture of several biological components and enzymes. This fluid film plays a key role in drug absorption and dilution, as well as the rapid removal of dosage forms from the vagina (Ensign *et al.*, 2013). In addition, drug absorption from vaginal dosage forms is governed by the dissolution of the drug in the vaginal lumen and subsequent membrane penetration (Sahoo *et al.*, 2013). Successful drug delivery via the vagina remains a challenge owing to the poor absorption across the vaginal epithelium (Hussain and Ahsan, 2005).

Another approach for delivery may be to utilise nanotechnology. Nanotechnology is a multidisciplinary scientific field, applying engineering and manufacturing principles at a molecular level. By introducing nanotechnology to medicine, formulations have been created to mimic, alter or improve biological processes (Saini *et al.*, 2010). Innovations in pharmaceuticals have led to the development of new formulations of existing drugs that are more beneficial to patients. Practical applications of nanotechnology in medicine include recent developments in dermatology, tissue engineering, biological assays and cancer therapy to improve the pharmacokinetic parameters of existing drug candidates (Nikalje, 2015). Novel approaches, such as nanoparticulate delivery systems, have been on the forefront of pharmaceutical research. And due to their small

size and large surface area, these drug delivery systems show improved solubility and enhanced bio-availability (Gunasekaran *et al.*, 2014). For example, it has been reported that particles in the size range of 100 nm demonstrated a 2.5-fold increased uptake at the site of absorption compared to 1 μm diameter particles, and a six-fold increased uptake than particles of 10 μm diameter (Desai *et al.*, 1997; Rizvi and Saleh, 2018). This fact served as motivation for this study to investigate nanoparticulate drug delivery for their potential to improve drug absorption of imidazole antifungals through the vaginal mucosa.

However, novel approaches to drug delivery extend far beyond nanotechnology. Hence, the potential use of bioadhesive polymers to provide controlled release (CR) was also investigated for the purposes of this study. Mucoadhesive drug delivery systems are one of the most studied novel delivery systems. Numerous polymers demonstrate characteristics of mucoadhesion and have been employed in the formulation of conventional and novel drug delivery systems (NDDS) (Brahmbhatt, 2017). These formulations not only show an increase in local therapeutic activity but also in the residence time of the dosage form at the site of application (Kumar *et al.*, 2013); all of which would be beneficial in improving the current treatment option of VVC.

1.2 PROBLEM STATEMENT

The prescribed first line treatment regimen of VVC involves the use of a locally-acting imidazole cream (WHO, 2017; SANDoH, 2017). Imidazole antifungals represent one of two main classes of antifungal azole derivatives. However, the majority of these drugs are limited in their clinical use by their adverse effect profile, solubility, spectrum of activity and potency (Fromtling, 1988). Miconazole nitrate (MNZ) and clotrimazole are examples of a commonly used imidazole antifungals for localised VVC treatment (Johnson, 2018). The clinical efficacy of these two drugs is comparable, with no distinction in their curative or reoccurrence rates (Groll *et al.*, 1998; Leberhz *et al.*, 1983). The recommended directions for use state that the cream should be applied intravaginally at night, or, if needed, twice daily. The duration of treatment, however, varies from seven to 14 days, depending on the severity of the disease and the strength of the dosage form (Rossiter, 2017). Higher strengths require shorter durations, but the contrary is true for lower strength dosage forms (Centres for Disease Control and Prevention, 2015). Shorter durations of treatment are also not ideal, as they are

associated with less clinical efficacy and a higher incidence of reoccurrence when compared to longer treatment periods of seven to 14 days (Young and Jewell, 2001).

Furthermore, conventional vaginal drug delivery systems possess limitations, such as leakage, messiness and low residence time at the site of application. Current drug duration, dosage and delivery tend to promote poor patient compliance to pharmacotherapy (Bhat and Shivakumar, 2010). In addition, Jin *et al.*, (2008) stipulates that stopping pharmacotherapy too soon or decreasing dosing frequency can be a type of non-compliance that hinders favourable therapeutic outcomes. These two types of non-compliant behaviour are often observed in women undergoing treatment for VVC with locally-acting agents (Dobaria *et al.*, 2007). The unfortunate consequences of poor compliance include the increased incidence of VVC reoccurrence, emergence of resistant *Candida* strains and sub-therapeutic clinical outcomes that warrant the use of systemic antifungal therapy (Powell, 2010). The use of systemic therapy is discouraged due to its strong association with a greater side-effect profile and increased possibility of drug-to-drug interactions (Faro, 1994).

It was, therefore, speculated in this study that *in vitro* drug release and antimicrobial characteristics of locally-acting vaginal formulations could be improved through the use of NDDS. It was hypothesised that through the introduction of a thermoresponsive and mucoadhesive rate regulating polymer(s), the residence time of the dosage form within the vaginal tract could be prolonged. In addition, the study attempted to present that the reduction of the API particle size by means of a bio-friendly solid lipid nanoparticles (SLNs) could improve the absorption of the drug at the target site. This study, therefore, focussed on the development and characterisation of a MNZ formulation, which possesses poor solubility characteristics, into nanosized colloidal carrier systems (CCS) that allow for improved solubility and controlled drug release of MNZ. The study then further incorporated the carrier system into a thermoresponsive bioadhesive system in order to extend the drug residence time at the site of application. All of this was in an effort to enhance the absorption of MNZ at the target site and prolong its drug release, thereby, consequently, reducing the need for frequent applications.

1.3 AIM AND OBJECTIVES

The aim of this study was to develop, optimise and characterise a mucoadhesive hydrogel incorporated with MNZ loaded solid lipid nanoparticles (MNZ-SLNs) for the intended treatment of VVC.

Based on this aim, the following objectives were defined:

1. To conduct pre-formulation studies on MNZ by means of high performance liquid chromatography (HPLC) and differential scanning calorimetry (DSC);
2. To develop and optimise MNZ-SLNs by means of high-speed ultrasonication and response surface methodology (RSM);
3. To characterise the developed MNZ-SLNs by determining particle size (z-avg.), zeta potential (ZP), polydispersity index (PDI), stability and entrapment efficiency (%EE);
4. To develop a mucoadhesive hydrogel incorporated with MNZ-SLNs by means of a cold mechanical method;
5. To characterise the formulated hydrogel by defining its organoleptic properties, rheology and *in vitro* drug release rate; and
6. To determine the *in vitro* efficacy of the MNZ-SLN loaded hydrogel against *Candida albicans* by means of a modified Kirby-Bauer disc diffusion assay.

CHAPTER 2

LITERATURE REVIEW

21 INTRODUCTION

VVC affects 70 to 75% of the total global female population, and South Africa is no exception (Denning *et al.*, 2018; Govind, 2016). Of those affected, up to 50% will experience multiple episodes of infection in their lifetime (Rathod and Buffler, 2014). Treatment factors, such as lengthy treatment duration and frequent need for application have contributed significantly to the lack of patient adherence to the current prescribed pharmacotherapy (Bhat and Shivakumar, 2010; Dobaría *et al.*, 2007). It is, therefore, imperative to make improvements to the current treatment options in order to offer dosage forms with more favourable dosing regimens and clinical outcomes.

In this chapter, the aetiology and treatment of VVC and the use of NDDS (such as SLNs and mucoadhesive systems) for the improvement of drug delivery are discussed.

22 VULVOVAGINAL CANDIDIASIS (VVC)

VVC, more commonly known as vulvovaginitis or vaginal thrush, is caused by an overgrowth of *Candida* on the vaginal mucosa. The species, *Candida albicans*, accounts for 80 to 92% of all symptomatic VVC infections (Dresser and Brown, 2014). This disease is characterised by a thick 'cottage cheese'-like discharge, severe pruritus, swelling and redness of the vulvar that is accompanied by an acidic vaginal pH of less than 4.5 (Bitew and Abebaw, 2018).

2.2.1 Classification and pathophysiology

Candida forms part of the normal vaginal microflora, along with other microorganisms, in a controlled balance of healthy, non-symptomatic women. VVC is then brought about due to an imbalance between the colonising microflora and yeasts, resulting in the excessive proliferation and pathogenicity of *Candida* (Zeng *et al.*, 2018).

VVC begins with the mucosal surface colonisation by *Candida spp.*, whereby surface molecules permit adherence of yeast to biological structures *viz.* human cells, proteases and phospholipids (Johal *et al.*, 2016). These surface molecules lead to the penetration and damage of cell envelopes that allow for the colonisation of *Candida*.

Candida spp. contain virulence factors that contribute to its disease causing ability. Moreover, an additional virulence factor, known as phenotypic switching, allows for the yeast to convert to its hyphal form, thus promoting pathogenicity and endorsing of resistant traits (Hildago and Vazquez, 2018). *Candida albicans* is the most common pathogen, followed by *Candida glabrata*, which is isolated in six to 16% of all cases (Turner and Butler, 2014). Figure 2.1 illustrates the pathophysiology of VVC.

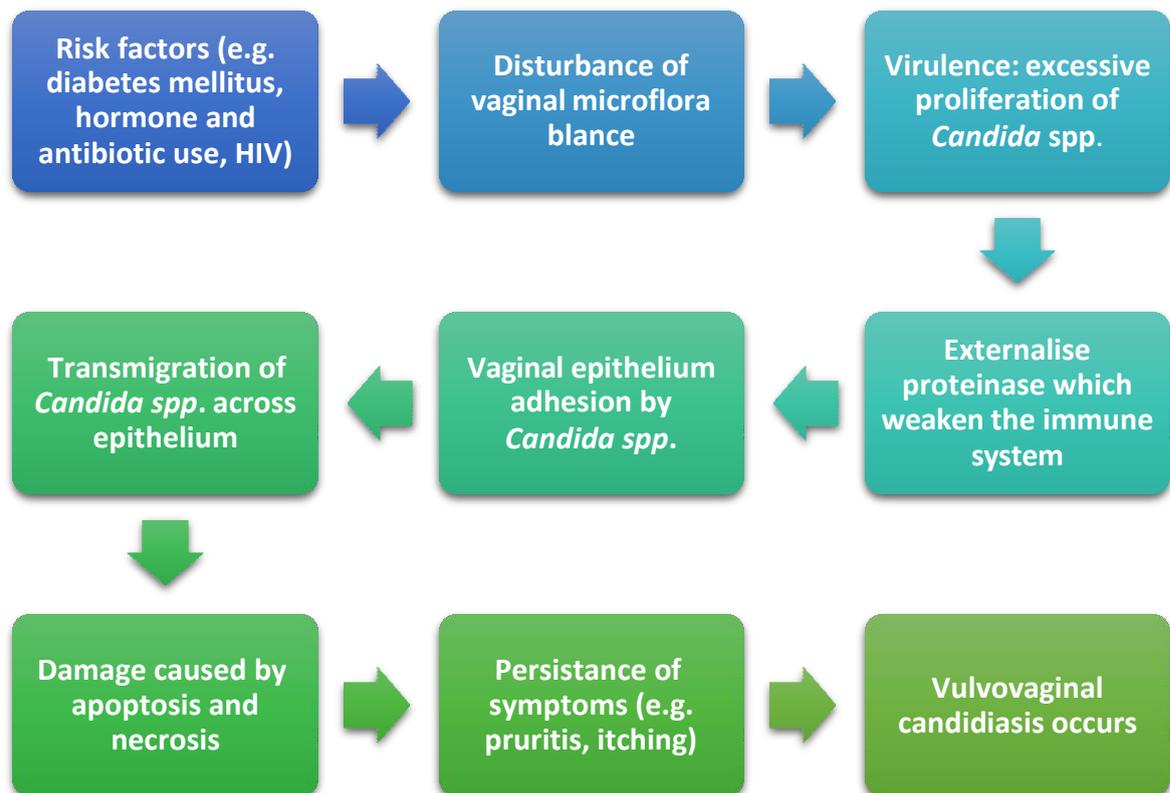

Figure 2.1: Pathophysiology of vulvovaginal candidiasis (VVC) (adapted from Johal *et al.*, 2016)

Symptomatic VVC infections are classified as ‘complicated’ or ‘uncomplicated’, depending on the clinical presentation, host factors, microbiology, response to pharmacotherapy and/or the severity or complexity of the infection (Centres for Disease Control and Prevention, 2015). Uncomplicated infections include sporadic and infrequent *Candida albicans* infections in non-pregnant women. Conversely, complicated infections encompass all chronic and recurrent infections (Owen and Clenney, 2004).

It is imperative that a healthcare professional makes a clear distinction between the various types of VVC infections in order to facilitate appropriate disease management strategies. Uncomplicated VVC is characterised by mild to moderate symptoms, visible hyphae or pseudo-hyphae under microscopic investigations and fewer than four episodes of infection in a year (Sobel, 2007). Complicated infections are characterised by moderate to severe symptoms, the visibility of budding yeast under microscopic examination, four or more episodes of infection in one year and the presence of adverse host factors, such as diabetes mellitus, pregnancy and immunosuppression (Rossiter, 2017). In addition, multitudes of non-*albicans* organisms are identified in complicated infections (Hainer and Gibson, 2011).

2.2.2 Epidemiology

Global statistics indicate that about 70 to 75% of all immunocompetent women will experience at least one episode of infection during their lifetime (Emeribe *et al.*, 2015). The highest rate of infection is observed in females of sexual maturity, between the ages of 20 to 40 years. Of this age group, nearly half will experience multiple episodes (Sobel, 2007; Rathod and Buffler, 2014).

Moreover, the incidence of infection in women of African origin compared to other ethnic groups is significantly higher (Sobel, 2017). However, updated and reliable data on the prevalence of VVC infections in South Africa is almost non-existent (Apalata *et al.*, 2014; Bongomin *et al.*, 2017). This can be attributed to the fact that VVC is not a notifiable disease and, therefore, all statistics and estimations are dependent on self-reported cases. Furthermore, these statistics are based on patient recollection or physician diagnoses (Sobel *et al.*, 1998). It should be noted that 50% of all cases may be mistaken for another vaginal condition, which, without microscopic examination, may deem the diagnosis inconclusive (Sobel *et al.*, 1998).

Factors, such as prolonged antimicrobial or hormonal therapy, pregnancy, HIV and AIDS infection, diabetes mellitus or any other immunocompromised status can contribute to the increased observance of VVC. These factors do so through different mechanisms, such as promoting biochemical changes in the vaginal tract and, consequently, increasing the likelihood of infection and re-infection (Sobel, 2017)

2.2.3 Diagnosis and treatment

Many treatment options are available to patients, but aspects like cost, availability, preference, tolerance and allergies all play a role in the selection of treatment for each individual patient (Nurbhai *et al.*, 2009; Rossiter, 2016). This section of the study focusses on the current pharmacological and non-pharmacological therapies available for the treatment of complicated and uncomplicated VVC infection. Furthermore, the limitations of these treatment options are discussed.

2.2.3.1 Pharmacological treatment options

Pharmacotherapy is the treatment of disease by the administration of drugs (Sanii *et al.*, 2016). For the purpose of this discussion, the current pharmacological treatment options have been divided into two major classes, namely systemic and locally-acting antifungals. Table 2.1 summarises the systemic pharmacotherapies available for the treatment of VVC.

Table 2.1: Current systemic pharmacotherapies for vulvovaginal candidiasis (VVC) (adapted from Rossiter, 2016; Krapf, 2018).

Active ingredient	Strength and dose	Comments
Ketoconazole	400 mg, orally daily for five days	Pharmacological class: Imidazole Drug interactions accredited to cytochrome P450 inhibition. Least effective and most toxic systemic antifungal therapy.
Fluconazole	150 mg, single oral dose	Pharmacological class: Triazole Attributed to numerous drug-to-drug interactions. Most implicated in antimicrobial resistance. Teratogenic effects.
Itraconazole	200 mg, orally daily for three days	Pharmacological class: Triazole Drug interactions accredited to cytochrome 3A4 inhibition.

Azole antifungals represent a class of drugs used for the treatment of various *Candida* infections (Rossiter, 2016). Ketoconazole, an imidazole antifungal, demonstrates *in vitro* activity against numerous fungi species including *Candida* (Bisschop *et al.*, 1979). Ketoconazole was introduced in 1972 by Jansen Pharmaceutica Research Facilities and is currently still in use. Since then, slow but gradual progresses have led to further developments of newer azole derivatives *viz.* fluconazole and itraconazole. These developments display favourable pharmacological characteristics, such as decreased toxicity and improved clinical efficacy which limit the use of ketoconazole (Fromtling, 1988; Khoza *et al.*, 2017).

However, the use of systemic therapies is limited to complicated infections, with the exception of fluconazole. Longer treatment periods with fluconazole, for up to six months, are required for the management of complicated infections (Rossiter, 2016; Krapf, 2018). Although the literature suggests that the efficacy of systemic therapies is comparable to that of local treatments, locally-acting agents are still preferred (Faro, 1994).

Furthermore, systemic therapies show a greater potential for teratogenicity and drug-drug interactions with drugs, such as oral hypoglycaemic and contraceptive tablets (Rossiter, 2016). The prescriber is also compelled to expend great efforts to monitor the patient during such treatment. This not only deters healthcare professionals from performing other duties, but also places an added financial burden on the patient (Pappas *et al.*, 2004). Table 2.2 provides a summary of current locally-acting pharmacotherapies for complicated VVC.

Table 2.2: Current locally-acting therapies for complicated vulvovaginal candidiasis (VVC (adapted from Krapf, 2018; Rossiter, 2016).

Active ingredient	Dosage form	Route of administration and dose
<u>Clotrimazole</u> 100 mg 10 mg/g	Tablet Cream	Pharmacological class: Imidazole One tablet inserted vaginally for six to 12 nights One applicator dose inserted vaginally for six to 12 nights, repeated twice a day if necessary.
<u>Miconazole</u> 20 mg/g	Cream	Pharmacological class: imidazole One applicator dose inserted vaginally for seven nights. Prolonged treatment necessary for severe infections.
<u>Nystatin</u> 10 000 IU	Tablet	Pharmacological class: Polyene antifungal One tablet inserted vaginally once or twice daily for two weeks.

Localised treatment for complicated VVC with imidazole antifungals requires shorter durations (\pm seven days) and is more effective but can be pricier than nystatin. Furthermore, nystatin is not absorbed systemically from the vaginal mucosa and its use is considered safe in pregnancy and lactation (Rossiter, 2016). As for miconazole and clotrimazole, their safety in pregnancy has not been established and they are only deemed acceptable for use in cases of infection that are not responsive to nystatin. For recurrent VVC, longer durations of 10 to 14 days of induction therapy with a topical agent is required; followed by fluconazole 150 mg weekly for six months (Pappas *et al.*, 2016). Current locally-acting pharmacotherapies for uncomplicated VVC are discussed in Table 2.3.

Table 2.3: Current locally-acting therapies for uncomplicated (VVC) (adapted from Krapf, 2018; Rossiter, 2016; Schneider *et al.*, 2018).

Active ingredient	Dosage form	Route of administration and dose
<u>Butoconazole</u> 2% m/m 2% m/m	Sustained release cream Cream	Pharmacological class: Imidazole One single-dose intravaginal application One applicator dose inserted vaginally for three nights
<u>Clotrimazole</u> 500 mg 10 mg	Tablet/cream Tablet	Pharmacological class: imidazole. Single-dose vaginal application at night Two tablets inserted vaginally for three nights
<u>Econazole</u> 150 mg 150 mg 1000 mg/100 g	Depot ovule Ovule Cream	Pharmacological class: imidazole Single-dose vaginal insertion at night One ovule inserted vaginally for three nights One applicator dose inserted vaginally for 14 nights
<u>Fenticonazole</u> 200 mg 600 mg 100 mg/5 g	Ovule Ovule Cream	Pharmacological class: Imidazole One ovule inserted vaginally for three nights Single-dose vaginal insertion at night One applicator dose inserted vaginally twice a day for three days
<u>Miconazole</u> 400 mg	Capsule	Pharmacological class: Imidazole One capsule inserted vaginally for three nights, accompanied by a 20 mg/g cream for external use
<u>Ticonazole</u> 6.5% m/m	Ointment	Pharmacological class: Imidazole Single-dose vaginal insertion at night
<u>Terconazole</u> 0.4% m/m 0.8% m/m	Cream Cream	Pharmacological class: Imidazole derivative One applicator dose inserted vaginally for seven nights One applicator dose inserted vaginally for three nights

Table 2.3 Current locally-acting therapies for uncomplicated VVC (adapted from Krapf, 2018; Rossiter, 2016; Schneider *et al.*, 2018) (Continued)...

Active ingredient	Dosage form	Route of administration and dose
<u>Methylrosanilinium chloride</u> (Gentian violet)	Solution	Pharmacological class: miscellaneous anti-infective 0.5 to 1% v/v solution inserted vaginally by means of a tampon twice a day. Caution note: may stain clothing.
<u>Povidone-iodine</u> 100 mg/g 100 mg/mL	Gel Douche	Pharmacological class: miscellaneous anti-infective One applicator dose inserted vaginally for 14 nights Dilute 30 ml with 1 L of water (H ₂ O) for daily douching
<u>Diiodohydroxyquinoline</u> 1-2%	Gel	Pharmacological class: Quinoline derivatives 4 ml inserted vaginally in the morning and evening for five days, then 2 ml inserted vaginally at night. Note: Available in combination with other anti-infectives

All agents in the imidazole group display equal clinical efficacy in the treatment of VVC caused by *Candida albicans* and other *Candida spp.* (Groll *et al.*, 1998). In addition to demonstrating activity against Gram-positive microbes, such as *Staphylococcus* and *Streptococcus spp.*, cross-resistance amongst different agents of this class occurs (Khoza *et al.*, 2017). Agents with unrestricted antifungal and bacterial activities, such as gentian violet, may be employed as second-line agents following the failure or unavailability of conventional therapies. These alternative agents provide cheaper and efficacious means of treatment. Finally, semisolid preparations, such as creams and gels, are useful for the treatment of a *Candida vulvitis* and a sexual partner (Rossiter, 2016).

2.2.3.2 Non-pharmacological treatment options

Non-pharmacological interventions (NPI) are literature- and scientific-based non-invasive interventions for human health. They aim is to prevent, care and cure ailments.

They are not limited to products but encompass methods or programmes for their users (Nguyen *et al.*, 2016). It is beneficial for healthcare professionals to be aware of all treatment options available to patients, whether conventional or unconventional. The most commonly used NPI are summarised in Table 2.4.

Table 2.4: Non-Pharmacological interventions (NPIs) for VVC (adapted from Sobel and Sobel, 2018).

Ingredient	Dose	Therapeutic benefit	Comments
<u>Lactobacillus capsules or yoghurt</u>	Five to 10 billion colony forming units (CFUs) orally, daily	Maintenance of immunity and vaginal microflora	No supporting evidence on efficacy from randomised control trials (RCT)
<u>Boric acid</u>	600 mg capsule inserted vaginally for seven to 10 nights	Relief of symptoms in recurrent VVC	Intravaginal capsule may cause burning or itchy sensation upon insertion which promotes poor compliance
<u>Douche</u>	Douching with 1% v/v hydrogen peroxide and 1% v/v acetic acid solution twice a day	Cleansing of the vaginal tract	Irritation to the vaginal mucosa. Increased risk of pelvic inflammatory disease, endometriosis and ectopic pregnancy.
<u>Tea tree oil</u>	Three to five drops every one to four hours until symptoms are alleviated	Alleviation of symptoms and discomfort	No supporting evidence of efficacy from RCT
<u>Garlic</u>	Standard extract of 400 mg (or one clove) inserted vaginally two to three times a day	Possible antifungal and immune stimulating activity	No supporting evidence of efficacy from RCT. Possible drug-to-drug interactions (e.g. warfarin).

Lactobacillus supplementation (or probiotics) through oral consumption or topical application is the most commonly used NIP for the treatment of chronic VVC (Xie *et al.*, 2013). Although 40% of women use alternative products, such as probiotics and 7% will seek advice from a complementary and alternative health specialist, there is limited literature on the use and efficacy NIP for the aforementioned NPI of VVC

(Morgan *et al.*, 2009). In addition to the recommended therapies, a healthcare professional could further advise a patient on supplementary precautions to promote favourable therapeutic outcomes. Table 2.5 provides a brief summary of such examples.

Table 2.5: Supplementary precautions for vulvovaginal candidiasis (VVC) management (adapted from Powell, 2010)

Precaution	Comments
Avoid excess sweating, keep vaginal area dry	Moist environment promotes excessive <i>Candida</i> proliferation
Avoid sexual intercourse until symptoms have cleared and treatment has been completed	VVC is not considered to be a sexually transmitted disease (STD), however, asymptomatic <i>Candida</i> colonisation of male genitalia is four times more likely in sexual partners of infected females (Centres for Disease Control and Prevention, 2015) Antifungal creams interfere with the barrier method of contraception, and sexual activity can decrease the residence time of locally-acting treatments
Take showers instead of baths and use unscented feminine hygiene products	Scented soaps may upset the natural flora balance or pH of the vaginal milieu, thus causing irritation or exacerbation of symptoms
Wear cotton underwear and loose-fitting clothes	Allows for the evaporation of excess moisture. Tight-fitting clothes promote friction and maceration, thereby increasing local acidity

Lifestyle habits play a key role in the introduction of microbes to the vaginal area and the changing of the normal microflora therein. Such changes can promote the pathogenicity of *Candida*. (Zeng *et al.*, 2018). Therefore, by promoting good hygiene practices frequent or persistent infections are reduced (Parsapure *et al.*, 2016).

2.2.3.3 Limitations of current treatment options

Uncomplicated VVC is the only vaginitis infection for which over-the-counter (OTC) treatments are readily available, and which allows women the liberty to self-diagnose and treat their ailment. It is critical, therefore, that patients are able to make a clear distinction between VVC and other vaginal infections so that appropriate treatment is not delayed. Topical azole formulations are available OTC and have been shown to have up to 90% clinical efficacy for the treatment of uncomplicated infection. These

products are considered safe, even though some patients have complained about a burning sensation (Angotti *et al.*, 2007). Short-course or single-dose treatments are the preferred dosing regimen, since they promote patient compliance. However, these preparations are closely linked to the rise in incidences of non-*Candida albicans* infections and cross-resistance amongst azole antifungals (Faro *et al.*, 1997).

Factors, such as cost, length of treatment, dosage form, ease of use and convenience, play a significant role in product selection and adherence to pharmacotherapy (Rossiter, 2016). Ideally, vaginal creams should be used at night with a sanitary pad to aid with the absorption of any leakage. Furthermore, sufficient patient counselling on the correct use and cleaning of the applicator device should be given in order to promote good hygiene practices and correct dose measurements (Vail *et al.*, 2004). Other drawbacks of locally applied treatments include their short residence time at the site of infection and the frequent and lengthy treatment periods; all of which promote poor adherence to pharmacotherapy (Dobaria *et al.*, 2007).

Patients should also be alerted to the fact that oil-based formulations, such as creams, weaken latex condoms and diaphragms, subsequently reducing the efficacy of contraceptive device (Meyboom *et al.*, 1995). Furthermore, locally-acting tablets and ovules are a more attractive form of treatment because they are not limited to nocturnal use, since their potential for leakage is diminished. However, they do not provide the benefit of vulvar application in cases of severe pruritus; yet, they do exhibit a greater extent of systemic absorption. Therefore, their potential for drug-interactions should be monitored carefully (Ringdahl, 2000).

With the exception of fluconazole, oral therapy is reserved for complicated VVC with moderate to severe symptoms. As previously stated, systemic treatments are not preferred over local therapies owing to their close association with drug-drug interactions and adverse systemic effects (Faro 1994; Rossiter, 2016). Furthermore, itraconazole and ketoconazole inhibit cytochrome 3A4 and P450, respectively; hence their implication in numerous drug interactions. Apart from its teratogenic effects and unsolicited systemic side-effects, fluconazole is the most implicated agent in the emergence of resistant fungi strains (Kaplan *et al.*, 2015; Whaley *et al.*, 2017).

2.3 INTRAVAGINAL DRUG DELIVERY

The route of administration for drugs is the path wherein the drug enters the body (Verma *et al.*, 2010). The vagina, as a means of drug delivery, offers many benefits, such as easy access, self-administration, systemic and localised drug delivery and the avoidance of the first-pass hepatic metabolism. Moreover, its large surface area promotes the absorption of various locally-acting agents with minimal side-effects (Andrade *et al.*, 2014).

The intravaginal route of administration also possesses some drawbacks, such as its self-cleaning nature which, in turn, reduces the residence time of conventional dosage forms at the site of application. Other drawbacks can occur in relation to hormonal fluctuations resulting from menopause or menstruation which bring about changes in vaginal characteristics (Sahoo *et al.*, 2013). These changes have a direct effect on conditions, such as pH and fluid volumes, which then affect the rate and extent of drug absorption (Khan and Saha. 2015). Factors that affect drug delivery from the vaginal mucosa, such as its anatomy and physiology, and variations in dosage formulations are discussed in more detail later in this chapter.

2.3.1 Anatomy and physiology of the vagina

The human vagina is a fibromuscular tube that connects the uterus to the exterior. It forms part of the female reproductive system, along with the fallopian tubes, ovaries, uterus, vulva and mammary glands (Amati *et al.*, 2003). Figure 2.2 illustrates the anatomical structure and location of the vagina.

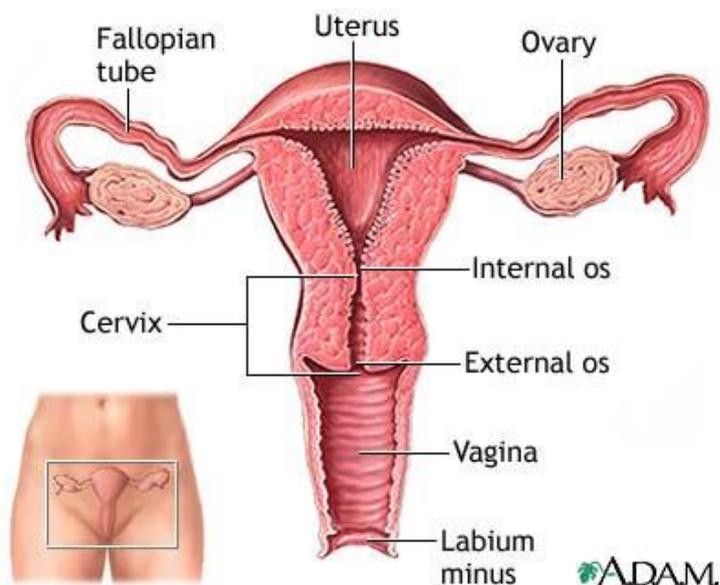

Figure 2.2: Anatomical structure of the human vagina (Microbewiki, 2016).

The vagina is made up of three distinct layers, namely the epithelial layer, *lamina propria* or *tunica adventia* and a muscular coat. The epithelial membrane layer lining the vaginal tract extends from the uterine cervix to the exterior genitalia and is covered with mucous. This membrane is comprised of stratified squamous cells that lie in sequential folds that increase its surface area. Although the surface lacks goblet cells and direct release of mucous, it is still considered a mucosal surface due to the fluid secreted by the cervix and uterus (Hussain and Hassan, 2005; Anderson *et al.*, 2014). Cervical and uterine secretions and transudation from blood vessels and desquamated vaginal cells and leucocytes constitute the vaginal mucous (Amati *et al.*, 2003).

Any alteration in the quantity, pH and constituents of fluid can affect the rate and extent of drug absorption. Similar to other mucosal surfaces, drug absorption via the vagina occurs transcellularly by means of concentration-dependent diffusion through cells; paracellularly by means of tight junctions; and via vesicularly- or receptor-mediated transport (Hussain and Ahsan, 2005). Moreover, the rate and extent of absorption is also influenced by factors like formulation type, vaginal physiology, menstrual cycle and patient age (Dodou, 2018).

2.3.2 Vaginal dosage forms

Conventional topical intravaginal systems have been used extensively to treat systemic and localised ailments. Ideally, intravaginal formulations should be non-toxic and non-irritating, and should possess wetting and emulsifying properties with adequate viscosity so as to avoid leakage. Mucoadhesive properties are also advantageous in

increasing the contact time between the formulation and site of application (Sahoo *et al.*, 2013). Table 2.6 presents examples of commonly used formulation systems intended for intravaginal delivery of various therapeutic agents.

Table 2.6: Formulation systems available for intravaginal drug delivery (adapted from Dodou, 2018).

Formulation type	Characteristics
Creams, gels, ointments	Semi-solid preparations utilised for localised or systemic drug delivery
Capsules	Single-dose, solid preparations with a smooth surface for localised or systemic drug delivery
Tablets	Single-dose, solid preparations with a smooth surface for localised or systemic drug delivery
Pessary	Single-dose, solid preparation for vaginal insertion
Foams, sprays	Drug and propellant contained as a solution or suspension under pressure
Suspensions, solutions, emulsions	Liquid preparations intended for localised drug delivery. Suspensions and emulsions require agitation prior to use, as phase separation and sedimentation can occur.
Films	Thin sheets for CR of localised or system-intravaginal drug release
Rings	Flexible circular system with drug contained in a polymer network
Medicated tampons	Single-dose solid preparations inserted in the vagina for a limited time and then removed

Based on the information presented in Table 2.6, there are a wide array of dosage forms available for intravaginal drug delivery. The variation in dosage formulations is to ensure accurate drug delivery, confer protection of the API, delivery of the API to the targeted site for optimal pharmacological action and to ensure the desired vehicle is used for insoluble drugs (Chatterjee *et al.*, 2008).

Solid formulation systems include tablets and pessaries. Pessaries are formulated to melt or dissolve upon vaginal insertion. The term 'pessaries' encompasses formulations, such as capsules and vaginal suppositories. They are spherical, conical or globular; weighing about 5 g (Dodou, 2018). Pessaries have been used extensively for the delivery of antimicrobial and contraceptive agents, and their benefits include cost-effective and easy manufacturing processes as well as accurate dose delivery upon administration (Punitha *et al.*, 2018). However, drawbacks of pessaries include their lack of symptomatic relief of pruritis which can contribute to low patient acceptability. Moreover, they are not ideal for highly lipophilic drugs, such as MNZ, which poses an issue for drug absorption at the site of infection (Rahman and Ahmed, 2016).

Douches are aqueous solutions administered vaginally for cleansing purposes. Regular douching is associated with increased susceptibility to pelvic inflammatory disease and is, therefore, discouraged (Martino and Vermund, 2002).

Vaginal rings are polymeric devices comprised of elastomeric polymers, such as silicone. They provide extended drug release and do not interfere with coitus; hence, they do not require frequent dosing or administration. A drawback of vaginal rings is, however, that they hold the potential for poor biotolerability of the elastomeric polymer (Punitha *et al.*, 2018).

Vaginal foams are a fairly new method of intravaginal drug delivery derived from the concept of vaginal rings. These formulations are used to deliver antimicrobial or anaesthetic medications. Most foams are non-irritant to the vaginal mucosa, as they are made from soft polyurethane (Dodou, 2018).

Vaginal tampons are traditional intravaginal formulations that have been approved by the food and drug administration (FDA) (Pollard, 2005). This feminine hygiene product is made up of soft material incorporated with the drug for vaginal insertion. This formulation facilitates the insertion of medicines without messiness and leakage. However, its drawbacks include low patient acceptability owing to its discomfort (Alexander *et al.*, 2004).

Vaginal films are a fairly new approach to vaginal drug delivery. They are thin sheets made up of polymeric materials that offer controlled drug release for localised or systemic action. Furthermore, they offer favourable organoleptic characteristics and homogenous drug delivery, thus making this product a good candidate for vaginal drug delivery (Machado *et al.*, 2013).

Finally, semi-solid preparations have been investigated extensively for vaginal drug delivery. Semi-solid formulations include the likes of creams, ointments and gels. Ointments and creams are comprised of a H₂O and oil phase, while gels are aqueous-based formulations (Chen *et al.*, 2016). These formulations are non-toxic and non-irritating, with high patient acceptability. The drawbacks of such products include messiness and leakage which promote discomfort. In addition to discomfort, leakage also results in non-uniform drug delivery (Bharat *et al.*, 2011).

The majority of vaginal formulations require a plastic insertion device to facilitate easy application and accurate dose delivery. If used incorrectly by a patient, optimal pharmacological benefits are not achieved (Dodou, 2018). Therefore, the main cause of therapeutic failure with topical agents is poor patient compliance (Cardot *et al.*, 2004). In order to address this issue, great interest has been shown in the pharmaceutical industry to make improvements in relation to this shortcoming. This study may aid the industry in this endeavour.

2.4 NOVEL APPROACHES TO INTRAVAGINAL DRUG DELIVERY

A growing interest in the use NDDS to overcome the limitation of conventional dosage forms has been observed in the pharmaceutical industry. The development of newer intravaginal drug delivery formulations is mainly driven by the need to increase choice and, thereby, compliance by the wider female population (Sawant and Khan, 2017). To achieve desirable bioadhesion, distribution, formulation retention within the vaginal tract and CR characteristics, novel approaches for intravaginal drug delivery have also been explored (Kenechukwu *et al.*, 2018).

Mucoadhesive drug delivery systems have been on the forefront of such pharmaceutical novel developments. Owing to their hydrating nature and good binding capacity to mucosal tissue for a considerable amount of time, these delivery systems

are investigated further in this research. This is because they offer an extended and predictable delivery rate of the API from the formulation, thus reducing the need for frequent application. Furthermore, a 25% reduction in the treatment time was reported for mucoadhesive formulations versus conventional treatments (Sahoo *et al.*, 2013).

Similarly, phase-transitioning polymers that respond to external stimuli, such as temperature and pH, are also drawing a lot of attention in pharmaceutical research. They can be formulated to undergo a sol-gel transition around a temperature range of interest. Furthermore, the combination of a mucoadhesive and phase-transitioning polymer allows for prolonged residence of the dosage form at the site of action (Baloglu *et al.*, 2009; Rencber *et al.*, 2016).

Effervescent vaginal tablets are also a recent development that allows for quick absorption of the API at the application site. They demonstrate a greater efficacy in antifungal delivery when compared to conventional solid formulations (Patel and Patel, 2010). Another distinct but equally exciting field of NDDS explored for intravaginal drug delivery is CCS. These systems include the likes of polymeric, micellar, liposomal and solid lipid nanoparticles. They focus on the improvement of API delivery and absorption at the application site through a reduction in particle size and targeted drug delivery (Mudshinge *et al.*, 2011).

The following factors should be taken into consideration when formulating any intravaginal formulation: (a) the maintenance of a desirable pH on the epithelial surface, (b) ease of application, considerable drug retention in the vaginal tract and (c) even drug distribution (Ibanga, 2012). Desirable formulation characteristics, such as compatibility with co-administered drugs, safety, efficacy, aesthetics, cost-effectiveness and acceptability by regulatory authorities promote patient use and compliance (Bharat *et al.*, 2011).

2.4.1 Colloidal carrier systems

CCS are particulate or vesicular formulations in the nanometre range size, ranging from 10 to 1000 nm (Mudshinge *et al.*, 2011; Sharma *et al.*, 2009). CCS were introduced to the pharmaceutical industry with the aim of improving the therapeutic index of many active compounds, either through the reduction of API's toxicity profile or through the improvement of its pharmacological efficacy (Tiwari *et al.*, 2012). CCS facilitate the protection, transportation and preservation of an API prior to delivering it

to the targeted site (Chashoo *et al.*, 2012).

There are many advantages of employing CCS in drug delivery, such as targeted delivery, the reduction of API size to facilitate better absorption and reduction in the amount of API required in various dosage forms; all of which minimise the potential for adverse effects and possible drug-drug interactions (Mudshinge *et al.*, 2011). Furthermore, CCS allow for the incorporation of compounds with poor aqueous solubility into particulate systems. These systems can then be formulated in a manner that facilitates sustained drug release, thereby reducing the dosing frequency and, consequently, promoting patient adherence (Gelperina *et al.*, 2005).

2.4.1.1 Comparison of colloidal carrier systems (CCSs)

CCS encompass a vast number of NDDS *viz.* nanoemulsions, mixed micelles and SLNs. Table 2.7 provides a brief summary of various CCS.

Table 2.7: Characteristics of various colloidal carrier systems (CCS)

Colloidal system	Size range	Characteristics	Applications
Non-ionic micelles	10 to 1000 nm	Biodegradable, complete API protection	Good candidate for sustained drug delivery. Passive or active drug delivery achieved with modifications.
Solid lipid nanoparticles	50 to 1000 nm	Biocompatibility, biodegradable, sustained drug release	Provides good encapsulation of poor hydrophilic compounds
Nano-crystal quantum dots	2 to 9.5 nm	Semi-conducting material synthesised from II-IV and III-V column elements. Bright fluorescence with narrow emission and high photo-stability.	Long-term colour imaging of hepatic cells. DNA hybridisation, immunoassay, labelling of breast cancer cells.

Table 2.7: Characteristics of various colloidal carrier systems (CCS) (continued)

Colloidal system	Size range	Characteristics	Applications
Carbon nanotubes	0.5 to 3 nm (diameter) 20 to 1000 nm (length)	Possess incredible strength and distinctive electrical properties. Third allotropic crystalline form of carbon sheets as a single or multiple layer.	Carrier for peptide and gene delivery
Dendrimer	<10 nm	Highly branched, mono-dispersed polymer system produced through controlled polymerisation	Controlled and targeted delivery of bio-actives. Macrophage hepatic targeting.
Metallic nanoparticles	<100 nm	Gold/silver colloidal systems with high surface area	Drug/gene delivery, diagnostic assay, thermal ablation, enhancement of radiotherapy
Polymeric micelles	10 to 100 nm	Amphiphilic polymer micelles with high drug entrapment, payload and stability	Long circulatory, target specific delivery and diagnostics
Liposomes	50 to 100 nm	Phospholipid vesicles, biocompatibility and fair entrapment efficiency	Long circulatory, passive and active delivery of gene, peptides and other drug candidates
Iron oxide nanocrystals	4 to 5 nm with a hydrodynamic radius of 15 to 25 nm	Supraparamagnetism	Magnetic resonance imaging
Silica nanoparticles	10 nm to 50 μ m	Coated by oligonucleotide and observed by fluorescence	Nucleic acid hybridisation Detection of DNA nanobiosensor

Based on the summary provided in Table 2.7, CCS are divided into two distinct groups, namely microparticulate and vesicular systems. Nanoparticulate systems include the likes of micelles, nanocapsules, magnetic and albumin microspheres, quantum dots and fullerenes. Vesicular systems include liposomes, niosomes, pharmacosomes, virosomes and immunoliposomes (Bhardwaj and Kumar, 2011).

Nanoparticulate systems comprise of synthetic or semi-synthetic polymers. They contain drugs embedded within a matrix or absorbed on the surface. Nanospheres are solid core spherical particulates, nanocapsules systems contain an API encapsulated within a central volume surrounded by an embryonic polymeric sheath and, finally, nanocrystals contain drugs that are encapsulated in a solution (Bhardwaj and Kumar, 2011). Some key advantages of nanoparticulate systems include their high stability and carrier capacity; their feasibility of variable routes of administration (ROA); and their incorporation of both hydrophilic and lipophilic drugs. In addition, they are designed to be able to facilitate controlled drug release from their matrices (Khadka *et al.*, 2014). In spite of these advantages, nanoparticulate systems possess some limitations, such as particle-particle aggregation, which makes physical handling difficult (Jawahar and Meyyanathan, 2012). The cytotoxicity of nanoparticulate systems or their degradation products remain a major concern for drug delivery in human and animal subjects (Tiwari *et al.*, 2012).

Vesicular CCS are highly ordered assemblies comprising of one or more concentric bilayers formed from the self-assembly of amphiphilic building blocks in the presence of H₂O. They are particularly useful for targeted drug delivery due to their ability of localising drug activity at the site of action (Jain *et al.*, 2014). Vesicular CCS offer many advantages, such as the incorporation of lipophilic and hydrophilic drugs, the improvement of bio-availability of API at the targeted site, the prolonging of the circulation time of drugs in the body and the resolution of stability and issues of labile drugs (Jadhav *et al.*, 2011). Liposomes, in particular, have gained great interest in the past decade for targeted drug delivery. These lipid structures comprise of an aqueous compartment enclosed in a bilayer membrane (Hirai *et al.*, 2013). Yet, despite offering many advantages of vesicular CCS, liposomes also possess drawbacks, such as premature drug release, poor encapsulation efficiency of hydrophilic drugs and a short life span (Biju *et al.*, 2006). Improvements in biocompatibility, drug loading (DL) and release are a major concern for future research.

SLNs are novel carrier systems derived from liposomes and were introduced in 1991 for the delivery of cosmetic and pharmaceutical ingredients (Ekambaram *et al.*, 2011). They are spherical structures with a lipid core that solubilises lipophilic molecules (see Figure 2.2) (Ramteke *et al.*, 2012). Their long-term physical stability, biodegradability, protection of API and the absence of organic solvents in their formulation make them ideal pharmaceutical carriers. SLNs combine the benefits of various colloidal systems whilst avoiding their drawbacks (Swain and Babu, 2015); therefore, this study limits itself to the investigation of SLNs as potential drug carriers in facilitating favourable intravaginal drug delivery.

2.4.1.2 Solid lipid nanoparticles (SLNs)

SLNs comprise a solid lipid core matrix that is stabilised in an aqueous solution by emulsifiers (Lin *et al.*, 2017). Their generic structure is illustrated in Figure 2.3, where the core contains the API dispersed or dissolved in the lipid matrix. This matrix offers protection of APIs against chemical degradation whilst providing sustained drug release. The hydrophobic portions of the surfactant layer are embedded into the lipid matrix and are responsible for the transportation of lipophilic and/or hydrophilic drugs or diagnostics (Bagul *et al.*, 2018).

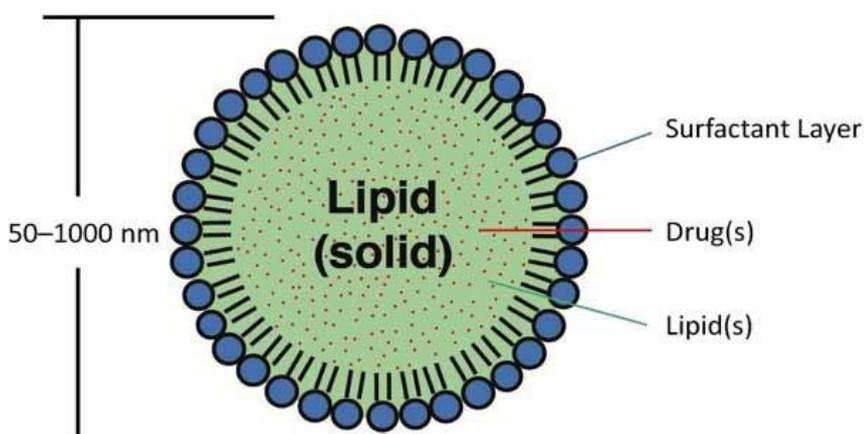

Figure 2.3: Generic structure of a solid lipid nanoparticle (SLN) (Khatak and Dureja, 2015).

SLNs utilise biodegradable lipids in their production that minimise the risk of toxicity to the mucosal tissue (Ekambaram *et al.*, 2011). They offer improved bio-availability of drugs that possess poor aqueous solubility and enhance the permeation of topically administered drugs (Shah *et al.*, 2007). The various production methods allow for possible scaling up at an industrial level, whilst simultaneously offering good stability and safety for intravaginal drug administration (Garud *et al.*, 2012). Drawbacks of this

delivery system include poor DL capacity, drug expulsion upon storage and high H₂O content (Schwarz *et al.*, 1994).

i. Constituents of solid lipid nanoparticles (SLNs)

The performance of an SLN formulation is highly influenced by its structure and composition (Shah *et al.*, 2015). Lipids, surfactants, co-surfactants and API account for the four basic materials used in the formulation of SLNs (Khatak and Dureja, 2015). Lipids are organic compounds that contain long-chain aliphatic hydrocarbons. These chains may be cyclic or acyclic, with an attached acid, alcohol or aldehyde derivative (Gigg, 2018). Table 2.8 illustrates some examples of commonly used lipids in the formulation of SLNs. The lipid materials are usually solid at room temperature, and are well-tolerated in physiological conditions (with the exception of cetyl palmitate). These selected lipids also possess low toxicity profiles and are biocompatible (Lin *et al.*, 2017). Based on their structural diversity, these lipids have been classified into fatty acids, alcohols, esters, triglycerides, partial glycerides and waxes (Shah *et al.*, 2015).

Table 2.8: Commonly used lipids in the formulation of solid lipid nanoparticles (SLNs) (adapted from Shah *et al.*, 2015).

Lipid group	Examples
Monoglycerides	Glyceryl monostearate
Triglycerides	Glyceryl tristearate, glyceryl palmitate, glyceryl trimyristate, glyceryl trioleate, medium chain triglycerides
Free fatty acids	Behenic acid, stearic acid, palmitic acid, myristic acid, oleic acid
Free fatty alcohols	Stearyl alcohol, cetyl alcohol, myristyl alcohol, lauryl alcohol
Waxes	Cetyl palmitate, beeswax, carnauba wax
Miscellaneous	Castor oil, hydrogenated castor oil, hydrogenated palm oil, cacao butter, goat fat, anhydrous milk fat
Mixtures	Glyceryl behenate, glyceryl palmitostearate, witepsol

Lipid compositions demonstrate the greatest effect on the overall quality of SLN formulation by influencing the API loading capacity, ZP and retardation of crystallisation processes (Pardeshi *et al.*, 2012). The solubility of the API candidate in the lipid matrix is pivotal, as it influences the drug encapsulation and loading efficiencies and,

consequently, the pharmacodynamics and pharmacokinetic parameters of the dosage form (Kasongo *et al.*, 2011).

Lipid polymorphisms are additional factors that affect the properties of an SLN formulation. The presence of multiple crystalline forms is beneficial in providing structural defects in which drugs molecules can be lodged (Schoenitz *et al.*, 2014). Complex mixtures of lipids are desirable, owing to variations in chain lengths which, in turn, produce less perfect crystals, thereby providing more space to accommodate drugs and decrease the likelihood of drug expulsion upon storage (Parhi and Suresh, 2010; Shah *et al.*, 2015).

Surface active agents, more commonly known as surfactants, are amphiphilic compounds that adsorb an interface in order to form orientated monolayers that aid in the reduction of surface tension between two immiscible media (Uner *et al.*, 2004). When a surfactant is placed in close contact with a polar medium (e.g. an aqueous solution) and a non-polar medium (e.g. a lipid), one section of the surfactant molecule will have an affinity for the non-polar medium and the other will orientate towards the polar component (Shi *et al.*, 2011).

SNLs can be categorised into three main groups, based on their respective charges (Naseri *et al.*, 2015; Shah *et al.*, 2015). For example, ionic surfactants are thought to impart electrostatic stability, whereas non-ionic surfactants infer steric repulsion stability. Similarly, amphoteric surfactants, such as phosphatidylcholines, possess both negatively- and positively-charged functional groups. They display features of cationic and anionic surfactant at high and low pH. Furthermore, non-ionic surfactants, such as poloxamer 470 or 188 are preferred for drug delivery, as they are less toxic and non-irritant than ionic surfactants (Uner *et al.*, 2004). They also do not alter the pH of a solution and they possess a higher critical micellar concentration (CMC), thus allowing the use of more surfactant in the SLN formulation without the risk of generating unwanted micelles (Shi *et al.*, 2011). A list of commonly used surfactants in the production of SLNs is provided in Table 2.9.

Table 2.9: Commonly used surfactants in the formulation of solid lipid nanoparticles (SLNs) (adapted from Shah *et al.*, 2015).

Surfactant group	Examples
Non-ionic	Polyoxyethylene (PEO) sorbitan fatty esters: polysorbate 20, 60, 80, 85
	PEO alkyl/aryl ethers: PEO(20)cetyl ether, polyoxyethylene(20)isohectadecyl ether, polyethylene(20)oleyl ether, PEO(20)stearyl ether, tyloxapol
	Ethoxylated castor oils: Polyethylene glycol (PEG) 35, castor oil, PEG 40, hydrogenated castor oil
	Poloxamers: 188, 407
	Miscellaneous: PEO-glycerine monostearate, macrogol(15)hydroxystearate, PEG caprylic/capric triglycerides, polyglyceryl-3-methylglucose distearate
Anionic	Sodium dehydrocholate, sodium taurocholate, sodium glycocholate, sodium cholate, sodium lauryl sulphate
Cationic	Cetrimonium bromide, DOTAP, DPTMA, chlorhexidine salts, dimethyldiocta-decylammonium bromide
Amphoteric	L- α -phosphatidyl-choline, soya lecithin, egg lecithin
Co-surfactants	1-Butanol, low molecular weight PEG, diethylene glycol, monoethyl ether, propylene glycol, ethanol, sorbitan monostearate

Surfactants used in the preparation of SLN formulation play two distinct roles. Firstly, they disperse the lipid-melt in the aqueous phase during the production process. Secondly, they stabilise the particles in the dispersion upon cooling (Uner *et al.*, 2004). The selection of an ideal surfactant for a given formulation is dependent on the intended route of administration, effect on particle size and lipid modification, *in vivo* degradation of material and hydrophilic lipophilic balance (HLB) value of the surfactant. The combination of two or more surfactants is encouraged for promoting particle stability by preventing agglomeration more effectively (Mukherjee *et al.*, 2009, Shah *et al.*, 2015).

2.4.1.3 Preparation techniques of solid lipid nanoparticles (SLNs)

The preparation of SLNs commences with the selection of an appropriate lipid base and surfactant (emulsifier), followed by the selection of an appropriate method of production (Naseri *et al.*, 2015). Selecting a good method of production is critical for obtaining favourable formulation characteristics, such as particle size, scalability and stability (Mukherjee *et al.*, 2009). Various formulation techniques are discussed in this section.

High pressure homogenisation (HPH) is the most commonly used technique for SLN preparation (Yadav *et al.*, 2014). The mechanism of nanoparticle formation begins with pushing a coarse dispersion under high pressure (100 to 200 bars) through a micron size gap. The pressure causes rapid acceleration of the liquid, reaching speeds of greater than 1000 km/h and resulting in the breakdown of particles by shear cavitation forces (Kokardekar and Mody, 2011). This well-established technique may be conducted at elevated or lowered ambient temperature. Elevated temperatures are referred to as hot homogenisation, while lowered temperatures are referred to as cold homogenisation (Parhi and Suresh, 2012). Figure 2.4 illustrates the process of both hot and cold homogenisation techniques. Both of these processes work on the same concept of mixing drugs into the bulk of the lipids above their melting points.

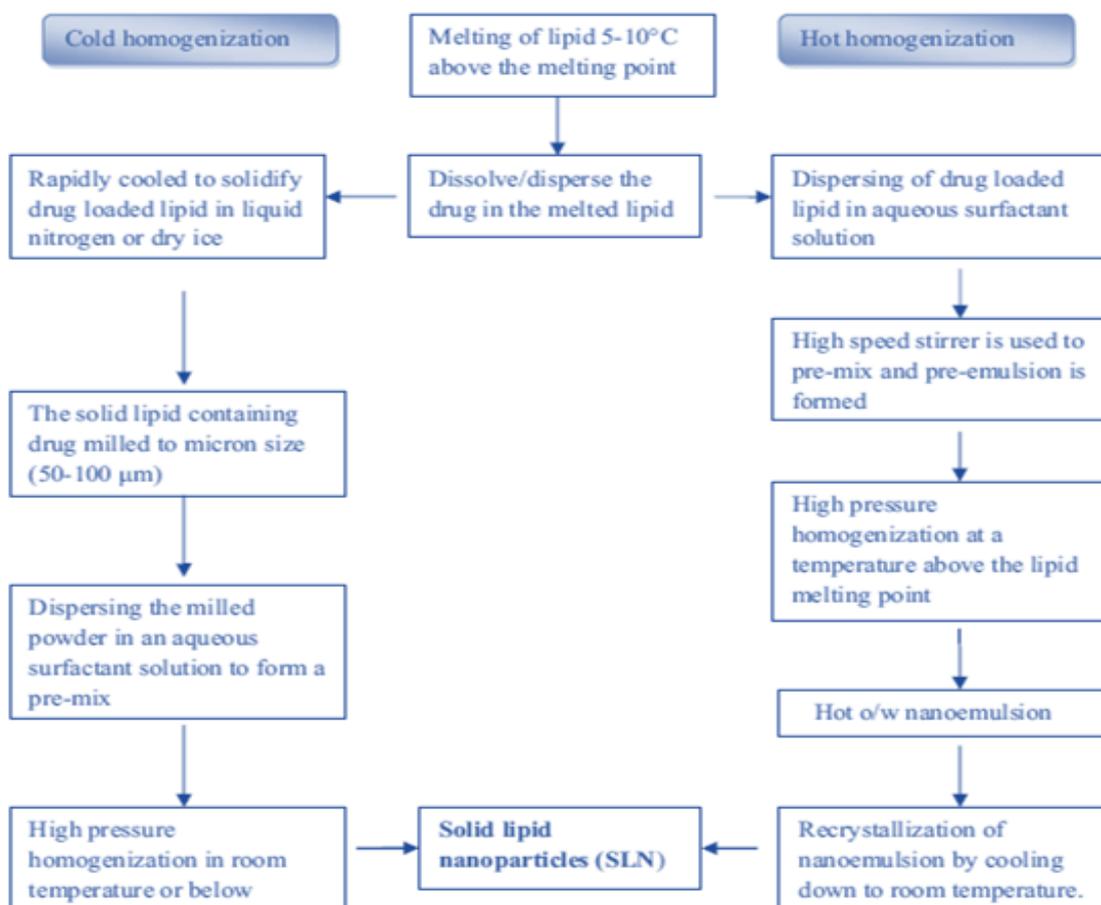

Figure 2.4: Schematic representation of high pressure homogenization (HPH) techniques for solid lipid nanoparticle (SLN) preparation (Parhi and Suresh, 2012).

High speed homogenisation (HSH) is a preparation technique employed in the preparation of SLNs by means of high speed stirring followed by sonication (Yadav *et al.*, 2014). High speed rates followed by ultrasound sonication are used to obtain a nanodispersion of melted lipids in a warm aqueous surfactant (Lason and Ogonowski, 2011). Figure 2.5 illustrates the formation of a solid lipid nanodispersion by means of high speed stirring and a bath sonication device. It should be noted that the energy input for the sonication step can be supplied through a bath or probe-tip ultrasonication (PUS) device. This high-energy input facilitates the breakdown of particles in the dispersion to nanosized particles (Ganesan and Narayanasamy, 2017).

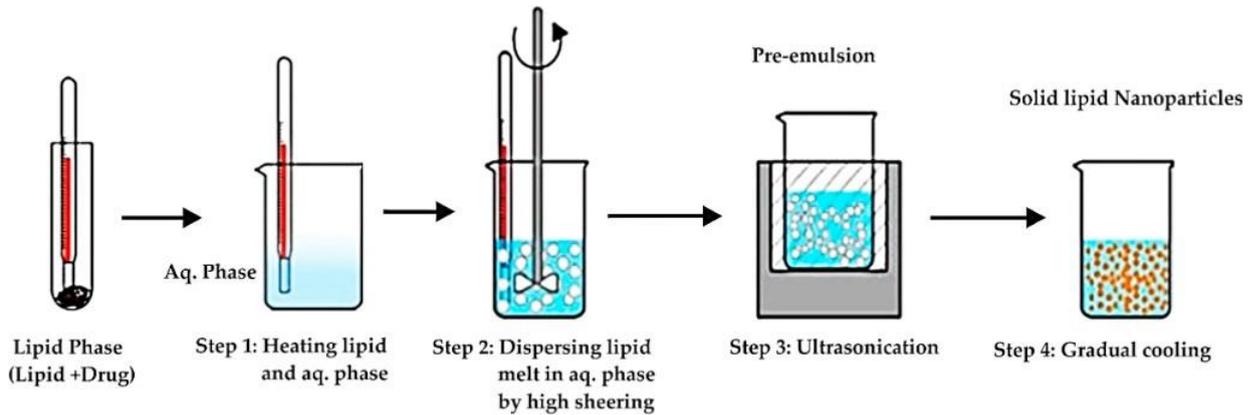

Figure 2.5: Schematic representation of High Speed Homogenisation (HSH) technique for solid lipid nanodispersion formation by means of a bath sonication device (Ganesan and Narayanasamy, 2017).

Solvent emulsification, also referred to as the solvent-emulsification-diffusion method, is a technique that involves the solubilisation of lipids in partially water-miscible solvents so as to yield an oil-in-water emulsion (o/w). The resultant emulsion is then passed through water under continuous stirring in order to solidify the lipid phase as a consequence of organic phase diffusion (Li *et al.*, 2017). Figure 2.6 provides a simple illustration of this preparatory technique.

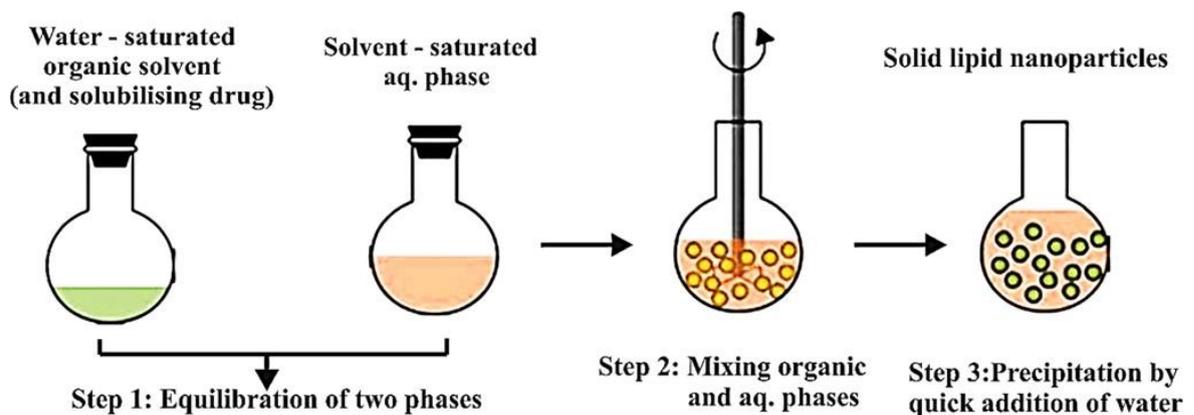

Figure 2.6: Schematic representation of solid lipid nanoparticle (SLN) preparation by solvent emulsification technique (Ganesan and Narayanasamy, 2017).

The microemulsion technique is a low-energy input technique employed for the preparation of SLNs (see Figure 2.7). A hot micro-emulsion of lipids and surfactants is prepared by dispersing them in cold water (Mao *et al.*, 2003). This process leads to the precipitation of the lipid phase that results in the formation of fine particles. The excess water is then removed by means of lyophilisation to form SLNs (Parhi and Suresh,

2012).

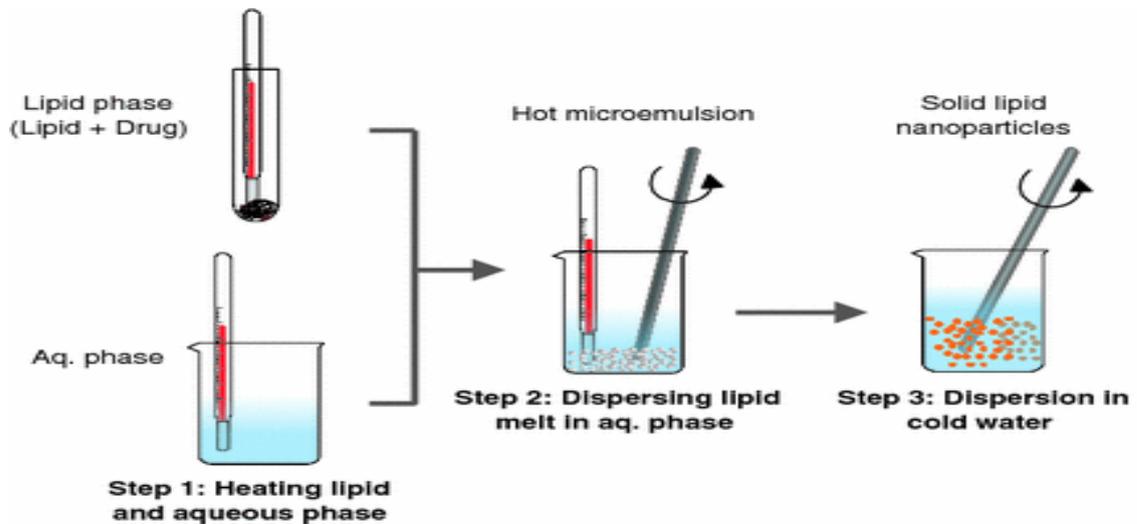

Figure 2.7: Schematic representation of the microemulsion based technique for solid lipid nanoparticle (SLN) preparation (Shah *et al.*, 2014).

Another low-energy approach to SLN preparation is the double-emulsion method. This method is derived from the aforementioned solvent-emulsification method. It entails the formation of two emulsions; the drug is encapsulated within a stabiliser to prevent the partitioning of the drug into the external aqueous phase during solvent evaporation (Nandini *et al.*, 2013). Figure 2.8 illustrates the process of SLN preparation by means of the double-emulsion method.

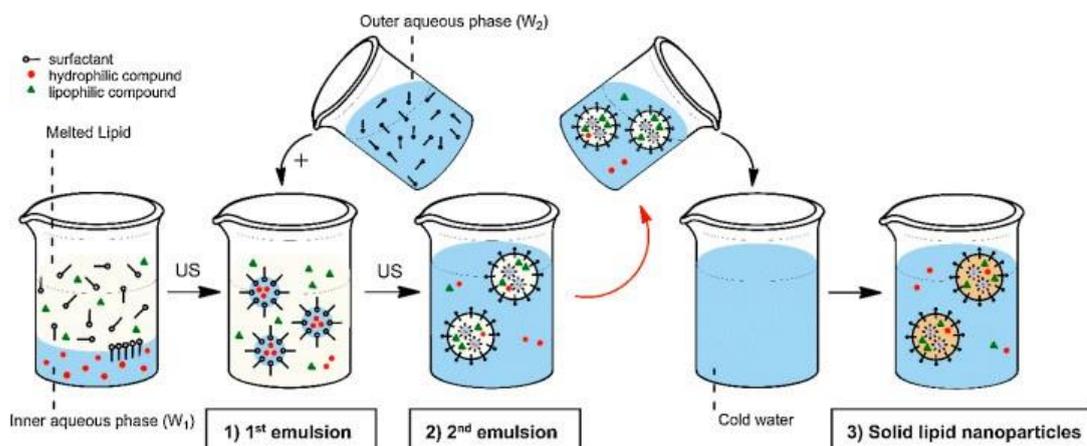

Figure 2.8: Schematic representation of the double emulsion technique for solid lipid nanoparticle (SLN) preparation (Peres *et al.*, 2016).

The solvent evaporation technique is a method of preparation that utilises organic solvents (see Figure 2.9). This process commences with the dissolution of the lipid in a water-immiscible organic solvent (Lason and Ogonowski, 2011). The mixture then undergoes emulsification in an aqueous phase prior to the evaporation of solvent. The final step results in lipid precipitation that forms nanoparticles (Ganesan and Narayanasamy, 2017).

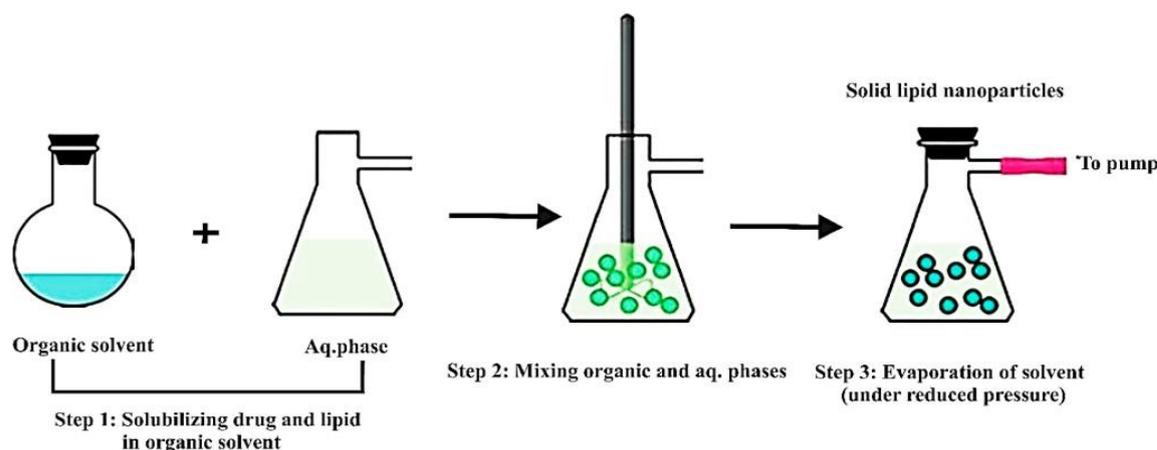

Figure 2.9: Schematic representation of solvent evaporation technique for solid lipid nanoparticle (SLN) preparation (Ganesan and Narayanasamy, 2017).

Another preparation technique that utilises organic solvents in the preparation of SLNs is the supercritical fluid (SCF) process. SCF is defined as a substance at a temperature and pressure above its critical point. The physiochemical properties of such fluids assume intermediate values of liquid and gasses which improve their solvent power (Noyori, 1999). Processes, such as rapid expansion of supercritical solution (RESS), particles from gas saturated solutions (PGSS), aerosol solvent extraction solvent (ASES) and supercritical fluid extraction of emulsions (SFEE) have been employed for nano-particle formation (Kankala *et al.*, 2017).

RESS, in particular, has been investigated extensively for the preparation of SLNs (Santo *et al.*, 2013). The process involves the dissolution of a nanodispersion product in a SCF. The resultant solution expands rapidly through the sprayer and causes rapid deposition of micro- and nanoparticles of the product. Figure 2.10 illustrates a simplified version of nanoparticle formation via RESS.

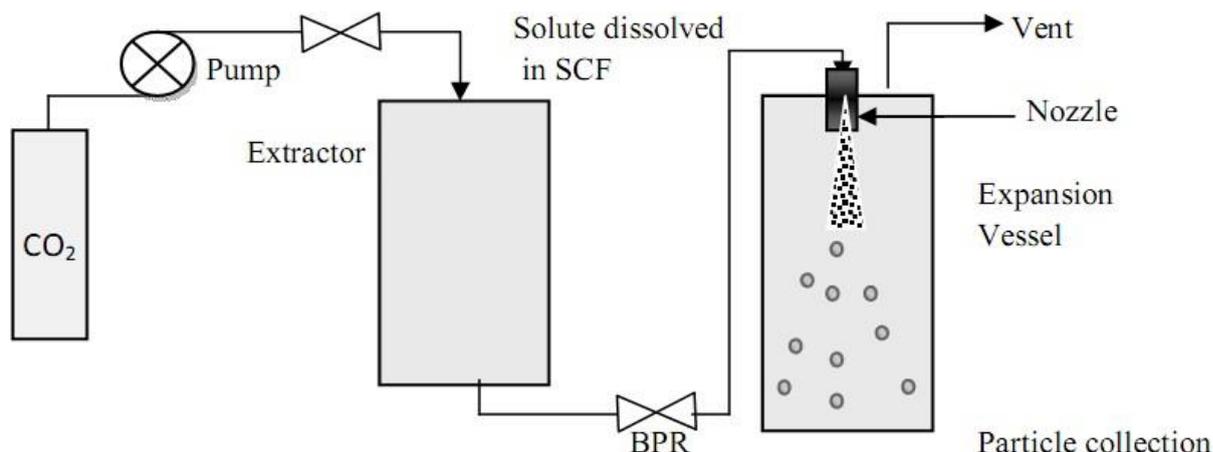

Figure 2.10: Diagrammatic layout of rapid expansion supercritical fluid (SCF) solution system for nanoparticle preparation (SLN) (Parhi and Suresh, 2012).

Finally, there are two emerging techniques related to SLN preparation, namely film ultrasound and spray drying. Spray drying is a novel technique that is employed to improve long-term storage stability of SLNs (Xia *et al.*, 2016). It is an alternative method to lyophilisation for converting liquid nanodispersions to a desiccated system which, consequently, promotes thermal stability and facilitates easy handling. Lipids with a melting point of greater than 70 °C are advised for spray drying (Pardeshi *et al.*, 2012).

Similarly, another fairly new technique is film ultrasound, in which lipids and drugs are dissolved in an appropriate organic solvent that then undergoes decompression, rotation and evaporation in order to yield a lipid film. An aqueous phase is then added, and a PUS device is used to provide high-energy input for the formation of mono-dispersed nanoparticles (Patel *et al.*, 2013).

i. Summary of solid lipid nanoparticle (SLN) preparation techniques

Table 2.10 provides a concise summary of the advantages and disadvantages of the most commonly used preparation techniques for SLNs. As noted previously, even though SLNs provide many advantages over other colloidal systems, many of their issues and limitations are attributed to their preparation process, where some processes are implicated in drug-induced degradation owing to high temperatures or pressure use, lipid crystallisation, low drug-loading capacity or the co-existence of multiple colloidal species (Yadav *et al.*, 2014).

Table 2.10: Summary of advantages and disadvantages of commonly used solid lipid nanoparticle (SLN) preparation techniques (adapted from Battaglia *et al.*, 2015; Kesharwani *et al.*, 2013).

Process	Advantages	Disadvantages
Hot homogenisation	Commercially available, likelihood of scalability	Increased rate of drug and carrier degradation, burst release effect for hydrophilic drugs, polydisperse distribution, energy intensive
Cold homogenisation	Ideal for thermolabile and hydrophilic drugs, less poly-dispersion and more stable dispersions obtained compared to HHT	High pressure-induced degradation, energy intensive
Bath sonication	Availability of equipment, cost-effective, reduced shear stress	Poly-dispersed particle distribution, large particle size, instability of particles, agglomeration of particles
Probe sonication	Availability of equipment, cost-effective, reduced shear stress	Contamination by metal particles, physical instability upon storage, overheating
Solvent emulsification	Small particle size, low-energy input, ideal for thermolabile drugs, large-scale production	Use of organic solvents, emulsion instability
Micro-emulsion	Low-energy input, stability	Labour-intensive, sensitivity of method, lipid crystallisation, low nano-particle concentration
SCF process	Absence of organic solvent, mild temperature, particles obtained as dry powder	Novel and costly method
Spray drying	Dry particles for long-term stability	Particle aggregation, high temperature and shear required
Double emulsion	Not ideal for lipophilic drugs	Large particles obtained
Solvent evaporation	Small mono-dispersed nano-particles, high encapsulation efficiency, ideal for large scale production	Use of organic solvent, increased likelihood of bio-toxicity
Film ultrasound	Uniform particle size	Limited research

With a wide array of experimental procedures available for the preparation of SLNs (see Figure 2.11) and no stringent guidelines, operators can often feel confused about selecting the most suitable method. Factors, such as the availability of equipment, time-constraints, cost and the physicochemical properties of the drug and excipients were investigated and considered prior to the selection of a formulation method for this study. Due to limitations in equipment availability for this study, high-energy approaches (i.e. bath and probe-tip sonication) were investigated.

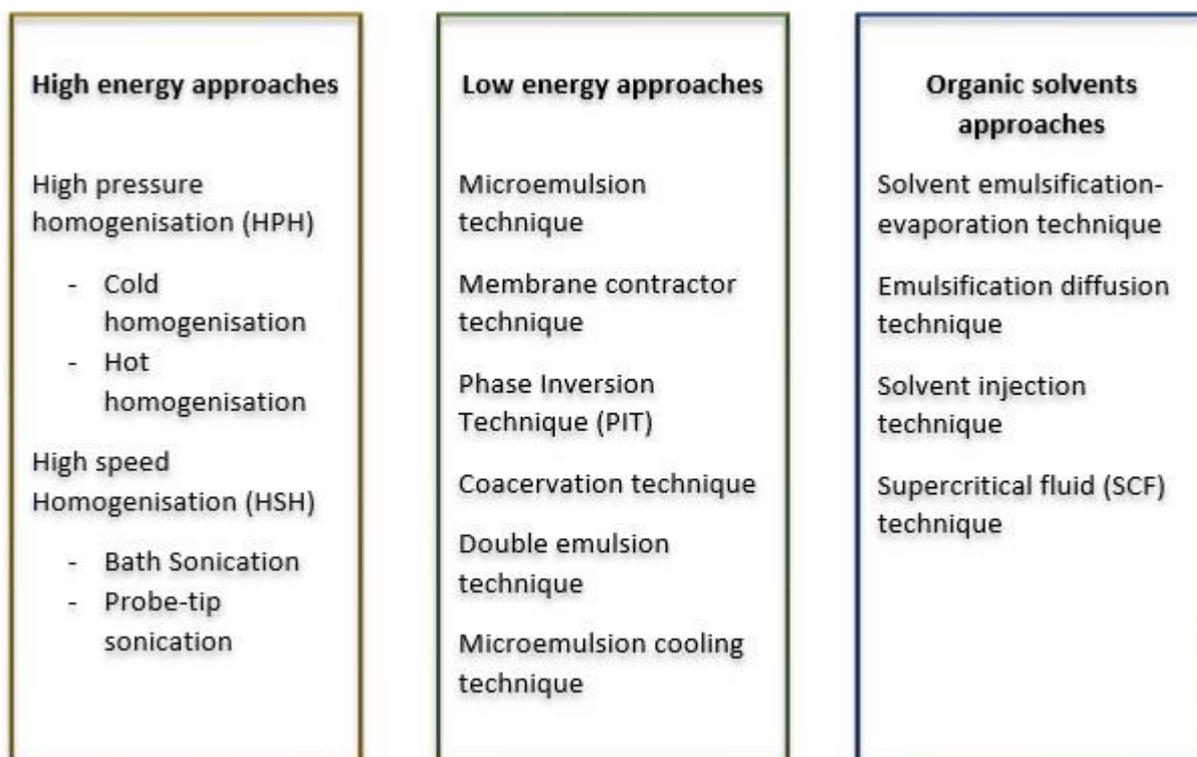

Figure 2.11: Summary of solid lipid nanoparticle (SLN) preparation techniques.

2.4.2 Mucoadhesive drug delivery systems

Mucoadhesion is defined as the adhesion between two materials, one of which is a mucosal surface (Shaikh *et al.*, 2011). This novel approach to drug delivery has received much attention, owing to its potential for improving drug delivery. Mucoadhesive formulations are designed to provide a controlled rate of drug release and prolong the retention of the dosage form at the site of application, thereby improving therapeutic outcomes (Shaikh *et al.*, 2011). Moreover, these formulations provide intimate contact between the dosage form and mucosa, which can cause high drug flux at the site of application (Boddupalli *et al.*, 2010).

As stipulated in Section 2.3, a major disadvantage of vaginal drug delivery is the short residence time of conventional formulations within the vaginal tract (Cardot *et al.*, 2004). Therefore, mucoadhesive systems for vaginal drug delivery have been extensively studied in order to remedy this issue. Mucoadhesive vaginal formulations prolong dosage form retention within the vaginal tract through the formation of physical and chemical bonds with the mucosa (Kaur *et al.*, 2016).

The initial step in the mechanism of mucoadhesion involves a contact phase in which hydration, wetting and spreading are pivotal steps. Upon completion of the contact phase, a consolidation phase follows, which includes the strengthening of polymer chains into the mucous layer and the formation of polymer-mucin bonding by means of electrostatic interactions or weak van der Waals forces (Caramella *et al.*, 2015). These dosage forms are put into various categories, such as gels, tablets, films, emulsions or pessaries. The focus of this study was, however, limited only to gels, owing to their ease of manufacture, superiority in patient preference and favourable pharmacokinetic profiles, such as sol-gel transition and controlled drug release (Acarturk, 2009).

2.4.2.1 Gels

A gel is defined as a semi-solid three dimensional (3D) polymer matrix made up of small quantities of solid material dispersed in large amounts of fluids (Rogovina *et al.*, 2008). The 3D polymeric network structure is responsible for the gel's viscoelastic properties that resist deformation. The classification of gels is dependent on the nature of the solvent. Two groups are available *viz.* organogels and hydrogels (Bhoyar *et al.*, 2012). Table 2.11 summarises the general characteristics of these two groups.

Table 2.11: General characteristics of organogels and hydrogels (adapted from Nabi *et al.*, 2016).

ORGANOGELES	HYDROGELS
Also known as oleaginous gels	Consist of a polar solvent and a polymer
Non-polar solvent phase	Consist of up to 90% H ₂ O
Consist of up to 35% H ₂ O	Polymers assemble to form 3D network which retains significant amounts of H ₂ O
Cross-linking prevents flow of external polar phase, thus increasing hydrophobicity and reducing drug release rate	

Organogels are regarded as bicontinuous systems comprised of gelators and organic solvents (Vintiloiu and Leroux, 2008). They are distinguished from hydrogels by their predominantly organic continuous phase. Furthermore, they are categorised as polymeric- or low-molecular weight organogelators (Swati *et al.*, 2014). In the pharmaceutical industry, they have been investigated for their potential in vaccine and lipophilic drug delivery (Vintiloiu and Leroux, 2008). Their ease of preparation, incorporation of lipophilic drugs and enhanced topical performance versus conventional dosage forms make organogels a vehicle of choice for topical drug administration (Fetih, 2010). However, their limitations, such as poor stability at elevated temperatures and greasiness (which reduces patient acceptability), make them unsuitable for vaginal drug delivery (Swati *et al.*, 2014).

2.4.2.2 Hydrogels

Hydrogels are polymer-based semi-solid dosage forms investigated for their potential in controlled drug release. The popularity of this novel dosage form has increased drastically owing to its flexibility, high water content and biocompatibility (Graham and McNeill, 1984). A visual representation of the 3D network structure formed by the cross-linking of polymers is illustrated in Figure 2.12.

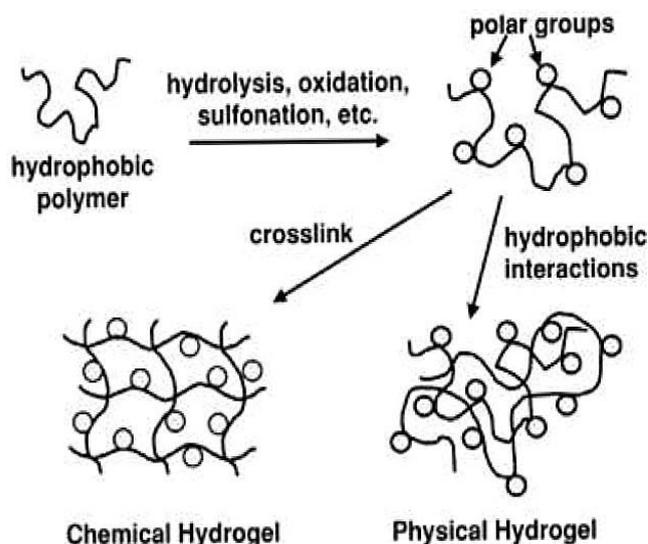

Figure 2.12: 3D polymeric structure of physical and chemical cross-linked hydrogels (Chirani *et al.*, 2015)

These cross-linked polymer networks display good swelling characteristics by absorbing large amounts of fluids (Chirani *et al.*, 2015). The mechanism of swelling begins with the primary bound water that is first absorbed by the hydrophilic groups of a dry hydrogel. Once the hydrophilic groups are hydrated, the network swells, causing hydrophobic groups to be exposed. These groups interact further with the fluid, leading to secondary bound water (Yang *et al.*, 2012).

Once the hydrophobic and hydrophilic sites have interacted with the water molecules, the network absorbs additional water as a result of the osmotic driving force of the polymers towards infinite dilution. Infinite dilution is, however, opposed by physical or chemical cross-linking which causes the hydrogel to reach an equilibrium swelling level and prevents gel deformation (Yahia *et al.*, 2015). Cross-linking refers to the bonds that link one polymer molecule to another, thus changing a polymer to a solid or gel by restricting its mobility. The nature of cross-links varies, and the extent of cross-linking correlates with hydrogel characteristics, such as viscosity, elasticity and solubility. By controlling the degree of cross-linking, it is possible to exploit and optimise polymers for different applications (Maitra and Shukla, 2014).

The various types of hydrogels are classified as conventional or stimuli-responsive gels. The former absorbs water or fluid in the presence of an aqueous environment and shows no change in response to the change in the surrounding environment. The latter, also known as smart hydrogels, displays a change in swelling behaviour in response to a change in the surrounding environment (Chaterji *et al.*, 2007). Stimuli-responsive hydrogels were explored in this study, as they provide reversible phase transitions which are particularly useful for intravaginal drug delivery by maintaining the dosage form *in situ* (Dorraj and Moghimi, 2015). Figure 2.13 illustrates the reversible stimuli-responsive nature of these stimuli-responsive hydrogels' polymer chains.

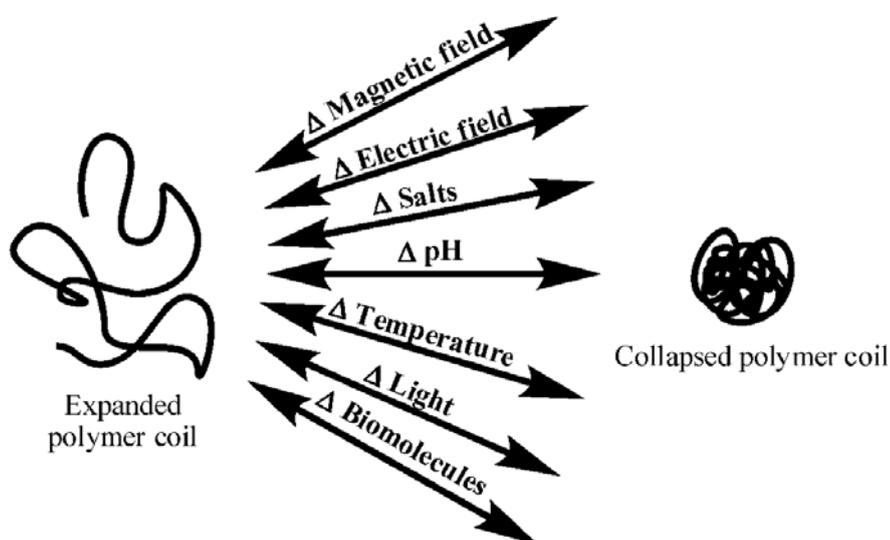

Figure 2.13: Stimuli responsive nature of polymer chains in smart hydrogels (Deen and Lab, 2018)

The type of stimuli responsible for inducing changes in a polymer network can be categorised into three groups, *viz.* physical, biological or chemical (Gandra, 2013). Examples of physical stimuli include magnetic and electric fields, temperature, pressure, light exposure and ultrasound. Biological stimuli include ligands, enzymes, antibodies or antigens. Chemical stimuli include the likes of pH and ionic strength (Almeida *et al.*, 2012). Thermo- and pH-responsive hydrogels account for the most commonly used systems in polymer-based drug delivery systems (Echeverria *et al.*, 2018). The use of stimuli-responsive hydrogels to circumvent issues of rapid drug release, fluctuations in API concentrations at the site of application, adverse effects, stability of APIs with short half-life and poor patient adherence as a result of frequent

dosing were investigated extensively in preparation of this study's literature review but, for the purposes of this study, thermosensitive hydrogels were the only ones considered for further research.

Thermosensitive, also referred to as thermoresponsive hydrogels are comprised of materials that facilitate a sol-gel transition in response to changes in temperature. Depending on the mechanism of response, they are classified as positive or negative polymers (Gandra, 2013). The majority of these polymers belong, however, to the former group and are characterised by swelling when temperatures increase above their critical temperature point. Simply stated, positive polymers solidify with increasing temperatures (Taylor *et al.*, 2017). They offer many advantages, such as site specificity, biotolerability and sustained release, a simple method of formulation and ease of administration for patients. Moreover, they do not make use of organic solvents or cross-linking agents in their preparations, which further deems them as biotolerable (de Souza-Ferreira *et al.*, 2015).

Gel formation occurs in response to the temperature difference between ambient and physiological temperature. In terms of intravaginal administration, thermoresponsive gels are characterised by easy application, owing to the low viscosity of their formulation which allows for complete spreading on the vaginal mucosa (Taurin *et al.*, 2018). Conversely, the formation of a gel following application overcomes the removal of the dosage form via mucocillary clearance, thus favouring the longevity of the loaded drug at the site of application (Caramella *et al.*, 2015).

Favourable characteristics attributed to hydrogels include their non-greasy and easily washable nature; their formation of a hydrating and protective layer at the site of application; and their incorporation of both hydrophilic and lipophilic drugs. Moreover, they can be formulated to provide intimate contact with the vaginal mucosal and establish controlled drug release (Andrade *et al.*, 2014; Fan *et al.*, 2016).

i. Polymers as materials for thermo-sensitive hydrogels

Polymers used in the preparation of thermoresponsive hydrogels are derived from natural or synthetic sources (Taylor *et al.*, 2017). Due to their availability in the study's laboratory, poloxamers and cellulose derivatives were investigated for their potential in thermoresponsive drug delivery.

Poloxamers, also referred to as Pluronic®, Kolliphor®, Tetronic® or Synpersonic® (Almeida *et al.*, 2018), are a class of block co-polymers synthesised from polyethylene oxide (PEO) and polyoxypropylene (PPO) in a tri-block structural arrangement (see Figure 2.14; Bodratti and Alexandridis, 2018).

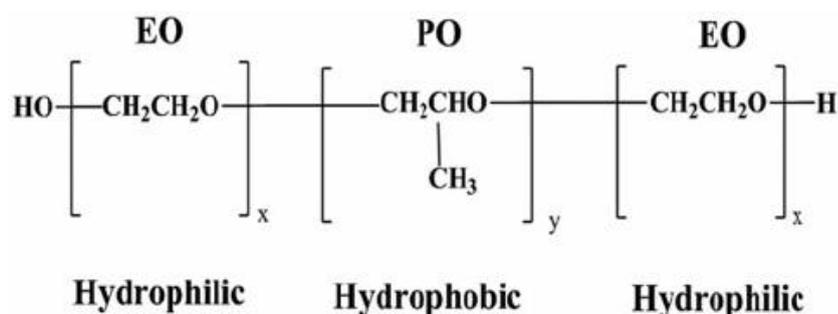

Figure 2.14: Generic structural arrangement of poloxamers (Shubhra *et al.*, 2014)

The x-y-x tri-block structure is formed by polymer chains of ethyleneoxide (EO) and propyleneoxide (PO) (Almeida *et al.*, 2018). This structure is responsible for defining surfactant characteristics. Through the modifications of various parameters, such as size, hydrophilicity and lipophilicity, the polymer can be altered (Yapar and Inal, 2012). Poloxamer solutions display temperature-dependent gelling and self-assembling behaviour that present great interest in optimising drug formulations (Shubhra *et al.*, 2014).

All poloxamers possess similar chemical structures, but have different molecular weights and compositions of EO and PO blocks (Bodratti and Alexandridis, 2018). The two most commonly used poloxamers are 188 and 407 (Patel *et al.*, 2009). A nomenclature system was established in 1950 in order to aid with the identification of each poloxamer type (Devi *et al.*, 2013). The naming of poloxamers includes three letters, *viz.* F, P or L that describe the physical state of the polymer at room temperature where solid flakes (F), liquids (L) or pastes (P) are represented (Bodratti and Alexandridis, 2018). This is then followed by two or three numerical figures which represent a code relating to the particular type's structural parameter. The first two (or one) digit translates to the molecular mass of the PPO multiplied by 300. The last digit translates to the hydrophilic content multiplied by 10 in order to yield the % of PEO content (Almeida *et al.*, 2018; Ban *et al.*, 2017).

Poloxamers possess high solubility capacity for many drugs and excellent compatibility with various pharmaceutical excipients (Almeida *et al.*, 2018). They are also soluble in most solvents (organic and inorganic) and extremely stable in the presence of metal ions, acids and alkalis. Due to these properties, poloxamers have established themselves as the preferred polymers for many formulations (Hurler *et al.*, 2012). They are used extensively in the preparation of thermoresponsive hydrogels, owing to their gel-forming abilities at elevated temperatures (Guiliano *et al.*, 2018). The use of poloxamers in isolation is, however, not encouraged, because of their weak mechanical strength which, consequently, promotes rapid erosion of the dosage form at the application site (Gandra, 2013). Rather, the blending of poloxamers with an additional co-polymer, such as HPMC, is recommended (Varshosaz *et al.*, 2008), as it not only improves the mechanical strength of the hydrogel, but also improves mucosal surface interactions. Thus, this approach prolongs dosage from retention at the site of application (Deshkar *et al.*, 2015).

Cellulose derivatives include, amongst others, HPMC, sodium carboxymethylcellulose (NaCMC) and methylcellulose (Granstrom, 2009). Cellulose is a linear homopolymer polysaccharide that is insoluble in aqueous solvents. It is comprised of D-anhydroglucopyronase units joined by β -1.4-glycosidic bonds (Marks, 2015). Its aqueous insolubility results from extensive inter- and intramolecular hydrogen bonding. Figure 2.15 illustrates the chemical structure of cellulose with two β -1.4-glycosidic bonds.

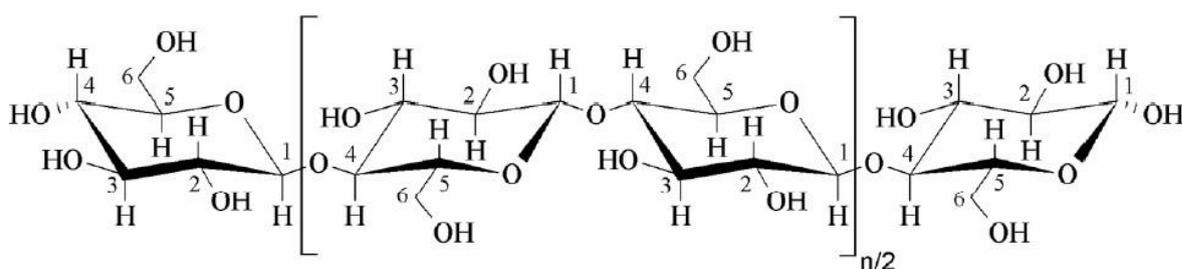

Figure 2.15: Chemical structure of cellulose with two β -1.4-glycosidic bonds (Marques-Marinho and Vianna-Soares, 2013)

Cellulose derivatives are amongst the excipients commonly used in pharmaceutical products (Marques-Marinho and Vianna-Soares, 2014). They are employed in a wide array of formulations, such as viscosity enhancers for topical dosage forms, suspending agents in liquid oral preparations, binding agents in tablet manufacturing processes and rate-controlling matrices for sustained release preparations (Jain *et al.*, 2013). Furthermore, favourable characteristics attributed to cellulose derivatives include low costs, reproducibility, recyclability and bio-compatibility, which make them ideal excipients for pharmaceutical formulations (Chambin *et al.*, 2004).

In addition to their use in many pharmaceutical preparations, they possess mucoadhesive characteristics that allow for strong hydrogen bonding with the mucin present on the mucosal surface (Roy *et al.*, 2009). The mechanism of bonding includes the formation of hydrogen bonds between the carboxylic acid group of the polymer and glycoprotein of mucin (Almeida *et al.*, 2018). HPMC, in particular, is used extensively to facilitate controlled drug release (Chatterjee *et al.*, 2017).

Most natural polymers, such as chitosan, gelatine and polysaccharides exhibit thermogelation characteristics upon temperature decreases (Curcio *et al.*, 2010). However, aqueous solutions of some cellulose derivatives (see Table 2.12) exhibit reverse thermogelation (Jain *et al.*, 2013).

Table 2.12: Examples of thermo-gelling cellulose ether derivatives (adapted from Jain *et al.*, 2013)

Cellulose derivative	Chemical structure	Gelling temperature range	Concentration
Methyl cellulose	-CH ₃	25-50°C	1-5%
Hydroxypropyl cellulose	-CH ₂ CH ₂ CH ₂ OH	46°C	2%
Hydroxypropyl methylcellulose	-CH ₃ or -CH ₂ CH(OH)CH ₃	75-90°C	1-5%
Hydroxyethyl cellulose	-CH ₂ CH ₂ OH	75°C	1-5%
Ethylhydroxyethyl cellulose	-C ₂ H ₅ or -CH ₂ CH ₂ OH	30-40°C	1-5%

When the compounds presented in Table 2.12 have an optimum balance of hydrophilic and hydrophobic moieties, they undergo a sol-to-gel transition in H₂O (Kim and Matsunaga, 2017). This transition is actually dependent on the substitution of the hydroxy group. H₂O then becomes a poorer solvent, with increasing temperatures, and polymer-to-polymer interactions become dominant at higher temperatures which result in a gel (Desbrieres *et al.*, 2000; Jain *et al.*, 2013).

ii. Preparation methods of temperature-responsive hydrogels

Hydrogels are prepared through a wide range of methods and precursors that allow for the alteration of properties, such as pore size, mechanical strength, degradability and rate of degradation (Sosnik and Seremeta, 2017). The process of hydrogel preparation is segregated into two major categories, namely physical and chemical cross-linking (Gandra, 2013). The former involves the preparation of a hydrogel through the growth of physically-connected aggregates (i.e. hydrophobic or electrostatic interactions or chain entanglements), whilst the latter is achieved by permanent covalent bonding (Ahn *et al.*, 2007). Physical cross-linking is more advantageous because physical junctions within the polymer display reversible transition behaviours in varying environmental conditions (Parhi, 2017). Further benefits of physical cross-linking include the absence of cross-linking agents, no organic solvents, and no heat and photo irradiation; all of which diminish toxicity and promote API stability (Gong *et al.*, 2013).

Physically cross-linked hydrogels are developed by crystallisation, ionic or protein interaction, stereo-complex formation, hydrophobised polysaccharides and hydrogen bonding (Maitra and Shukla, 2014). Table 2.13 provides a brief discussion of these methods.

Table 2.13: Mechanisms of physical cross-linking of hydrogels (adapted from Maitra and Shukla, 2014; Akhtar et al., 2016).

Mechanism	Comments
Ionic interactions	Gentle cross-linking conditions including ambient temperature and physiological pH Example(s): Alginate, chitosan
Crystallisation	Involves thawing and freezing processes to form highly elastic gel Example(s): Polyvinyl alcohol (PVA)
Stereo-complex formation	A hydrogel is formed via cross-linking that is produced between lactic acid oligomers of reverse chirality Example(s): enantiomeric lactic acid
Hydrogen bonding (H-bonding)	H-bonding between polymer chains can also lead to hydrogel formation. H-bond is produced by connecting an electron-deficient hydrogen atom and a functional group of high electronegativity. Example(s): Polyacrylic acid (PAAc)
Protein interactions	This method involves co-polymers that contain the repetition of silk-like and elastine-like blocks called ProLastins. These ProLastins are fluid solutions that occur in H ₂ O and can undergo a transformation from solution to gel under physiological conditions because of the crystallisation of the silk-like domains. Example(s): natural and synthetic amino acids
Hydrophobised polysaccharides	Hydrophobic interactions result in polymer swelling and, subsequently, take up H ₂ O to form the hydrogel Examples: Dextran, pullulan and carboxymethyl curdlan

The preparation of cellulose-based hydrogels normally consists of two steps. Firstly, there is the solubilisation of cellulose fibres or powder (Akhtar *et al.*, 2016). Secondly, there is the chemical and/or physical cross-linking in order to obtain a 3D network of hydrophilic polymer chains, which are able to absorb and retain a significant amount of water (Yahia *et al.*, 2015). Through the modification of the cross-linker and polymer concentrations, it is possible to optimise the hydrogel swelling capabilities and mechanical properties of the polymers (Navarra *et al.*, 2015). For the purposes of this study, only physical cross-linking methods have been investigated.

2.5 SUMMARY

As outlined in this chapter, poor patient adherence due to the shortcomings of conventional VVC dosage forms contributes to reinfection or poor therapeutic outcomes in the treatment of VVC (Cardot *et al.*, 2004; Dobarina *et al.*, 2007). While determining effective therapeutic strategies, it would be logical to optimise existing dosage forms in order to circumvent issues of poor adherence to VVC pharmacotherapy. Novel pharmaceutical drug delivery devices show the potential of optimising localised drug delivery by (a) improving drug absorption, (b) controlling the rate of drug release or (c) prolonging intimate contact of the dosage form at the site of application (Kenechukwu *et al.*, 2018). Any of these three solutions could aid in promoting better patient compliance in order to facilitate effective treatment outcomes.

By combining the advantages of SLNs with thermogelling mucoadhesive systems, the pharmacokinetic and pharmacodynamics parameters of locally-acting imidazole formulations could be improved; thereby potentially providing an alternative means of VVC treatment. The following chapter focuses on the methodology for the development and characterisation of a MNZ formulation into SLNs. The study then further incorporated the carrier system into a thermoresponsive bioadhesive system in order to extend the drug residence time at the site of application.

CHAPTER 3

METHODOLOGY

3.1 INTRODUCTION

For this study, various formulations of MNZ-SLNs were prepared by means of a novel low-temperature emulsification and ultrasonication method. The resultant formulations were optimised statistically through response-surface methodologies. Characteristics of the optimal formulation were determined by means of transmission electron microscopy (TEM), photon correlation spectroscopy (PCS), and HPLC. Upon preparation of the MNZ-SLNs, the optimal formulation displaying maximum entrapment efficiency and minimal particle size was chosen for incorporation into various mucoadhesive hydrogel preparations. The resultant hydrogel formulations were assessed for drug content uniformity and rheology. Formulations which displayed favourable sol-transitions were further characterised for *in vitro* drug release and antimicrobial susceptibility. The development, optimisation and characterisation of the NDDS are discussed in this chapter, along with formulation issues encountered during this process.

3.2 INSTRUMENTATION

3.2.1 High Performance Liquid Chromatography (HPLC)

Chromatography is an analytical technique that separates components in a mixture, based on their differences in distribution between two phases (Coskun, 2016). It currently serves as the strongest analytical tool available to modern scientists, hence its extensive use in analytical method development and validation (Prathap and Nishat, 2013; Chauhan *et al.*, 2015). HPLC evolved from classic column chromatographic (CCC) techniques. When compared to CCC, HPLC provides higher resolution, faster analysis, small reusable columns, controlled flow of mobile phase (MP) and the detection of minute sample amounts (Gupta *et al.*, 2012). Figure 3.1 illustrates a simplified layout of a modern-day reversed phase HPLC (RP-HPLC) apparatus that was utilised in this study to obtain chromatographic profiles of MNZ in bulk and complex pharmaceutical preparations.

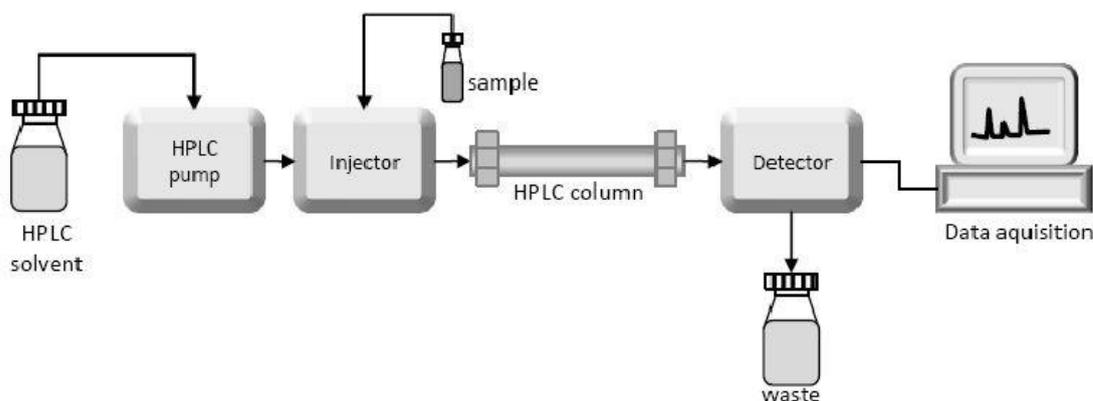

Figure 3.1: Layout of a modern day RP-HPLC apparatus (Czaplicki, 2014).

Chromatographic profiles MNZ in bulk and complex formulations were recorded and translated on a HPLC apparatus (Shimadzu™, Kyoto, Japan) and fitted with a SIL-20AFT autosampler, LC-20AB prominence solvent delivery module and CTO-20A prominence column oven. The solvent reservoir comprised the contents of the mobile phase (MP), where two individual containers holding the respective solvents were employed and mixed online. Liquefied samples for chromatographic analysis were placed inside the injector and pushed through the column under high pressure. The column was employed to effect a separation of sample components, after which it was translated into a chromatographic profile by the detector. Data acquisition was the final step and was achieved through the use of LCSolutions™ software (Shimadzu™, Kyoto, Japan).

3.2.2 Differential Scanning Calorimetry (DSC)

DSC is a thermal analytical technique utilising controlled resistance heaters to individually heat a sample and a reference compound at a predetermined rate (Gill *et al.*, 2014). The change in heat flow between the sample and reference compound are monitored against time and temperature so as to determine drug-excipient compatibility (Mazurek-Waldolkowska *et al.*, 2013).

A thermal analysis of the MNZ microcrystalline powder, excipient and MNZ-excipient mix was conducted by simultaneous thermo-gravimetric analysis (TGA) and DSC using a SDT Q600 (TA instrument™, Utah, USA).

3.2.3 Probe-tip ultrasound sonication (PUS)

Ultrasound sonication involves the use of ultrasonic frequencies (>20 KHz) to agitate particles (Majumdar and Devi, 2010). A probe-tip sonication device (Bandelin Sonoplus™, Berlin, Germany) was used in the preparation of SLNs. Optimal parameters for PUS were established through RSM.

3.2.4 Photon Correlation Spectroscopy (PCS)

Photon correlation spectroscopy (PCS), also known as dynamic light scattering (DLS), utilises a laser of known wavelengths which pass through a dilute sample solution; the intensity of the scattered light is collected by detectors in order to establish particle distribution characteristics (Tscharnuter, 2000). For this study, SLN characteristics of size, ZP and PDI were determined using a Malvern Zetasizer Nano-ZS particle analyser (Malvern Instruments™, United Kingdom).

3.2.5 Centrifugation

A centrifuge apparatus causes the separation of compounds in a mixture, based on differences in sedimentation velocities of components within a given mixture. The apparatus comprises a rotor to grip tubes containing the liquid mixture. This rotor is mounted on a drive shaft which rotates when powered by the motor (Majekodunmi, 2015). An indirect method using centrifugation apparatus (Hermle™ Z300, Germany) was used in the determination of drug entrapment efficiency of the prepared nanoparticles in this study.

3.2.6 Transmission Electron Microscopy (TEM)

Particle size and surface morphology assessments were done through a JEOL JEM 2100 LaB6 (JOEL Limited [Ltd]™, Japan) transmission electron microscope. TEM works by bombarding the sample with a stream of electrons and, consequently, monitoring the resultant transmission in order to produce detailed images of nano- or microscopic samples (Winey *et al.*, 2014).

3.2.7 Rheometer

Rheology is a branch of science concerned with the study of the deformation and flow of matter (Rueda *et al.*, 2017). For this study, a rheometer (Anton Paar™ MCR 72, Austria) was used to assess the viscosity and rheological properties of the prepared hydrogel formulations.

3.2.8 pH meter

A measure of the hydrogen ion concentration in a solution yields a pH value (Bates, 1948). pH measurements of developed hydrogel formulations were determined using pH instrumentation (Metrohm™, Herisau, Switzerland).

3.2.9 Franz vertical diffusion cells (FVDC)

Franz diffusion vertical cells (FDVC) provide a reliable and reproducible means of *in vitro* drug release-testing (IVDRT) for various dosage forms (Kanfer *et al.*, 2017). Vertical diffusion cells (VDC) have been investigated extensively for their use in IVDRT in hydrogels (Naik *et al.*, 2016). An illustration of the FVDC apparatus utilised in this study is given in Figure 3.2.

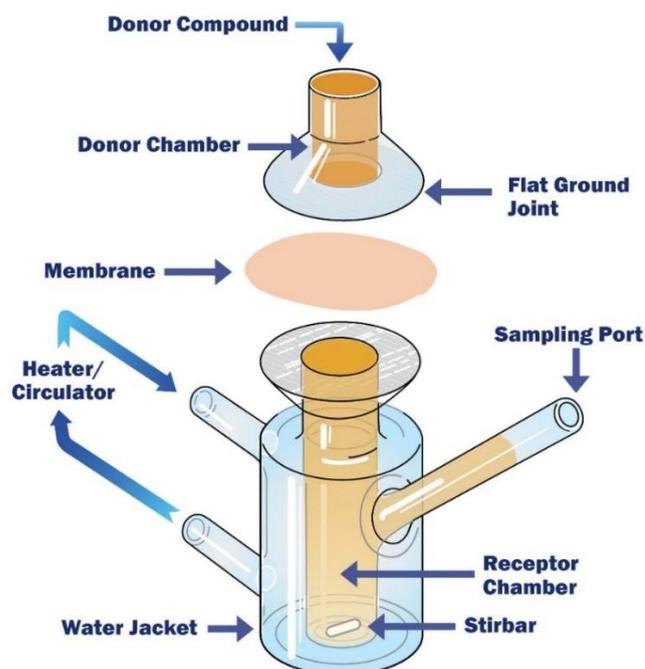

Figure 3.2: Illustration of Franz vertical diffusion cell (FVDC) apparatus (Dandamudi, 2017).

IVDRT, by means of FVDC, requires minute sample amounts (Cabral *et al.*, 2014). The sample is placed on the membrane surface on the donor component side. The sample is then allowed to permeate through the membrane into the receptor fluid, after which aliquots are withdrawn for assay (Naik *et al.*, 2016). Additional parts of the FVDC include, amongst others, a receptor chamber filled with a receptor fluid, sampling ports and water jacket. The donor chamber comprises a donor compound and a flat ground

joint resting on the membrane, which connect to the receptor chamber (Dandamudi, 2017).

The membrane used may be synthetic or natural, depending on the nature of the sample and the study. The receptor chamber is filled with a suitable medium that is maintained at a fixed temperature by a circulating water jacket (Kanfer *et al.*, 2017).

The selection of a receptor medium is dependent of the type of cell used and the nature and solubility of the drug. An ideal medium should mimic *in vivo* environmental conditions for the intended use (Salamanca *et al.*, 2018). Mediums, such as phosphate-buffered saline (PBS) are first-choice agents for IVDRT, since they closely resemble physiological fluids (Modi and Shah, 2016). The stir bar is located inside the filled receptor chamber and is responsible for providing mechanical agitation so as to ensure even distribution of the donor compound within the cell. The recommended IVDRT temperature for intravaginal mucosal drug delivery systems is 37 °C (Dandamudi, 2017)

3.3 MATERIALS

3.3.1 Miconazole Nitrate (MNZ)

MNZ (Acros Organics™, ThermoFischer Scientific™, Massachusetts, USA) is an antimycotic drug belonging in the pharmacological class of imidazole antifungals. The members of this class (e.g. clotrimazole, ketoconazole, etc.) are structurally related and have comparable physicochemical properties and mechanisms of action (Ghannoum and Rice, 1999). For the purposes of this study, MNZ was selected as the API of choice. This choice was based on its availability in the study laboratory and the fact that MNZ is listed as an essential medicine by both the WHO and South African DoH (SANDoH, 2017; WHO Expert committee, 2017).

3.3.1.1 Pharmacological action and uses

MNZ elicits its pharmacological action by causing a disruption of ergosterol (a vital fungal cell component) synthesis (Sud and Feingold, 1981). The disruption occurs through the inhibition of the enzyme cytochrome p450 14-alpha demethylase, which results in an accumulation of ergosterol precursors and peroxides that, in turn, cause cytolysis. Additional mechanisms of action include the inhibition of oxidative and peroxidative enzymes by influencing triglyceride and fatty acid synthesis, thereby increasing the amount of reactive oxygen species in susceptible yeast (Francois *et al.*, 2006).

MNZ possesses both antifungal and antibacterial activities with its spectrum extending to dermatophytes, gram-positive cocci, gram-positive bacilli and *Candida spp.* (Cope, 1980). In the treatment of VVC, MNZ is formulated into solid or semi-solid dosage forms that are administered intravaginally for localised effect (Rossiter, 2016). The side-effect profile of these dosage forms includes local irritation, sensitisation and rashes. If absorbed systemically diarrhoea, gastric pain, fever, drowsiness and flushing may ensue (Francois *et al.*, 2006). Adverse effects of pharmacotherapy often influence a patient's adherence to treatment (Roose, 2009). Therefore, through the use of biotolerable excipients, this study aims to lessen the potential of such effects. The excipients employed in the preparation of this novel formulation include physiological lipids with low acute and chronic toxicity with minimal mucosal irritation (Das and Chaudhury, 2011).

3.3.1.2 Pharmacokinetic profile of miconazole nitrate (MNZ)

Pharmacokinetic parameters describe the process by which the body handles a specific drug (de Campos *et al.*, 2014). By being aware of and modifying pharmacokinetic parameters, developers can select an appropriate route of administration and optimise therapeutic efficiency of a drug (Tiwari *et al.*, 2012). The pharmacokinetic profile of MNZ is summarised in Table 3.1.

Table 3.1: Pharmacokinetic profile of miconazole nitrate (MNZ) (adapted from Pershing *et al.*, 1994; Stevens *et al.*, 2013).

Pharmacokinetic parameter	MNZ
Absorption (A)	Vaginal: 1.4% absorption following a single-dose insertion of a 1200 mg vaginal capsule Oral: 25-30% absorption Topical: <0.013% absorption
Distribution (D)	90-93% protein bound with an intravenous (IV) volume of distribution of 1400 L in normal patients and 800 L in renal-impaired patients
Metabolism (M)	Undergoes extensive hepatic metabolism upon oral administration so as to yield metabolites 2.4-dichlorophenyl-1-H imidazole ethanol and 2.4-dichloromandelic acid
Elimination (E)	Undergoes three phases of elimination, which are centred, fast and slow, with respective elimination half-lives of 0.4, 2.1 and 24.1 hours. Haemodialysis does not affect its half-life.
Excretion (E)	Mostly excreted as unchanged drug with about 50% faecal excretion and 1% renal excretion
Vaginal drug concentration	Time to peak concentration: 18.4 hours after administration of 1200 mg intravaginal capsule. 10.72-12 ng/mL was noted in the blood. Area under the curve: 329-338 × hrs/mL from zero to 48 hours after a single dose of 1200 mg

MNZ is metabolised by the liver in order to yield inactive metabolites that are excreted via the faecal and renal routes (Pershing *et al.*, 1994). The distribution of vaginal-administered MNZ is unknown (Stevens *et al.*, 2013). Finally, MNZ displays a terminal half-life of about 24 hours, with triphasic elimination.

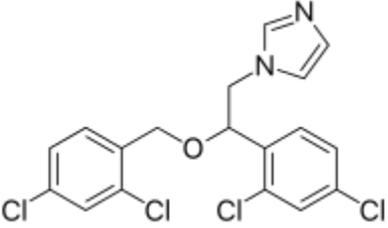

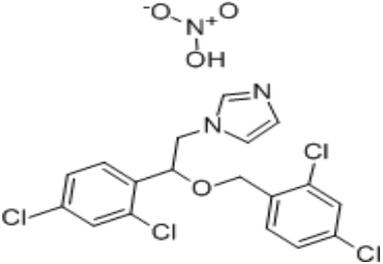

Systemic absorption of MNZ is minimal (<1%), which suggests that the majority of the drug remains localised (Daneshmend, 1986; Merkatz *et al.*, 2017). This is ideal for reducing drug interactions and adverse effects. Effective pharmacotherapy of topical disease, however, requires that the API is delivered to the site of infection in sufficient concentrations in order to produce a pharmacological effect (Pershing *et al.*, 1994). In

the case of VVC, where the pathogen resides on or within the vaginal mucosa, the antifungal agent must be delivered in adequate concentrations and maintain intimate contact with the mucosa for maximal periods so as to inhibit the growth of the fungal pathogen (Daneshmend, 1986).

3.3.1.3 *Physicochemical properties of miconazole nitrate (MNZ)*

Physicochemical properties describe the chemistry and physical attributes of a compound. They are useful in advising developers of possible optimisation strategies for a pharmaceutical compound and its dosage form (Shah *et al.*, 2014). A comparative analysis of miconazole versus salt and MNZ is shown in Table 3.2.

Table 3.2: Comparative analysis of miconazole and miconazole nitrate (MNZ) (adapted from The Pharmaceutical Society of Great Britain. 1979).

Physicochemical property	Miconazole	Miconazole nitrate (MNZ)
Chemical structure		
Chemical formula	C ₁₈ H ₁₄ Cl ₄ N ₂ O	C ₁₈ H ₁₅ Cl ₄ N ₃ O ₄
Molecular mass	416.127 g/mol	479.135 g/mol
Elemental analysis	C 51.96%; Cl 34.08%; N 6.73%; O 3.84%	C 45.12%; Cl 29.59%; N 8.77%; O 13.36%
Appearance	White to pale cream, crystalline powder	Odourless white, microcrystalline powder
Route of administration	Oral and intravenous	Topical and vaginal
Melting point	178 to 184 °C	78 to 82 °C
Solubility	Less soluble than MNZ. Freely soluble in ethanol, chloroform, acetone, dimethylformamide, isopropanol, methanol (MeOH) and propylene glycol	Slightly soluble in H ₂ O, soluble in 140 parts of alcohol, very slightly soluble in ether, hot chloroform, dimethylformamide and dimethylsulfoxide
Partition coefficient (pKa)		6.7
Storage conditions	Powder should be stored in an airtight container away from direct light in order to avoid photochemical degradation.	

MNZ is a nitrate salt form of miconazole, designed to improve the aqueous solubility profile of antifungal drugs and, consequently, improve their absorption (Singh *et al.*, 2014). As depicted in Table 3.2, the melting point of miconazole was reduced greatly through the formation of a salt base; furthermore, its solubility was enhanced but the

pKa remained constant. The discussion of this study is limited to the MNZ and its solubility.

The International Union of Pure and Applied Chemistry (IUPAC) defines solubility as the analytical composition of a saturated solution, expressed in terms of the proportion of a designated solvent (IUPAC, 1997). Solubility is a critical parameter for achieving desirable drug concentrations at the site of action (Singh *et al.*, 2014). It has a direct effect on the bioavailability of an active ingredient and, consequently, its therapeutic response; therefore, an increase in solubility is accompanied by an increased therapeutic response (Kadam *et al.*, 2013).

MNZ is a BCS class II drug, which indicates high permeability characteristics accompanied by low solubility (Singh *et al.*, 2014). The biopharmaceutics classification system (BCS) is a structure that is employed in segregating and classifying drugs, based on their solubility and permeability. MNZ's poor aqueous solubility of less than 1 µg/mL contributes to its less-than-ideal therapeutic efficacy (El-Garhy, 2013). Therefore, particle size reduction and lipid carrier encapsulation by means of SLN preparation was investigated in this study as a means of improving absorption properties of this BCS II drug.

3.3.2 Inactive pharmaceutical ingredients (IPIs)

IPIs, better known as excipients, are inert components of a drug product that do not add to or affect the intended action of therapeutically-active ingredients (Haywood and Glass, 2011). These ingredients are included in pharmaceutical formulations for a variety of reasons, including long-term stabilisation, bulking agents and lubricants. Table 3.3 provides a concise summary of all IPIs used in this study.

Table 3.3: Summary of excipients used in this study

Ingredient	Source	Function
Cholesterol	AppliChem™, GmbH, Darmstadt, Germany	Lipid for SLN preparation
Soy lecithin	AppliChem™, GmbH, Darmstadt, Germany	Co-emulsifier for SLN preparation
Polysorbate 80	Sigma-Aldrich™, Steinheim, Germany	Emulsifier for SLN preparation
Poloxamer 188	Sigma-Aldrich™, Steinheim, Germany	Emulsifier for SLN preparation, thermo-responsive polymer for hydrogel preparation
Hydroxypropyl methylcellulose (HPMC)	Aspen Pharmacare™, Port Elizabeth, South Africa	Mucoadhesive and thermoresponsive polymer for hydrogel preparation
Methylcellulose 450	Aspen Pharmacare™, Port Elizabeth, South Africa	Mucoadhesive and thermoresponsive polymer for hydrogel preparation

An ideal excipient should be multifunctional so as to reduce manufacturing costs (Good and Wu, 2017). It should also be suitable for the intended dosage form, should enhance patient experience with great organoleptic properties, should be easy to source and should adhere to pharmacopeial regulations (Quijano, 2017). All of the selected excipients for this study were freely available in the laboratory, with good toxicity profiles. As a result, poloxamer 188, HPMC and methylcellulose 450 served dual functions. Poloxamer 188 was used as an emulsifier in the preparation of SLNs and as a thermogelling polymer in the preparation of the hydrogel. HPMC and methylcellulose 450 both served as mucoadhesive and thermo-gelling agents in the preparation of the hydrogel.

3.3.3 Solvents

Solvents account for more than half of the materials used in the manufacturing process of pharmaceutical products (Welton, 2015). Solvents are chemical substances that dissolve, suspend or extract materials without altering the chemistry of the material in question or the solvent itself. In pharmaceutical manufacturing, solvents provide a reaction medium, or can be used for the extraction or purification of compounds (Grodowska and Parczewski, 2010).

Unless otherwise stated, all solvents and reagents were obtained from Sigma Aldrich™ (Steinheim, Germany) or Merck™ (Dramstadt, Germany) and were of analytical grade. Filtration of all solvents by means of a vacuum filter was done prior to use. All waters used underwent reverse osmosis purification (Purite™ Select Analyst, Camlab, United Kingdom).

3.4 ANALYTICAL METHOD DEVELOPMENT

3.4.1 Introduction

In the field of pharmaceutical drug development, analytical method development is a process of selecting and assaying for the determination of constituents within a formulation. This process comprises the development and validation of an assay method that can successfully identify, quantify and separate active ingredient(s) within a complex mixture (Chauhan *et al.*, 2015). Analytical method development and validation run parallel to the evolution of the dosage form. The initial phase of method development focusses on the chemical behaviour of an active ingredient(s) in order to generate a model that supports stability, pre-clinical and toxicity evaluations (Ahmad *et al.*, 2018).

There are countless techniques used to generate this initial model, such as HPLC, gas chromatography, capillary electrophoresis and proton nuclear magnetic resonance (NMR) that have been employed for the quantification of MNZ in bulk or complex pharmaceutical mixtures (Belal and Haggag, 2012). However, these methods are rarely utilised due to their high costs, complexity or rarity of equipment in most standard laboratories. Therefore, techniques which promote simplicity, selectivity and rapidity are considered more ideal (Paczkowska *et al.*, 2014). Thus, HPLC with PDA detection

was selected as the instrumentation of choice for this study, owing to its availability in the laboratory facility, simplicity and frequent use in published literature (see Section 3.21). This choice was also made based on how HPLC demonstrates high sensitivity and selectivity when compared with traditional chromatographic techniques (Guillarme *et al.*, 2010).

3.4.2 Principles of high performance liquid chromatography (HPLC)

3.4.2.1 Separation of analyte

Analyte separation by means of chromatography is reliant on molecular size, net charge of molecule and the affinity of the analyte for the organic solvent at high pressure (Coskun, 2016). Several methods, such as ion-exchange, size-exclusion and normal (NP-HPLC) or reverse phase (RP-HPLC) chromatography are used as separation techniques (Thammana, 2016). Characteristics of the various separation techniques are summarised in Table 3.4.

Table 3.4: Characteristics of high performance liquid chromatography (HPLC) separation techniques (adapted from Thammana, 2016)

Separation technique	Mobile phase (MP)	Stationary phase	Analyte characteristics
Normal phase	Non-polar solvent	Polar	Longer retention of polar compounds
Reversed phase	Polar solvent	Non-polar	Quick elution of polar compounds
Ion exchange/Ion pair	Aqueous buffer	Ionic groups	Suitable for charged molecules only
Affinity	Multi-component MP	Gel matrix (e.g. cellulose beads)	For isolation of proteins, enzymes and antibodies
Size exclusion	Organic solvent	Porous silica/gel	Large molecules undergo rapid elution

Normal- and reversed-phase techniques are characterised by the polarity of mobile and stationary phases, respectively (Ačanski *et al.*, 2003). In NP-HPLC, the stationary phase (e.g. silica gel) is polar with a non-polar MP that causes prolonged retention of polar samples within the column packing. Conversely, RP-HPLC utilises non-polar stationary material with a polar MP in order to prolong the elution of non-polar materials (Jandera, 2002). Furthermore, the elution polarity allows for additional classification into isocratic or gradient elution. In isocratic elution, the MP composition is kept constant for the entire analysis, whilst the latter requires a variation of the MP throughout a single analysis (Schellinger and Carr, 2006).

Ion-exchange chromatography comprises of a charged surface stationary phase which interacts with sample ions that carry the opposing charge. This technique is suitable for ionic or ionisable analytes (Moustafa and Morsi, 2013). The strength of the charge determines the extent of affinity of the analyte to the surface. The MP is an aqueous buffer where pH and ionic strength can be manipulated to vary the retention times of the analyte (Kunin and McGarvey, 1962).

For the purposes of this study, RP-HPLC was selected as the analytical method of choice for the quantification of MNZ. This choice was based on how RP-HPLC represents the most common analytical method of separation in the pharmaceutical, biomedical and food industries (Prathap and Nishat, 2013). It is also useful in the separation of many compounds, and can employ a wide range of stationary phases and MPs so as to alter the retention and sensitivity of a given analyte (Sabir *et al.*, 2013).

3.4.2.2 Method of detection

HPLC detectors obtain spectral profiles of a compound. To facilitate adequate detection, the analyte absorbance of light should exceed that of the matrix at the given wavelength (Swartz, 2010). The selection of the correct detector type is dependent on the physicochemical properties of the analyte, its limit of detection (LoD), cost and availability of equipment (Wittrig, 2003).

Ultraviolet (UV)/visible (VIS) detectors are able to measure compounds in the absorption spectrum of the UV and VIS region. These detectors employ a deuterium (D₂) lamp as a light source, with a wavelength range of 190 to 300 nm. For analytes

requiring detector wavelengths of greater than 380 nm, a tungsten (W) lamp is used (Swartz, 2010). The detection of MNZ is conducted at a lower wavelength (UV) since it lacks strong chromophore groups (Patel *et al.*, 2016).

Single UV/VIS detectors generate information at a single wavelength, which can be impractical and time-consuming in the development of new analytical methods. To optimise practicality and method efficiency, the use of multiple diode array detectors (DADs) is encouraged (Swartz, 2010). DADs facilitate the generation of information over a wide range of wavelengths, concurrently. Furthermore, photodiode array DADs offer rapid, low-noise analysis (Martono *et al.*, 2017) that deemed this detection method the appropriate choice for the purposes of this study.

3.4.2.3 Column selection

HPLC columns are responsible for the separation of compounds in a mixture into their various components. These columns constitute the stationary phase in HPLC (Ncube *et al.*, 2016). RP-HPLC columns are comprised of non-polar hydrophobic packing materials. Modern columns derived from silica packing material contain hydrophobic coatings that ensure the rapid elution of hydrophobic compounds. Various matrices, such as silica, polymers and alumina are also available for use (Kazakevich and Lobrutto, 2007).

Great emphasis is placed on column selection during method development as this demonstrates a direct effect on the selectivity and efficiency of a method (Taylor, 2016). Silica columns are used in abundance in related literature, due to their strength, easy derivatisation and manufacturing. In addition, the minimum compression of packing materials occurs under high pressure, which results in negligible deformation of the column (Young and Weigang, 2002). For analyses requiring a pH of greater than seven, standard silica columns are not ideal (Kirkland *et al.*, 1997). Table 3.5 provides a review of several RP-HPLC column types.

Table 3.5: Comparison of RP-HPLC column types showing compounds in order of increasing polarity and decreasing retention of non-polar compounds (adapted from Claessens, 1999; Cledera *et al.*, 2007).

Column type	Structure	Polarity	Retention of non-polar compounds
C ₁₈ (octadecyl) – C ₁₈ H ₃₇		↓	↑
C ₈ (octyl)			
C ₄ (butyl)			
Cyano (CH ₂) ₃ CN			
Phenyl – C ₆ H ₅ (-C ₁₂ H ₉)			
Amino (CH ₂) ₃ NH ₂			

The most commonly used columns in RP-HPLC are silica-based gels in which octadecyl chains are covalently bound in order to free hydroxyl groups (Kazakevich and Lohrutto, 2007). These columns are referred to as the C₁₈ phase. The silica particles contained within the column contain unreacted silanol groups that may form secondary polar interactions with the analyte, which can result in peak broadening and is considered to be disadvantageous (Claessens, 1999). Modification of silica gels with increasing polarity, such as the C₈ phase, can be used at higher pressures and across a wider pH range of 2-8.5 (Nagy and Vekey, 2008).

Although an existing pharmacopeia method is available for the quantification of MNZ by means of RP-HPLC which utilises a C₁₈ phase, its limited availability in the study's laboratory and time constraints for delivery warranted the use of a C₈ column for the purposes of this research. This column was ideal due to its particle size and porosity that aid in the separation of compounds. Furthermore, its inert nature minimises interactions with other materials in the sample phase or MP (Claessens, 1999). The retention of compounds occurs by means of apolar interactions between the stationary phase and the analyte (Jandera and Hajek, 2017).

3.4.3 Experimental

3.4.3.1 Sample preparation

Sample preparation is a critical step of method development (Ravisankar *et al.*, 2015). Therefore, the following points need to be taken into consideration prior to the preparation of each sample:

1. The stability of the analyte in solution. This ensures that the solution does not undergo rapid degradation under laboratory or storage conditions;
2. For RP-HPLC, the solubility of the analyte. This needs to be in an appropriate polar organic solvent, such as methanol. It is of great importance to ensure the absence of precipitation materials during analysis, as precipitated materials often lead to blockages of columns and HPLC lines that can lead in poor results or damage to the apparatus; and
3. The filtration of samples prior to analysis. This is done by means of suitable micron pore filters and is adequate for the removal of particles in the solution.

In addition, filtration functions as a preventative maintenance tool for the apparatus (Smith, 2011).

Based on these aforementioned considerations, a stock solution was prepared by dissolving 20 mg of accurately-weighed (Mettler Toledo™ XP205, Ohio, USA) MNZ in 8.5 ml of methanol. The resultant solution was agitated mechanically to facilitate adequate dissolution of MNZ, after which water was added to yield a final volume of 10 ml. The stock solution was prepared freshly prior to use in order to ensure that no degradation of the sample occurred prior to analysis. This stock solution would undergo necessary dilution with a premixed solution of methanol, namely water (85:15) in order to yield the required concentration for a specific experimental run. Proper

3.4.3.2 Mobile phase (MP) optimisation

MP composition demonstrates the greatest influence on sample retention times and separation characteristics (Guillaume and Peyrin, 2000). As a result, the selectivity of a method can be manipulated through the alteration of the quantity of the organic modifier or the pH (in cases where a buffer is utilised) (Crawford Scientific, 2017). Some of the most commonly used solvents in RP-HPLC are illustrated in Figure 3.3.

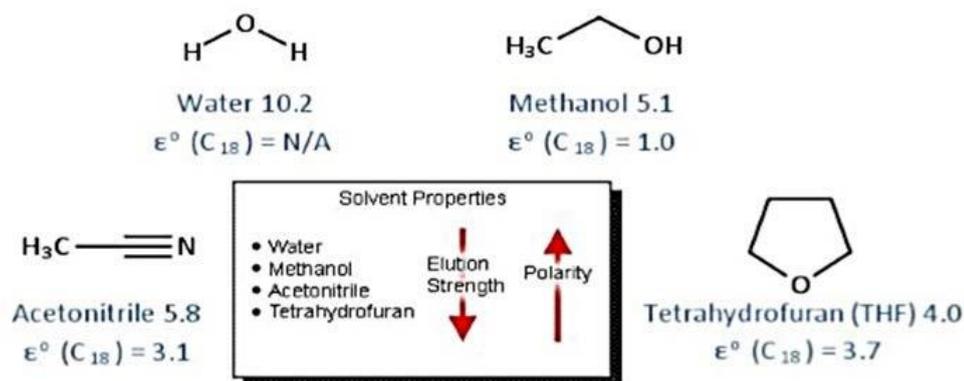

Figure 3.3: Commonly used solvents for RP-HPLC (Crawford Scientific, 2017).

An ideal solvent should be water miscible, have favourable solubility properties, be chemically inert and possess low viscosity and UV detection absorbance (Crawford Scientific, 2017).

i. Selection of organic phase ratio

Hermawan and colleagues (2017) proposed an RP-HPLC method for the quantification of miconazole using a C₈ column. Up to the date of their publication, the authors had not come across any other published literature that had successfully used a C₈ column for the quantification of MNZ by means of RP-HPLC (Hermawan *et al.*, 2017). The outcomes of their research resulted in highly sensitive and reproducible results, however, due to limited information provided by the authors regarding the chromatographic conditions, the method could not be replicated. Yet, the Hermawan *et al.* (2017) study served as a template for the selection of the MP composition used in this current study.

Specifically, MeOH and H₂O were utilised for the MP in various ratios. MeOH provides excellent retention characteristics and allows for sufficient solubility of MNZ (Cavrini *et al.*, 1989). MeOH is also an organic solvent that has been employed in the RP-HPLC analysis of many compounds. It is readily available in many standard laboratories, is cost-effective and has demonstrated sufficient compatibility with MNZ (Crawford Scientific, 2017). H₂O is considered chromatographically weak due to its polarity, as it repels hydrophobic analytes into the stationary phase which results in the extension of analyte retention. The addition of the organic modifier (i.e. MeOH) to the H₂O results in rapid elution of the analyte as a result of the decreased polarity of the MP (Gillar *et al.*, 2014).

Additionally, in this study, a 0.25 mg/ml standard solution was prepared by the dilution of stock solution with a premix solution of H₂O and MeOH (15:85). The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, polyvinylidene fluoride (PVDF) filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. One millilitre of the resultant solution was transferred into three respective 1.5 ml (32 × 11.6 mm) sample vials (LaPha-Pack™, ThermoFischer Scientific™, Massachusetts, USA) for assay. The influence of the organic modifier was investigated by varying its composition at predetermined concentration levels, at a fixed temperature and flow rate. Analytical grade MeOH and vacuum-filtered reverse osmosis H₂O were then placed in separate containers and were mixed online.

ii. Use of buffers

Buffers are aqueous systems that facilitate the resistance of pH changes when small quantities of acid or base are added. They are comprised of a weak acid and a conjugate base, or vice versa (Heinisch and Rocca, 2004). Buffers function by minimising changes in hydrogen ion concentration, thus stabilising the pH within a narrow range. Their potential for use to control the ionisation state of analytes in RP-HPLC has been explored extensively (Lupo and Kahler, 2017).

For the purposes of this study, the use of buffers within the MP was investigated so as to ascertain whether or not its use resulted in better selectivity and retention of MNZ when compared to the proposed organic phase and water mixture. Preliminary investigations and literature reviews conducted suggested that an ammonium acetate buffer (pH 4) was the most suited for RP-HPLC analysis of MNZ (Sahoo and Jain, 2016). The alteration of MP pH can change the extent to which compounds like MNZ are ionised, thus influencing their hydrophobicity. Consequently, such alteration can affect their interaction with the stationary phase and elicit a change in selectivity and elution (Dayyih *et al.*, 2012).

For the preparation of a 0.2 M ammonium acetate buffer solution (pH 4), ammonium acetate salt (15.42 g) was weighed accurately and dissolved in 1000 ml of vacuum-filtered reverse osmosis water and stirred using a magnetic stirrer to facilitate adequate dissolution. The pH of the resultant solution was later adjusted through the dropwise addition of glacial acetic acid (Merck™, Germany) until a final pH of 4 was obtained. The final solution was vacuum-filtered prior to use.

Sample preparation involved the dilution of stock solution with a premix solution of H₂O and MeOH (15:85) to yield a standard concentration of 0.25 mg/ml. The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, PVDF filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. One millilitre of the resultant solution was transferred into three respective 1.5 ml (32 × 11.6 mm) sample vials (LaPha-Pack™, ThermoFischer Scientific™, Massachusetts, USA) for assay. The use of H₂O in the MP was replaced with an ammonium acetate buffer (pH 4). The mixing of the MP occurred online at predetermined concentration levels. All other chromatographic conditions remained unchanged.

iii. Flow rate optimisation

The volume of MP passing through the column per unit time is known as the flow rate (IUPAC, 1997) and is expressed in ml/min. Adjustments to flow rate demonstrate a direct effect on peak symmetry and analyte elution time. The effect of flow rate is minor when compared to other chromatographic variables; therefore, it is only utilised to fine-tune separation (Crawford Scientific, 2017). Its effect on the developed method was investigated in this study to ensure that a highly sensitive yet rapid method was established. Through a review of the literature it was found that an increase in flow rate results in shorter retention times (Keunchkarian *et al.*, 2006). However, this is not always ideal, as it may cause poor separation of peaks that elute closely. In addition, caution should be taken when working at high rates to ensure that the pressure limit of the apparatus is not exceeded so as to maintain apparatus integrity (McCalley, 2000).

Sample preparation in this study involved the dilution of stock solution with a premix solution of H₂O and MeOH (15:85) to yield a standard concentration of 0.25 mg/ml. The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, PVDF filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. One millilitre of the resultant solution was transferred into three respective 1.5 ml (32 × 11.6 mm) sample vials (LaPha-Pack™, ThermoFischer Scientific™, Massachusetts, USA) for assay. The prepared samples were analysed in triplicates at each flow rate level, as demonstrated in Table 3.6. Great caution was taken to ensure that the resultant pressure was maintained below 2000 psi.

Table 3.6: Flow rate specifications for optimisation of mobile phase (MP) parameters.

Run	MNZ concentration	Flow rate
1	0.25 mg/ml	0.8 ml/min
2	0.25 mg/ml	1.0 ml/min
3	0.25 mg/ml	1.2 ml/min
4	0.25 mg/ml	1.5 ml/min
5	0.25 mg/ml	2.0 ml/min

3.4.3.3 Injection volume optimisation

Column overloading, poor retention times and asymmetrical peaks are issues associated with poor selection of injection volume. This is due to an increase in the diffusion process time when a sample is loaded on the column (Kazakevich and Lobrutto, 2007). Large injection volumes promote the generation of asymmetrical peaks, which take longer to elute, and, conversely, smaller injection volumes may result in the loss of response (Keunchkarian *et al.*, 2006). The effect of the injection volume on the quantification of MNZ by means of RP-HPLC was investigated in this study to ensure that symmetrical peaks with sufficient purity and clarity were obtained.

The sample preparation process was similar to that of Section 3.4.3.2. Where, sample preparation involved the dilution of stock solution with a premix solution of H₂O and MeOH (15:85) to yield a concentration of 0.25 mg/ml. The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, PVDF filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. One millilitre of the resultant solution was transferred into three respective 1.5 ml (32 × 11.6 mm) sample vials (LaPha-Pack™, ThermoFischer Scientific™, Massachusetts, USA) for assay. The prepared sample was analysed in triplicates, whilst varying the injection volume with each run. All other chromatographic conditions were kept constant.

3.5 ANALYTICAL METHOD VALIDATION

3.5.1 Introduction

The conduction of method validation is pivotal in proving that the developed method in a study is, indeed, suitable for its intended use. This process assesses the quality, reliability and consistency of analytical results (Ravisankar *et al.*, 2015). The application of method validation is required before the initial use of a method in routine testing, when process is transferred to another laboratory or when conditions or parameters of a method have been altered (Huber, 2007). Figure 3.4 illustrates the International Conference of Harmonisation (ICH) guideline for validation parameters which are discussed in detail in Section 3.5 (*ICH Harmonised Tripartite Guideline Q2 (R1)*, 1994). For the purposes of this study, the following validation parameters have been discussed in the methodology: peak symmetry, specificity, linearity, accuracy, intra- and inter-day precision, limit of quantitation (LoQ) and LoD.

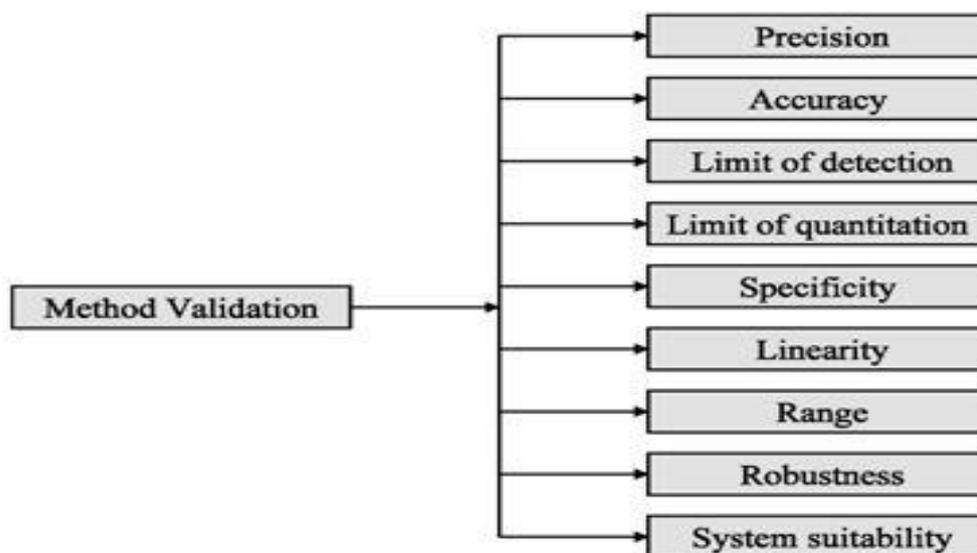

Figure 3.4: International Conference of Harmonisation (ICH) (2005) method validation parameters.

3.5.2 Experimental

3.5.2.1 Peak analysis

A chromatogram is a graphical depiction of the separation of compounds that has occurred in the HPLC system; each observed peak is a representative of the detector response for each analyte (Stoll, 2007). The analysis and optimisation of peak shape and symmetry is vital for ensuring good resolution and the accurate quantification of the analyte (Ravisankar *et al.*, 2015).

The sample preparation process in this part of the study was replicated from Section 3.4.3.2. Where, sample preparation involved the dilution of stock solution with a premix solution of H₂O and MeOH (15:85) to yield a standard concentration of 0.5 mg/ml. The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, PVDF filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. The freshly-prepared samples were analysed in accordance with the optimised chromatographic conditions (see Section 4.1.2) to yield peak models. With the aid of Equation 3.1, the symmetry of the MNZ peak was calculated. CorelDRAW™ software was employed for the generation of peak dimensions, where information of *a* and *b* values were obtained. Where *A_s* is the symmetry factor, *a* is the peak width before the centre at baseline and *b* represents the peak width after peak centre at 10% of peak height.

$$A_s = b/a$$

Equation 3.1: Calculation of chromatographic peak asymmetry factor (Wahab *et al.*, 2017)

3.5.2.2 Linearity

In method validation, linearity is the process of evaluating an analytical procedure within a particular range in order to obtain a response that is directly proportional to the concentration of an analyte in a given sample (Kazusaki *et al.*, 2012). It is expressed as the confidence limit around the slope of a linear regression line (*ICH Harmonised Tripartite Guideline Q2 (R1)*, 1994).

In this study, a freshly-prepared stock solution underwent serial dilution with a MeOH:H₂O (85:15) mixture so as to yield concentrations of 0.25, 0.4, 0.5, 0.6, 1 and

1.5 mg/ml, respectively. Commencing with the most dilute concentration, seven samples ($n=7$) at each concentration level were prepared in three clear glass 1.5 ml (32×11.6 mm) short-thread vials (La-Pha-Pack™, ThermoFischer Scientific™, USA). Each sample was then analysed in triplicates by means of RP-HPLC under the optimised conditions.

Data of the peak area was generated, and the corresponding concentration was calculated. The resultant data was analysed on Microsoft Excel® (2016) software in order to generate a graph of the observed signal response as a function of analyte concentration. In addition, relative standard deviation (RSD) values of the mean peak area, assessment values and % RSD were determined. The significance of the plot, as illustrated by Equation 3.2, was also determined.

$$\text{Assessment value } (z) = \frac{y - \text{intercept}}{50\% \text{ of measured response}} \times 100$$

Equation 3.2: Calculation of linearity assessment value (z).

3.5.2.3 Accuracy

Accuracy, also referred to as recovery, is the expression of the closeness of agreement of data between an experimental value and its theoretical value (Paithankar, 2013). It is reported as the % recovery of known amounts of analytes and is expressed in Equation 3.3.

$$\% \text{ Recovery} = \frac{\text{experimental yield}}{\text{theoretical yield}} \times 100$$

Equation 3.3: Calculation of % recovery.

A freshly-prepared stock solution was prepared, as previously described in Section 3.4.3.1. Where, sample preparation involved the dilution of stock solution with a premix solution of H₂O and MeOH (15:85) to yield a standard concentration of 0.5 mg/ml. The solution was agitated mechanically to facilitate adequate mixing, after which it was filtered using a 0.45 µm, PVDF filter (Sartorius™, Goettingen, Germany) to remove any suspended particles. This solution underwent further dilution with a MeOH:H₂O (85:15) mix so as to yield concentrations of 0.5 and 1.0 mg/ml, respectively. Commencing with

the most dilute concentration, each solution was filtered into six ($n=6$) clear short-thread vials (La-Pha-Pack™, Thermofischer Scientific™, USA). Each sample was then analysed under optimised chromatographic conditions in triplicates, where the consequent data of peak area was gathered. This information was later used to calculate % recovery with the aid of the linear regression equation of the MNZ calibration curve.

3.5.2.4 Precision

Precision, also termed repeatability, is the measurement of variation experienced by a single analyst on a given instrument (Paithankar, 2013). Unfortunately, the determination of precision does not distinguish system variations from other variations experienced during the sample process. It does, however, assume that all variables remain constant for each analysis (Betz *et al.*, 2011).

Six samples ($n=6$) were prepared by diluting a freshly-prepared stock solution (see Section 3.4.3.1) with an 85:15 mix of MeOH and H₂O so as to yield a concentration of 1.5 mg/ml. One millilitre of the resultant solution was filtered into clear short-thread vials and analysed by means of RP-HPLC in triplicates. All samples were analysed under the predetermined chromatographic conditions. The mean % recoveries and respective % RSD of each sample were determined.

i. Intermediate precision

Intermediate precision focusses on the influence of variations within a laboratory as well as on the overall recovery of the analyte in a sample (Betz *et al.*, 2011). Factors for assessment in this section include the variation of machinery, working days or operator (Tiwari and Tiwari, 2010). For the purposes of this study, machinery, chromatographic conditions and operating personnel were kept constant, whilst the days of operation were varied.

Six samples ($n=6$) were prepared by diluting a freshly-prepared stock solution (see Section 3.4.3.1) with an 85:15 mix of MeOH and H₂O so as to yield a concentration of 1.5 mg/ml. One millilitre of the resultant solution was filtered into clear vials and analysed by means of HPLC in triplicates. The % recovery and RSD were calculated accordingly. This process was then repeated on day three and seven after the initial run by keeping all variables constant.

3.5.2.5 *Limit of detection (LoD)*

The LoD of a sample is defined as the smallest quantity that can be detected by a given method above the noise level of a system (Armbruster and Pry, 2008). The simple approach to determining the LoD is based on the signal-to-noise ratio in which measured signals from samples of known concentration are compared to those of blank samples (Sengul, 2016). An alternative approach to LoD determination is based on the standard deviation (SD) of the response and slope, as expressed by Equation 3.4, where σ is the SD of the slope and S is the gradient of the calibration curve.

$$\text{Limit of detection (LoD)} = \frac{3.3\sigma}{S}$$

Equation 3.4: Calculating limit of detection (LoD).

A further alternative approach to LoD determination is based on the visual assessment method. This method entails the definition of LoD through the analysis of various samples of known concentration and the establishment of the minimum level at which the analyte can be reliably detected (Sengul, 2016). Piano and Moore (1999) suggest that any of the aforementioned methods are favourable for the determination of LoD. Therefore, the final choice of technique is governed by the operator. Owing to the simplicity of the method, the LoD approach was determined best for the purposed of this study, with the aid of the aforementioned equation.

3.5.2.6 *Limit of quantitation (LoQ)*

The lowest amount of analyte that can be reliably quantified is known as the LoQ (Armbruster and Pry, 2008). Detector sensitivity and appropriate sample preparation techniques are the main influencers of LoQ data reliability (Paithankar, 2013). It is critical, therefore, that the operator ensures that the preparation of samples is conducted with the outmost accuracy and that the apparatus is well-maintained (Smith, 2011).

Additionally, the technique for the establishment of LoQ is left to the discretion of the operator (Piano and Moore, 1999). For the purposes of this study, LoQ was determined through from the signal-to-noise ratio, where the LoQ corresponds to 10 times the noise level (see Equation 3.5), and where σ represents the SD of the linear calibration curve and S is the slope of the regression line (Shrivastava and Gupta, 2011).

$$\text{Limit of quantitation (LoQ)} = \frac{10\sigma}{S}$$

Equation 3.5: Calculation of limit of quantitation (LoQ).

3.5.2.7 Specificity

The ability to distinguish an analyte in a complex mixture without interference from other components is referred to as the specificity of an analytical method (McPollin, 2009). Various tests need to be conducted to ascertain specificity. Firstly, identification tests are employed to establish the identity of the analyte being investigated. This process comprises qualitative data in which the ability to discern between compounds of closely linked structures or comparisons of reference material is demonstrated (Ravisankar *et al.*, 2015). These identification tests are run concurrently to the assays that assist in the quantification of the analyte, where content or potency of the analyte are established (Betz *et al.*, 2011). Secondly, samples are spiked in order to illustrate that the method results are unbothered in the presence of impurities, excipients or degradants. Lastly, purity tests are carried out so as to ensure that the developed method allows for accurate statements of impurity content that could result from the contamination of organic solvents in the MP or degradants from stress testing (McPollin, 2009).

When it is impossible to demonstrate specificity by spiking the sample, the operator can opt to compare their results with a well-characterised procedure, or include results of samples obtained under appropriate stress conditions (Swartz, 2006). For the purposes of this study the sample was not spiked with an internal standard to ascertain specificity. Rather, the samples underwent forced degradation studies under predetermined stress conditions.

Forced degradation studies, also referred to as stress testing, are procedures that subject an API or drug product to severe and accelerated conditions so as to generate degradation products, which are, in turn, used to establish the stability of the molecule

(Iram *et al.*, 2016). The chosen stability-indicating method used for the quantification of the API should be able to detect the loss of content and subsequent increase in degradation compounds (Bajaj *et al.*, 2012). The information generated from these forced degradation studies aided the selection of the appropriate dosage forms for the API, storage conditions and primary or secondary packaging of the API or the final drug product in this study.

i. Selecting experimental conditions

The ICH has developed and adopted a set of guidelines for forced degradation studies which are alluded to in general terms for commercialisation purposes (*ICH Harmonised Tripartite Guidelines Q1A*, 2003; *ICH Harmonised Tripartite Guidelines Q1B*, 1996). However, these guidelines can also be applied to the development of stability-indicating methods during the developmental phase (Venkataraman and Manasa, 2018). Due to the very general conditions stated by the ICH and the structural diversity of analytes, there is a wide array of experimental conditions available for the conduction of stability-indicating studies. For established molecules, such as MNZ, the stability-indicating studies are defined by previous work in well-documented literature to facilitate consistency throughout development (Hicks, 2012).

General experimental conditions include acid/alkali hydrolysis, oxidation, photolysis and thermal degradation (Venkataraman and Manasa, 2018). Striking a balance between experimental conditions with regard to temperature, extent of degradation or duration of experiment is vital because if minimal stress is applied, some degradation pathways may not be apparent, which can result in partial detection of the API and its degradant products. Conversely, if excessive force is applied, then unrealistic results may be obtained, which could deem the method unsuitable for use. It is, therefore, suggested that careful consideration of API physicochemical properties and degradation under typical conditions, use and storage be taken into account when selecting these experimental conditions (Reynolds *et al.*, 2002).

ii. Identification and characterisation of drug products

Conventional methods, such as liquid chromatography (LC), mass spectrometry (MS) and NMR spectroscopy can be used in the identification and quantification of drug products. RP-HPLC, however, remains the preferred method of quantification for

stability-indicating assays (Khoshk and Afshar, 2014; Bisht *et al.*, 2017). Advantages of RP-HPLC include its compatibility with numerous organic solvents, precision, sensitivity and ability to detect polar compounds (Amanolahi *et al.*, 2017). Therefore, RP-HPLC was selected as the method of choice for this study, where the optimised chromatographic conditions were applied for the quantification of MNZ and separation of peaks.

iii. Acid/alkali hydrolysis

Hydrolysis is the decomposition of a compound by its reaction with H₂O. Acids or alkali catalyse the hydrolysis of ionisable functional groups that are present in the analyte (Iram *et al.*, 2016). Degradation happens when an interaction between an analyte and acid/base occurs and produces primary degradants within a desirable range (Rao *et al.*, 2015).

Strong acids, such as hydrochloric acid or sulphuric acid, in the concentration range of 0.1 to 1 M are employed for acidic hydrolysis tests. Sodium or potassium hydroxide, in the concentration range of 0.1 to 1 M is employed for basic hydrolysis testing (Blessy *et al.*, 2014). For the acid and alkali stress testing that took place in this study, two separate 10 ml solutions (0.5 mg/ml MNZ) were prepared and equal amounts of 1 M of HCL and 1 M of NaOH, respectively, were added. Each solution was then refluxed for 120 minutes at 80 °C. Upon completion, all solutions were neutralised prior to assay in order to maintain system integrity. The resultant solutions were filtered and transferred to sample vials and analysed by means of RP-HPLC under optimised chromatographic conditions.

iv. Oxidation

Many drugs have the potential to undergo autoxidation as a consequence of long-term storage conditions. This process involves a free-radical reaction that requires an initiator to facilitate a chain reaction. Hydrogen peroxide, metal ions or minute levels of impurities can act as potential initiators for autoxidation (Rawat and Pandey, 2015). For stability-indicating methods, hydrogen peroxide (H₂O₂) is a commonly used oxidant that produces degradants during long-term stability studies of pharmaceutical formulations (Sharma and Murugesan, 2017). It is used at concentrations of three to 30% at temperatures below 40 °C for a maximum of eight days.

In this study, equal amounts of a 3% v/v H₂O₂ solution were added to 10 ml of a 0.5 mg/ml MNZ solution. The resultant solution was transferred into a round bottom flask and refluxed at 80 °C for 120 minutes. The solution was then allowed to cool to room temperature and filtered into clear short-thread vials and analysed by means of RP-HPLC.

v. Photolytic degradation

Photolytic stress studies investigate the potential of light to produce degradants within pharmaceutical ingredients and preparations. The rate of degradation is often directly proportional to the light intensity and the amount of light absorbed by a sample (Venkataraman and Manasa, 2018). This kind of investigation can be carried out by exposing a drug product to a combination of VIS and UV light in the range of 300 to 800 nm (Iram *et al.*, 2016).

Photolytic degradation occurs through oxidative or non-oxidative degradation (Shinde *et al.*, 2013). Isomerisation, cyclisation, dimerisation, decarboxylation and haemolytic cleavage of X-C bonds, rearrangement, dealkylation and deamination all constitute as non-oxidative reactions. Furthermore, oxidative reactions occur through singlet oxygen or triplet oxygen mechanisms. Oxidative reactions assume that light can act as a catalyst for oxidation reactions (Rawat and Pandey, 2015).

In this study, a 0.5 mg/ml MNZ solution was prepared by diluting the stock solution with the MP (MeOH 85% v/v and H₂O 15% v/v). The resultant solution was filtered and transferred to a stoppered glass vial and placed in an incubation chamber (Binder™, Tuttlingen, Germany). The sample was then stored for 48 hours at ambient conditions at 1.6-ICH compliant UV-A Illumination (ICH Harmonised Tripartite Guidelines Q1B, 1996), after which the sample was analysed by means of RP-HPLC in triplicates. An additional control sample was prepared and placed in a 'dark-room'; after 48 hours this control sample was also analysed by means of RP-HPLC.

vi. Thermal degradation

Temperature has a direct effect on the rate of a chemical reaction, where its increase directly results in an increase of the reaction rate. Hence, the analyte and formulation of a sample are susceptible to degradation when exposed to higher temperatures (Kaul

et al., 2005). The mechanism of thermal degradation involves hydrolytic, pyrolysis, isomerisation, decarboxylation, rearrangement and polymerisation reactions. Temperatures exceeding 80 °C result in sporadic outcomes that are not indicative of the analyte's pathway of decomposition (Rawat and Pandey, 2015).

For the purposes of this study, a 0.5 mg/ml solution was prepared by diluting the stock solution with the MP (MeOH 85% v/v and H₂O 15% v/v). The resultant solution was filtered and separated into three stoppered vials. Each vial was then either placed in a 25, 60, or 80 °C incubation chamber. Withdrawal of sample solutions from each vial for RP-HPLC analysis at 60 minutes, 24, 72 and 120 hours was done in triplicate.

3.6 DRUG-EXCIPIENT COMPATIBILITY STUDIES

3.6.1 Introduction

It is of great importance that the compatibility of excipients with the APIs are investigated prior to the formulation of a dosage form. This kind of investigation ensures that the excipients' interaction do not lead to instability or the formation of new chemical entities that possess alternative physiochemical or pharmacological properties. Investigative methods, such as thermal, chromatographic or spectroscopic analysis have been employed for compatibility studies (Patel *et al.*, 2015; Ozioko, 2017).

This study determined that thermal analysis comprises numerous techniques that aid with the monitoring of physical and chemical changes of a sample that occur when the temperature is varied (Radic, 2017). Techniques, such as DSC or differential thermal analysis (DTA), are used to determine sample purity, polymorphism, heat of solvation, thermal degradation of API or excipients, as well as the glass transition temperature of polymers. All these techniques allow for the determination of drug-excipient compatibility. However, DSC provides rapid identification of the physicochemical interactions (Deangelis and Papariello, 1968), and was, therefore, chosen for the purposes of this study.

3.6.2 Differential scanning calorimetry (DSC)

DSC is a thermal analytical technique that utilises controlled resistance heaters to individually heat a sample and a reference compound at a predetermined rate (Gill *et al.*, 2010). The change in heat flow between the sample and reference compound are monitored against time and temperature when the substances undergo a thermal event, such as melting or crystallisation. Probable interactions between components

are noted according to their change in corresponding enthalpy, appearance or disappearance of shift in endo- or exothermic peaks (Steinmann *et al.*, 2013). DSC is ideal for the purposes of this study as it operates over a wide range of temperature changes, produces rapid results and consumes miniscule sample quantities. Furthermore, the results obtained from DSC studies correlate with those of stability tests (Navartilova *et al.*, 2014). Thus, it was deemed to be the ideal method for the prediction of pharmaceutical product stability in this study.

It should be noted, however, that some limitations of DSC include the poor detection of samples upon long-term storage, high sensitivity, the inability to effectively monitor minute sample changes and possible misinterpretation of data by the operator. The observation of interactions at high temperatures is also not guaranteed upon storage of a product at ambient temperature (Deangelis and Papariello, 1968).

3.6.3 Experimental

3.6.3.1 Thermal analysis

For this study, thermal analysis of MNZ microcrystalline powder, cholesterol and MNZ-cholesterol mix was conducted using simultaneous thermogravimetric analysis (TGA) and DSC utilising a SDT Q600 (TA instrument™, Utah, USA). An empty aluminium pan was used as a reference. DSC scans were recorded at a flow rate of 100 ml/min and a heating rate of 10 °C/min in the temperature range of 25 to 350 °C.

Sample preparation consisted of the accurate weighing of MNZ and cholesterol, respectively, onto the sample pan and analysing the compounds individually. For the preparation of an MNZ-cholesterol mix, a ratio between lipid and API for the solid lipid nanoparticles (SLNs) was proposed. This ratio was then utilised to formulate a binary mix of MNZ and cholesterol. The two compounds were dissolved in 10 ml of a 1:1 mixture of chloroform and methanol. The solvent was then removed by means of a rotary evaporator (Buchi-210 Rotavapor™, Switzerland). The resultant solid was weighed and placed on the DSC sample pan for analysis. Further details regarding the findings of this process will be presented in the following chapter.

3.7 DEVELOPMENT AND OPTIMISATION OF MNZ-LOADED SOLID NANOPARTICLES (MNZ-SLNs)

3.7.1 Introduction

The development of novel pharmaceutical dosage forms, such as SLNs, follows a process of combining various chemicals and compounds with the API to form a final dosage form (Patel *et al.*, 2015). For the purposes of this study, SLNs functioned as a carrier for the API. This carrier was later incorporated into a semi-solid dosage form for its intended clinical use.

Optimisation is a method of improving the performance of a process, system or product in order to gain maximal benefit. Pharmaceutical optimisation is achieved by realising conditions that yield the best response (Garg and Singhvi, 2015). Formerly, optimisation involved the monitoring of the influence of one factor at a time for a specific experimental response. This way of thinking resulted in lengthy processes that yielded no information on the interactive effect between the studied factors. Consequently, it also resulted in increasing expenses owing to the consumption of more materials (Vakilinezhad *et al.*, 2018). To overcome these shortcomings, multivariate statistical techniques, such as response surface methodology RSM were adapted into the optimisation of analytical processes (Bezerra *et al.*, 2008). Figure 3.5 illustrates a simple flow chart of an ideal optimisation process.

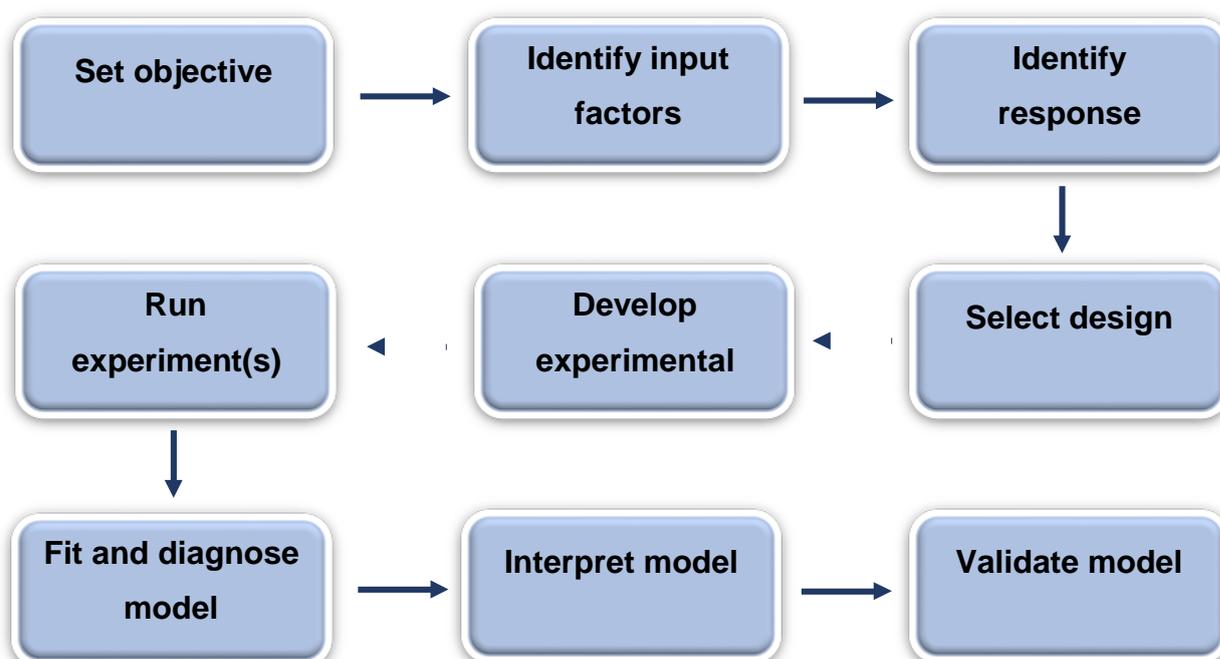

Figure 3.5: Flow chart of pharmaceutical optimisation process (SixSigma, 2018)

Prior to the application of RSM, it is vital that objectives, input variables and expected responses (i.e. output variables) are defined in order to serve as a guide for the experimental procedure (Garg and Singhvi, 2015). Once these variables have been identified, a statistical design should be selected in order to generate an experimental run sheet for the operator. Upon the completion of the experiments, the findings are used to fit and diagnose a model, after which the model is interpreted and validated.

3.7.1.1 Response surface methodology (RSM)

RSM is a statistical tool that is used to empirically derive a functional relationship between an input variable and an experimental response so as to aid with the development, improvement and optimisation of processes. RSM is used extensively in the industrial field to identify input variables that can potentially influence the performance or quality of a product (Behera *et al.*, 2018). It was employed in this study to optimise formulation parameters and identify possible interactive effects between the selected variables.

The term 'response' implies the measurement of performance or product characteristics. A variable is a feature or characteristic that is altered during an experiment (Garg and Singhvi, 2015). During RSM, the operator is responsible for the control of input variables, which are also commonly referred to as independent variables. Output variables, also known as dependent variables, are measured responses or characteristics (Schneider *et al.*, 2010). The operator should be mindful when selecting these variables, because an increase in the number of output factors can result in a more complex optimisation process. A response surface can only be generated once a relationship between input and output variables have been established (Raissi and Eslami-Farsani, 2009).

The improvement of statistical methods through the introduction of RSM has allowed for the simultaneous consideration of possible interacting factors, thereby saving time and finances within pharmaceutical developmental processes. In addition, RSM also enables the detection of faults in the process since a trial and error method is not used (Bezerra *et al.*, 2008). RSM also accounts for interactions between many variables and maximises the generation of information through minimal experimental runs (Spall, 2010). When compared to conventional statistical methods, RSM offers a greater amount of data and is a more economical approach since a small number of

experiments are performed for monitoring the interaction of the independent variables on the response (Wani *et al.*, 2012), hence was selected as the method of choice for the purposes of this study.

i. **Mathematical modelling**

Empirical mathematical models are employed in RSM for the estimation of process performance and the generation of approximation models which are, in turn, used for the prediction of a response in a given process (Chhabra and Singh, 2011). Once an appropriate model has been identified, an approximated surface is produced. The gathered data of the approximated surface is then used for the optimisation of process conditions (Malakar *et al.*, 2012). Equations 3.6, 3.7 and 3.8 demonstrate the most commonly used mathematical models, respectively.

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \dots + \varepsilon$$

Equation 3.6: 1st order empirical model.

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_{12}x_1x_2 + \dots + \varepsilon$$

Equation 3.7: Screening response model.

$$y = \beta_0 + \beta_1x_1 + \beta_2x_2 + \beta_{12}x_1x_2 + \beta_{11}x_1^2 + \beta_{22}x_2^2 + \dots + \varepsilon$$

Equation 3.8: 2nd order empirical model.

In each of these equations, y is the estimated response, x_i represents the input factors, β_0 is the intercept constant, β_i is the first-order co-efficient, β_{ii} is the co-efficient of the second-order terms and β_{ij} is the co-efficient of the second-order interaction terms.

The first-order empirical model is appropriate when an operator is investigating the true response surface over a small region of the input variable in a linear location of the function (Myers *et al.*, 2009). If there are any notable interactions between the variable (x_i), the addition of the interaction term (see Equation 3.7) introduces a curvature. For situations where the interaction term is inadequate for producing linearity in the response function, a second-order model (see Equation 3.8) is employed. This model is commonly used in RSM due to its flexibility, where it can take on a wide array of functional forms and the least squares are easily used to estimate co-efficient parameters (β) (Carley *et al.*, 2004). The pharmaceutical industry employs second-

order empirical modelling extensively, thus allowing operators to establish a relationship between input variables and a response; determine the significance of input factors; and define optimum values for these variables over a region of interest (Peasura, 2015).

ii. Experimental design

Within an experimental design, the introduction of statistical analysis during the initial stages of research and not in the final product is implemented to ensure that quality is built into the product (Politis *et al.*, 2017). For the purposes of this research, statistical design of experiments (DoE) by means of a central composite rotatable design (CCRD) was investigated for establishing a relationship between process input factors and the generated response.

CCRD, also referred to as a Box-Wilson design, is a systematic statistical method (Dutka *et al.*, 2015). This method incorporates five levels, coded $-\alpha$, -1 , 0 , $+1$ and $+\alpha$. It is the largest factorial design for three factors and the smallest for ≥ 5 factors. CCRD comprises axial and factorial points around a centre point using second-order statistics where $2 \leq n \leq 6$ (Muriithi *et al.*, 2017). A graphical representation of a two-factor CCRD is illustrated in Figure 3.6.

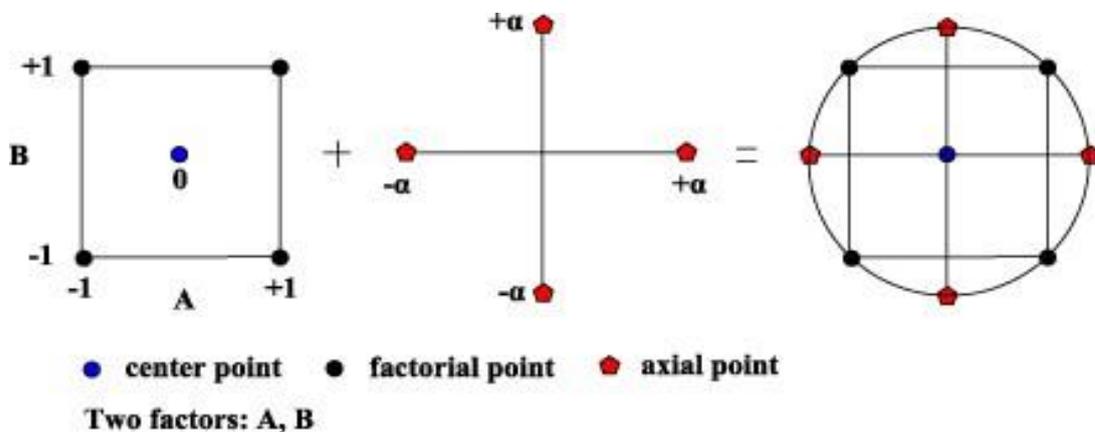

Figure 3.6: Two-factor central composite rotatable design (CCRD) (Salehi *et al.*, 2012).

Equation 3.9 defines the total number of points in a CCRD, where n is equal to the total number of design points and k represents the number of input variables.

$$n = 2^k + 2k + n_0$$

Equation 3.9: Number of design points in a central composite rotatable design (CCRD).

The axial consists of 2^k points arranged in a star; the two points lie on the axis of each control variable at a distance of α (see Equation 3.10) from the design centre, where the distance from the centre to any point is always alpha (i.e. axial or factorial points are always alpha units away from the centre, and are, therefore, rotatable) (Salehi *et al.*, 2012). CCRDs are rotatable in a manner that all points are equidistant from the centre. Rotatability denotes the variance of the response function. A rotatable design exists when there is an equal prediction variance for all points at a fixed distance from the centre (Pennsylvania State University, 2018). The factorials then form a cube around the centre using coded levels of -1 and +1, respectively.

$$\alpha = \sqrt{n}$$

Equation 3.10: Defining alpha (α) in central composite rotatable designs (CCRDs).

3.7.2 Experimental

3.7.2.1 Formulation of MNZ-loaded solid lipid nanoparticles (MNZ-SLNs)

For this study, MNZ-SLNs were prepared by means of a novel melt-emulsion ultrasonication and low-temperature solidification method. A lipid phase was first prepared by dissolving a weighed amount of MNZ, cholesterol and soy lecithin in 10 ml of a 1:1 MeOH and chloroform mixture. The organic phase was then removed by means of a rotary evaporator (Buchi210, Rotavapor™, Switzerland) at 70 ± 2 °C for 20 minutes. Meanwhile, an aqueous phase was prepared concurrently by dissolving equal amounts of surfactant (2% v/v polysorbate 80 and 2% m/v poloxamer 188 solution) in H₂O so as to yield a clear solution. The aqueous phase was maintained at 70 ± 2 °C in a warm bath over a hot plate.

Upon complete evaporation of the organic phase, 20 ml of the aqueous phase was added to the lipid phase (under mechanical agitation) in order to yield an opaque white

coarse emulsion. The resultant emulsion was split into two equal parts, where one part underwent PUS and the other underwent bath sonication.

For PUS, the emulsion was placed in an open McCartney glass jar over a warm bath (70 ± 2 °C) and sonicated at 40% power for four minutes. The remainder of the emulsion was poured into a McCartney jar, which was later sealed and placed inside a warm bath sonicator (70 ± 2 °C) for four minutes. The respective nanodispersions were rapidly cooled in an ice bath immediately after sonication so as to facilitate the solidification of the nanoparticles. PCS was then employed for size and dispersion stability characterisation.

3.7.2.2 Design of Experiments (DoE)

A CCRD generated by DesignExpert® software (Version 7.0 StatEase™, Minneapolis, USA) was used to investigate the influence of lipid concentration and sonication time on MNZ-SLNs formulation characteristics. Preliminary studies (drug excipient compatibility studies) assisted with the selection of lipid type, concentration range and sonication time parameters in this study. The investigated input variables and their respective ranges are recorded in Table 3.7.

Table 3.7: Level of factors in central composite rotatable design (CCRD) for the preparation of MNZ-solid lipid nanoparticles (MNZ-SLNs).

Parameters	Levels		Alpha	
	-1	+1	- α	+ α
X _A – Lipid conc. (% m/v)	3	4	2.79289	4.20711
X _B – Sonication time (sec.)	240	200	227.574	312.426

DoE involves the planning of experiments to ensure that relevant data is extracted and analysed statistically (Weissman and Anderson, 2015). A 13-run, two-factor and five-level CCRD was generated for the optimisation process within this study. Table 3.8 illustrates the values of lipid concentration and sonication time for each individual run.

Table 3.8: Design of Experiments (DoE) for the evaluation of MNZ loaded solid lipid nanoparticles (MNZ-SLNs).

Run	Constants				Variables			
	API	Co-emulsifier	Surfactants		Lipid conc.		Sonication time (sec.)	
	MNZ % m/v	Soy lecith. % m/v	Tween 80% v/v	Kolliphor 188% m/v	Level	% m/v	Level	Sec.
1	2	3	2	2	-1	3.0000	+1	300.00
2	2	3	2	2	- α	2.7900	0	270.00
3	2	3	2	2	0	3.5000	0	270.00
4	2	3	2	2	+ α	4.2100	0	270.00
5	2	3	2	2	0	3.5000	- α	227.57
6	2	3	2	2	-1	3.0000	-1	240.00
7	2	3	2	2	0	3.5000	0	270.00
8	2	3	2	2	+1	4.0000	+1	300.00
9	2	3	2	2	0	3.5000	0	270.00
10	2	3	2	2	+1	4.0000	-1	240.00
11	2	3	2	2	0	3.5000	0	270.00
12	2	3	2	2	0	3.5000	0	270.00
13	2	3	2	2	0	3.5000	+ α	312.43

Thirteen MNZ-SLN formulations were prepared through PUS, as described in Section 3.7.2.1. The lipid and sonication time parameters were varied for each run in accordance with the DoE set out in Table 3.8. The total volume and concentration of the API and surfactant within each formulation was kept constant for each run. Each resultant formulation was split into two, where one part was stored at room temperature (25 ± 2 °C) and the other in a refrigerator (4 ± 2 °C). The resultant formulations were analysed in triplicates for particle size, ZP, PDI and drug content characteristics on days zero, 14 and 28.

3.8 CHARACTERISATION OF OPTIMISED MNZ LOADED SOLID NANOPARTICLES (MNZ-SLNs)

3.8.1 Introduction

Solid lipids are dispersed in an aqueous medium to form SLNs (Mukherjee *et al.*, 2009). Although many advantages, such as bio-tolerability, are attributed to them, SLNs exhibit low DL capacity and drug expulsion upon storage as a result of crystalline transition (Attama *et al.*, 2007). Therefore, characterisation testing is conducted on pharmaceutical formulations to gain insight on SLNs' physical and chemical properties. These properties can demonstrate a direct impact on formulation performance, appearance and stability (Liu, 2005). Characterisation testing can also be conducted on raw and intermediate materials, as well as on the finished product (Anacleto *et al.*, 2018). Various tests and methodologies for the characterisation of SLNs are discussed in this section.

3.8.2 Micro-structure analysis

The determination of particle characteristics is critical for controlling the quality of dispersion and to provide confirmation that the formulated product is indeed within the nanometre range (Singh and Lillard, 2009). PCS, coulter counter (CC), laser diffraction (LD), photosensitive intensity diffraction (PIDS), atomic force microscopy (AFM), field flow fractionation (FFF), transmission or scanning electron microscopy (SEM) and cyrofield scanning microscopy are some techniques that are employed for particle size determination in novel pharmaceutical systems (Akbari *et al.*, 2010).

For the purposes of this study, PCS was employed as the technique of choice, owing to the availability of equipment and simplicity of the method. This commonly used method works by measuring the fluctuation of the intensity of scattered light caused by particle kinetics. The resultant measurement yields a mean diameter (z-avg.) of the bulk population of the particles (Tscharnuter, 2000). In this study, the size measurements obtained from PCS were later validated by means of TEM.

Advantages of PCS include its simple experimental set-up, high-speed analysis, use of low sample volumes, repeatability, reliability and cost-effectiveness. Its use is, however, limited to particles within the nano- to micrometre range (Brar and Verma, 2011).

Particle size (z-avg.), PDI and ZP are additional parameters for demonstrating the production quality and stability of a solid lipid nanodispersion (Akbari *et al.*, 2010). Altogether, these parameters can have a direct effect on the release kinetics and clearance of nanoparticles (Gaumet *et al.*, 2008).

3.8.2.1 Polydispersity index (PDI)

As noted previously, the PDI is a vital parameter that is also defined through PCS. This ratio gives an indication of size distribution within a dispersed system and is defined by Equation 3.11.

$$\text{Polydispersity Index (PDI)} = M_w / M_n$$

Equation 3.11: Polydispersity index (PDI) ratio

In this equation, M_n and M_w represent the mean number of molar mass and weight, respectively (Rane, 2005). The numerical values of PDI can range from 0.0 (perfect uniform sample) to 1.0 (highly poly-dispersed sample with multiple size populations). Although pharmaceutical quality standards do not specify criteria for an acceptable PDI of nanodispersions, values below 0.2 are acceptable for polymer-based colloidal systems. As for lipid-based carrier systems, a PDI of <0.3 is acceptable for indicating homogeneity (Danaei *et al.*, 2018).

3.8.2.2 Zeta potential (ZP)

Virtually all particles that come in contact with a liquid acquire an electric charge on their surface. This electrical potential at the shear plane is referred to as the ZP (Khoshnevisan and Barkhi, 2015). ZP is defined as the electrical potential that is created by the presence of a charge on the particle surface, which expresses a degree of repulsion between similarly charged particles. It is quantified from the mean electrophoretic mobility of particles and expressed in millivolts (mV). Depending on the chemistry and the nature of the particle, ZP may have a negative or a positive value

(Ostolska and Wiśniewska, 2014). Figure 3.5 illustrates the schematic distribution of ions around a charged particle.

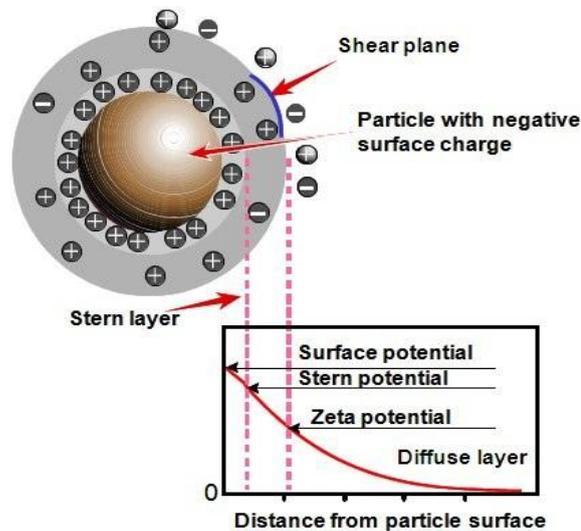

Figure 3.7: Distribution of ions around a charged particle (Malvern™ Instruments, 2018).

This parameter is a useful indicator of surface charge and, consequently, serves as a predictor of dispersion stability by offering insight on the aggregation ability of colloidal systems. Variables, such as pH and temperature, can affect ZP measurements (Emami *et al.*, 2015).

ZP values of ± 0 to 10 mV are characteristic of highly unstable systems, ± 10 to 20 mV point to relatively stable systems, ± 20 to 30 mV indicate moderately stable systems and the highest stability is expressed by a ZP value of ± 30 mV (Bhattacharjee, 2016).

3.8.2.3 Particle morphology

Particle morphology plays a vital role in validating the reliability of routine sizing techniques like PCS. It is responsible for generating detailed nano- and microscopic images for the visualisation of surface morphology and dimensions (Jain *et al.*, 2009) Although a vast number of imaging techniques are available, micro-structure analysis by means of TEM or SEM have proved to be the most popular techniques (Das and Chaudhury, 2011).

Electron microscopy produces detailed images of nano- or microscopic samples (Voutou and Stefanaki, 2008). It works by bombarding the sample with a stream of electrons and, consequently, monitoring the resultant transmission (TEM) or scattering

(SEM) effects. The scattered or transmitted electrons are then detected and converted into enlarged images (Johari, 1968). Furthermore, image analysis software (e.g. ImageJ®, National Institute of Health [NIH], Maryland, USA) utilises this information to generate data on the morphology and dimensions of each individual particle within the nanodispersion.

The primary difference between the two imaging techniques is their data output. SEM produces 3D imaging, whilst TEM produces two-dimensional (2D) imaging (Stadtlander, 2007). The former method is preferred for morphological characterisation of nanoparticles. However vacuum drying utilised in the sample preparation process causes shrinkage in size SLN size. The latter renders better resolution and derives internal composition details within the nanoparticle, such as lattice structures (Pardeshi *et al.*, 2012). Therefore, it was selected as the method of choice for microstructure analysis of the developed SLNs in this study.

3.8.3 Drug entrapment efficiency (%EE)

Entrapment efficiency (%EE) is the expression of the amount of drug incorporated into the nanoparticle and is commonly defined as the % of drug bound to a nanoparticle relative to the total amount of drug in the dispersion (Ekambaram *et al.*, 2011). Determining the %EE is pivotal to the performance of SLNs, since it has a direct influence on the rate and extent of drug release which, in turn, affects therapeutic outcomes (Emami *et al.*, 2015).

To facilitate the improvement of drug encapsulation, operators should aim for high DL capacity with minimal nominal DL. Theoretically, %EE is directly proportional to DL until saturation of the carrier occurs, where the maximum loading capacity is reached, and further DL can have a negative impact on efficiency (Lecaroz *et al.*, 2006). The physicochemical properties of the API and the extent of interactions between the drug, carrier matrix and surrounding environment have a direct effect on DL and entrapment efficiency. Therefore, to obtain high drug entrapment, it is beneficial for the API to interact preferentially with the carrier system rather than with the surrounding environment (Rana *et al.*, 2013).

Methods of %EE determination include gel filtration, dialysis bag diffusion, ultrafiltration and ultracentrifugation. Presently, there is overwhelming literature available related to the use of dialysis or ultracentrifugation for the determination of %EE in SLNs

(Andanova and Peneva, 2017; Uner, 2006). The use of the dialysis bag method is, however, time-consuming and impractical for drugs like MNZ, which possess poor aqueous solubility (D'Souza, 2014). Alternatively, centrifugation offers rapid analysis and was, therefore, chosen as the method used for the purposes of this study.

3.8.3.1 Principles of centrifugation

A centrifuge apparatus causes the separation of compounds in a mixture, based on the difference of sedimentation velocities of components within that mixture (Majekodunmi, 2015). The apparatus comprises a rotor to grip tubes containing the liquid mixture. This rotor is mounted on a driveshaft which rotates when powered by the motor. The centrifugal forces generated by this rotary motion cause particles of higher densities to sediment to the bottom, whilst the lighter particles float to the top (Roberts *et al.*, 1999). The basic principle of sedimentation is explained in Equation 3.12, where F is the relative centrifugal force (RCF), M represents the mass of the particles, r is the distance of particles from the axis of rotation and ω is the mean angular velocity expressed as radians/sec.

$$F = M\omega^2r$$

Equation 3.12: Basic principle of sedimentation.

Many centrifuge apparatus have settings of revolutions per minute (rpm) and it is, therefore, necessary to use Equation 3.13 to convert and express this setting in units of gravitation time (Pierce Biotechnology™, 2005), where the RCF is denoted by g , R is the radius of the rotor (cm) and S is the rotary speed (rpm).

$$g = (1.118 \times 10^{-5})RS^2$$

Equation 3.13: Conversion formula for RCF and RPM (Pierce Biotechnology™, 2005)

For the centrifugation of lipid nanodispersions, following the initial formation of a fatty layer (where most oil droplets are deposited and compressed), an aqueous phase of free-oil is then observed on top of the tube (Laouini *et al.*, 2012). It should also be noted that the breakdown of an emulsion reaches a threshold with prolonged centrifugation, which causes redistribution of the API into the supernatant.

This can be a cause for concern when employing ultracentrifugation as a method of choice for %EE determination (Hao *et al.*, 2011).

3.8.3.2 Calculating entrapment efficiency (%EE)

In this study, the amount of encapsulated drug per unit weight was determined after separating the lipid phase from the aqueous phase by means of centrifugation. The supernatant obtained after this process was then analysed by means of HPLC or spectrometry to determine the quantity of free drug. The loading capacity and %EE of the SLNs are expressed by equations 3.14 and 3.15, respectively.

$$\% DL = \left(\frac{W_{\text{initial compound}} - W_{\text{free compound}}}{W_{\text{lipid}}} \right) \times 100$$

Equation 3.14: Calculating % drug loading (%DL) of SLNs.

$$\% EE = \left(\frac{W_{\text{initial compound}} - W_{\text{free compound}}}{W_{\text{initial compound}}} \right) \times 100$$

Equation 3.15: Calculating % entrapment efficiency (%EE) of SLNs.

In these equations, $W_{\text{initial compound}}$ is the total mass of MNZ assayed in the nanodispersion, or the theoretical mass loaded in nanodispersion; W_{lipid} represents the mass of lipids added to the nanodispersion; and the $W_{\text{free compound}}$ is the mass of MNZ assayed in the clear supernatant after centrifugation of the nanodispersion (Pardeshi *et al.*, 2012). For the purposes of this study on %EE has been discussed.

3.8.4 Accelerated stability testing

Inappropriate storage conditions can lead to the physical and chemical deterioration of pharmaceutical products, which can result in the reduced activity and formation of toxic by-products (Shafaat *et al.*, 2013). Due to the potential for chemical reactions taking place between excipients and APIs, dosage forms are more susceptible to degradation

than bulk or pure drug products (WHO, 1997). External factors, such as high temperature, humidity and exposure to light have all also demonstrated their potential to induce degradation (Bajaj *et al.*, 2012).

Accelerated stability tests offer a way of comparing the stability of alternative formulas, effect of packaging materials and manufacturing processes during the developmental phase (Arunachalam and Shankar, 2013). The WHO classification of climatic regions lists South Africa under the zone IVA (WHO, 2009) for the purposes of stability testing of pharmaceutical products (see Table 3.9). Long-term stability studies conducted at zone IVA and IVB conditions, instead of, or in addition to, zone II, is also acceptable (Hela, 2012).

Table 3.9: WHO climatic classification for stability testing of pharmaceutical products (Hela, 2012).

Climatic zone	Definition	Criteria Mean annual temperature measured in open/ Mean annual partial water vapour pressure	Long-term Testing conditions
I	Temperate climate	$\leq 15\text{ }^{\circ}\text{C}/\leq 11\text{ hPa}$	21 °C/45% RH
II	Subtropical & Mediterranean climate	$>15\text{ to }20\text{ }^{\circ}\text{C}/11\text{ to }18\text{ hPa}$	25 °C/60% RH
III	Hot and dry climate	$>22\text{ }^{\circ}\text{C}/\leq 15\text{ hPa}$	30 °C/35% RH
IVA	Hot and humid climate	$>22\text{ }^{\circ}\text{C}/>15\text{ to }27\text{ hPa}$	30 °C/65% RH
IVB	Hot and very humid climate	$>22\text{ }^{\circ}\text{C}/>27\text{ hPa}$	30 °C/75% RH

For accelerated studies, a minimum of three intervals, inclusive of the initial and final time points, from a six-month study is recommended (WHO, 2009). Table 3.10 illustrates the general storage conditions of finished pharmaceutical products under refrigeration conditions.

Table 3.10: General storage conditions for finished pharmaceutical products (FPPs) under refrigeration conditions (Hela, 2012).

Study	Storage conditions	Minimum time period covered by data at submission
Long-term	5 ± 3 °C	12 months
Accelerated*	25 ± 2 °C / 60 ± 5% RH or 30 ± 2 °C / 65 ± 5% RH or 30 ± 2 °C / 75 ± 5% RH	Six months

**Whether accelerated stability studies are performed at 25 ± 2 °C / 60 ± 5% RH, 30 ± 2 °C / 65 ± 5% RH or 30 ± 2 °C / 75 ± 5% RH is based on a risk evaluation. Testing at more severe accelerated conditions can be an alternative to the storage condition at 25 °C / 60% RH or 30 °C / 65% RH (Hela, 2012).*

The WHO (1997) general request is that a stability report be established for internal use and registration purposes. The results within this report should propose appropriate storage conditions and shelf-life of the dosage form (WHO, 1997). The storage stability of SLNs can be simply assessed by monitoring the physical or chemical properties (i.e. the lipid and drug stability) of the SLNs upon storage (Bahari and Hamishehkar, 2016). Physical characteristics, such as ZP, drug content, particle size and organoleptic properties are examples of factors that were monitored during this course of this study.

3.8.5 Experimental

3.8.5.1 Photon correlation spectroscopy (PCS)

For the determination of particle characteristics (z-avg., ZP and PDI), PCS was employed in this study. Each formulation was analysed by dispersing 1 ml of the resultant suspension in 10 ml of reverse osmosis H₂O and vortexed (Gemmy Industrial Corporation™ VM300, Texas, USA) in order to yield a 10-fold diluted suspension. The diluted suspension was then filtered through a 0.45 µm micropore PVDF membrane filter (Satorius™, Germany) into clear disposable zeta cells. The samples were loaded onto and analysed by a Malvern Zetasizer Nano-ZS particle analyser (Malvern Instruments™, United Kingdom) at ambient conditions (25 ± 2 °C) in triplicates using

H₂O as the dispersant medium. The number of sub-runs and attenuator settings were automatically set by the instrument in accordance with the generated phase plot data.

3.8.5.2 Transmission electron microscopy (TEM)

TEM was selected as a visualisation aid in the microstructure analysis of the developed MNZ-SLNs in this study. Preliminary studies that were first conducted under a standard electron microscope indicated that the direct analysis of the developed MNZ-SLNs without dilution yielded clumpy, unclear images with no separation of the individual nanoparticles. Therefore, MNZ-SLNs samples were prepared by adding 4 ml of reverse osmosis H₂O to a 1 ml MNZ-SLN suspension. The prepared samples were agitated and vortexed at low speed to facilitate adequate mixing. Using a tweezer, a mesh carbon-coated copper grid was dipped into the sample. The grid was rapidly stained with phosphotungstic acid and the excess was removed using filtered paper and left to dry in a vacuum desiccator for 24 hours. The dried sample was then analysed by TEM (JOEL™ Ltd, Japan).

3.8.5.3 Calculating drug entrapment efficiency (%EE) of MNZ loaded solid lipid nanoparticles (MNZ-SLNs)

For this study, the drug entrapment efficient was determined through an indirect method by measuring the concentration of free drug in the dispersion medium. Firstly, the total amount of API (MNZ) in each formulation was determined by dissolving 1 ml of the suspension in 8.5 ml of methanol; the resultant solution was mechanically agitated and 1.5 ml of H₂O was then added to yield a final mixture. The resultant mixture underwent filtration (0.45 µm PVDF membrane filter, Sartorius™, Germany) into three (*n*=3) 1.5 ml (32 × 11.6 mm) clear glass short-thread vials (La-Pha Pack™ ThermoFischer Scientific™, Massachusetts, USA). This mixture was then analysed by means of RP-HPLC in triplicates under the optimised chromatographic conditions. The peak area generated was used to calculate the concentration of MNZ in the solution, with the aid of the determined calibration curve of MNZ.

For the determination of free drug, 2 ml of each MNZ-SLN formulation was centrifuged (Hermle™ Z300, Gosheim, Germany) at 50 000 rpm for one hour so as to yield a clear supernatant liquid at the top of the test tube. Half a millilitre of the supernatant liquid was removed using a pipette (Eppendorf™, Germany) and transferred into a clear

glass test tube where 4.25 ml of MeOH and 0.75 ml of H₂O were subsequently added in order to yield a clear solution. The resultant solution was filtered and analysed by means of RP-HPLC in triplicates under the optimised chromatographic conditions. Equations 3.14 and 3.15 were used to calculate the % DL and %EE respectively.

3.8.5.4 Storage stability determination of MNZ loaded solid lipid nanoparticles (MNZ-SLNs)

In this study, the stability of the formulated nano-dispersion was determined by investigating the change in particle characteristics over a period of six months. Changes in z-avg., PDI and ZP were monitored by means of PCS. MNZ-SLNs were prepared in duplicates and stored at 4 ± 2 °C and 25 ± 2 °C, respectively; with the sample analysis occurring at predetermined time intervals at months zero, one, three and six.

3.9 DEVELOPMENT AND CHARACTERISATION OF *IN SITU* VAGINAL HYDROGEL

3.9.1 Introduction

NDDS are a rapidly developing field of study. This development has been strengthened by innovative developments in, amongst others, the fields of pharmaceuticals, biotechnology, nanotechnology and chemistry (Rangasamy and Parthiban, 2010). Hydrogels have also recently become a key focus in the field of pharmaceutical drug delivery, owing to their versatility in terms of compositions and their adjustability to a variety of ROA (Sosnik and Seremeta, 2017). Thermoresponsive polymers, in particular, provide triggered drug release; hence, they have been exploited for pharmaceutical drug delivery (Taylor *et al.*, 2017). Because of its many uses, this current research limits its focus to localised vaginal drug delivery by means of thermoresponsive hydrogels.

The vaginal route is useful for both systemic and localised drug delivery, since first-pass hepatic metabolism is bypassed. Moreover, its dense vascularisation and high mucosal permeability allows for the administration of various classes of drugs, such as antifungals and hormones (Srikrishna and Cardozo, 2013). Systemic drug delivery is often associated with toxicity and increased manifestations of adverse effects (Faro,

1994). Localised drug delivery, on the other hand, allows for drug administration at lower doses and direct tissue targeting (Tiwari *et al.*, 2012).

Thus, *in situ* gels that respond to external thermal stimuli are ideal for intravaginal drug delivery. They have the ability to overcome limitations like messiness, leakage and the uneven spreading of dosage forms within the vaginal tract (Gandra, 2013). At room temperature, their sol state facilitates easy insertion and spreading. Once in the vaginal tract, the change in temperature from the external to internal environment causes a phase transition into a gel. The solid state of the gel ensures that the dosage form maintains intimate contact with the vaginal mucosa for prolonged periods (Taurin *et al.*, 2018).

3.9.2 Methods of thermoresponsive hydrogel preparation

There are three methods of gel preparation, *viz.* fusion, cold or dispersion. The fusion method employs waxy materials in non-polar media. The drug is then incorporated when the waxy material is melted by fusion until a gel is formed. The dispersion method, on the other hand, involves the dispersion of the gelling agent at high speeds (1 200 rpm) for 30 minutes. For this method, a non-aqueous solvent is required for API incorporation (Arun *et al.*, 2016). The cold method (CM) of gel production was investigated for the purposes of this study. This commonly used method allows for physical cross-linking between the chosen polymers in the absence of organic solvents. CM involves the dissolution of polymers at ambient temperature under vigorous stirring. The resultant formulation is then refrigerated (4 ± 2 °C) to facilitate complete cross-linking (Chakraborty *et al.*, 2014).

3.9.3 Characterisation of thermo-responsive hydrogels

For the purposes of this study, characterisation studies for the prepared hydrogels were limited to rheology, organoleptic properties, pH, drug content uniformity, sol-gel transition, *in vitro* drug release and antimicrobial susceptibility testing (AST).

3.9.3.1 Rheology

Rheology is a branch of science concerned with the study of deformation and flow of matter. An instrument used for the measurement of viscosity and rheology is called a rheometer (Korolczuk-Hejnak, 2014). The conduction of rheological studies on semi-

solid preparations is critical for demonstrating their flow properties that influence packaging, storage stability and ease of application of the dosage form (Sivaraman and Banga, 2015).

Rheometer should not be confused with a viscometer, which is only capable of conducting viscosity measurements. Viscosity defines a fluid's resistance to flow, and plays a vital role in rheology as it affects the flow of matter and materials (Malkin and Isayev, 2017). A rheometer works by determining the stress-deformation relationships of materials and is classified according to the flow type wherein material properties are investigated according to two main groups (Chen *et al.*, 2010).

The two groups comprise shear (rotational) and extensional rheometers. Extensional rheometry is, generally, not performed on low-viscous materials, such as suspensions or semi-solid preparations, and therefore, is not discussed in this study. Shear rheometers include the likes of rotational and capillary rheometers (Gandra, 2013). Extensional rheometers generate shear between fixed and moving surfaces, whilst shear rheometers are pressure-driven and generate shear through a pressure difference along the channel through which a material flows (Galindo-Rosales *et al.*, 2013). Rotational rheometers are ideal for measuring the complex flow and oscillatory properties of materials. They are also used for viscosity measurements where fluids cannot be defined by a single value of viscosity and offer greater measurements and parameters than viscometers (Brockel *et al.*, 2013). Equation 3.16 illustrates the mathematical relationship of viscosity, shear stress and shear rate.

$$\eta = \frac{F/A}{dv_x/dz}$$

Equation 3.16: Mathematical relationship between viscosity, shear rate and shear stress.

In the aforementioned equation, η denotes viscosity in millipascal second (mP·s), F/A is the force per unit area representing shear stress and dv_x/dz represents the shear rate. Factors like temperature, concentration, attractive forces and particle size can influence the flowability of materials (Likavcan *et al.*, 2014).

The flow properties of a substance are then determined by two methods known as controlled stress or rate mode (Gandra, 2013). In the former mode, a known amount of stress (torque) is applied to a material and its resultant strain (shear rate) is measured. For the latter mode, a defined shear rate is applied and the subsequent stress (torque) is measured (Janmey and Schilwa, 2010). The information generated from these two modes is used to obtain a shear stress versus shear rate plot (see Figure 3.8, which provides insight on the flow properties of the test material).

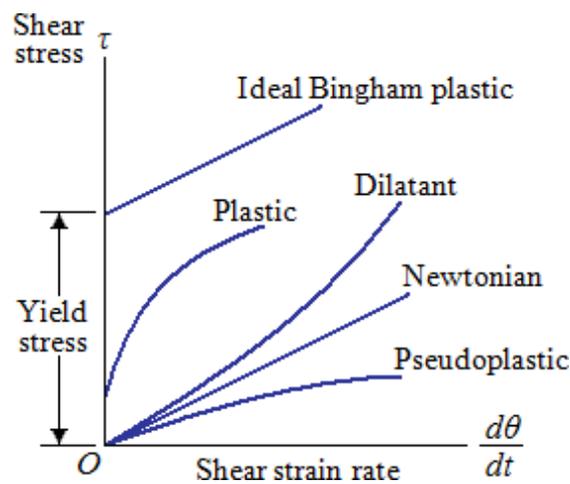

Figure 3.8: Flow curve of shear stress as a function of shear rate for various fluids (Kazemian *et al.*, 2012).

Material flow behaviour is classified into various groups, as depicted in Figure 3.8. The first group is Newtonian fluids which are characterised by a linear relationship between applied stress and shear rate. Examples of Newtonian fluids include cooking oil and corn syrup. The second group is known as Bingham bodies or non-Newtonian fluids and demonstrate a change in flow or viscosity under stress (Chharbra, 2010). Characteristic differences between Bingham bodies and non-Newtonian materials are that the former can maintain shapes or peak when no stress is applied, whilst the latter is a flat and featureless surface. Further classification of non-Newtonian material is dependent on their viscosity (Abegunrin *et al.*, 2016).

The third group is shear thinning (pseudoplastic) behaviour, which is characterised by a decrease in viscosity and an increase in shear stress (Chharbra, 2010). Conversely, shear thickening (dilatant) behaviour is characterised by an increase in viscosity with an increase in shear stress. The fourth group consists of Bingham plastic materials

that behave as rigid bodies at low stresses but begin to flow under high stress once the yield point has been surpassed (Barnes, 1999). Examples of such materials included clay suspensions and toothpaste. The final group is Bingham pseudoplastic behaviour, which comprises materials that require minimum stress application before they flow; after which any addition in strain results in reduced viscosity (Moller *et al.*, 2006).

Viscoelastic investigations determine the interactions between polymers and additives with great sensitivity. The flow characteristics of poloxamer-based solutions can be Newtonian or non-Newtonian, dependent of the temperature and concentration of the polymer (Chharbra, 2010). The flow characteristic of the prepared hydrogel formulations was investigated for the purposes of this study.

i. Plate geometry

The generic structure of a parallel plate measuring system was employed for the purposes of this study and is illustrated in Figure 3.9. The sample is loaded into the gap between the upper measuring plate and the temperature controller, thereafter shear flow is generated by rotation or oscillatory motion (Gandra, 2013). Generally, the type of measuring plate used is dependent on the sample being analysed. This plate may be a cone and plate or cylinder/parallel system (Khan *et al.*, 2009). The upper measuring plate is supported by a near-frictionless air-bearing beam and driven by an ultra-low inertia motor coupled with a high-position encoder. The temperature of the sample is maintained by the lower plate/temperature controller (i.e. the upper heated or Peltier plate) (Gandra, 2013; Mendez *et al.*, 2014).

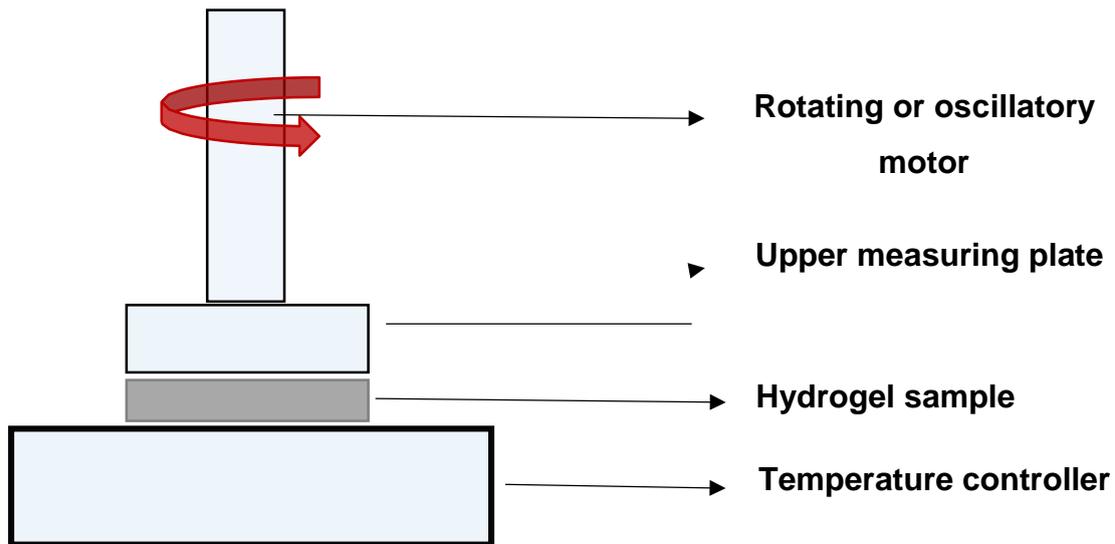

Figure 3.9: Generic diagram of a parallel plate measuring system.

The rheological characteristics of the prepared hydrogel can be determined by rotating or oscillatory motions or by applying a step-function within the measuring system. Common modes for rheometry include the rotational mode for the measurement of stress viscosity and the oscillatory mode for the measurement of dynamic material properties like phase angle and viscoelastic properties (Mendoza, 1998).

The oscillatory mode employs a motor oscillating shaft and a plate of varying frequencies that maintains constant shear. The material exerts a torque on the rheometer in response to applied stress (Kocen *et al.*, 2017). For viscoelastic materials, the torque is dependent on the applied frequency, as is the phase angle between the torque and shear. The loss modulus (G'') is then calculated based on the phase, storage (G') and torque (Franck, 2016). In the rotational mode, the rheometer is maintained at a constant speed by the motor by using a torque detection system. When the suspended measuring plate is rotated, the flow resistance (viscosity) of the sample tries to twist the measuring plate. By determining the resultant 'twisting' force and knowing the stiffness of the plate, the torque may be obtained (Gandra, 2013). This method was employed for rheological testing of prepared hydrogel formulations in this study.

3.9.3.2 Organoleptic assessments

Organoleptic evaluations make use of sensory organs in the determination of product characteristics. They are applicable in cases where scientific testing is unavailable or

not yet established. The organoleptic properties of materials are determined through tactile, olfactory, visual and gustatory perceptions (Patil *et al.*, 2017). The information gathered from organoleptic evaluations correlate strongly with patient compliance and adherence. Unacceptable sensory properties, such as bad odour, taste or texture contribute to compromised pharmacotherapy adherence (Morrow *et al.*, 2015).

The physical properties of vaginal dosage forms, including the mode of application and organoleptic properties are strong determinants of patient acceptability and can influence patient adherence and, subsequently, therapeutic outcomes (Rosen *et al.*, 2015). Semi-solid preparations, such as gels, demonstrate the highest patient acceptability for intravaginal drug delivery (Ndesendo *et al.*, 2008; Rohan and Sassi, 2009; Sahoo *et al.*, 2013). A descriptive cross-sectional study conducted by Palmeira-de Oliveira and colleagues (2014) utilising a web-based survey concluded that odour was the most important sensory characteristic that influenced women's decisions on using intravaginal products. Odour was closely followed by colour and flavour, respectively. The majority of the respondents indicated that they preferred transparent products with little to no odour and taste, and which could be applied by means of an applicator. Sensory characteristics will be evaluated in this study.

3.9.3.3 pH assessment

pH is a measure of hydrogen ion concentration $[H^+]$ in a solution (Bates, 1948). This term is expressed mathematically as the logarithmic (base 10) of the reciprocal of hydrogen ion concentration (see Equation 3.17).

$$pH = -\log[H^+]$$

Equation 3.17: Mathematical expression of pH (Munhoven, 2013).

An acidic pH is characterised by a low pH corresponding to a high value of hydrogen ion concentration. The contrary is applicable for a basic or alkaline pH, where the concentration of hydrogen ions in the solution is low with a high numerical pH value (Hamm *et al.*, 2015). Physiological pH ranges from one to eight, depending on the site or function of the organ, surrounding tissue or fluid. The vast pH range creates a basis for pharmaceutical dosage forms that ionise in response to the pH gradient (He *et al.*, 2003). For example, the pH of an API is governed by ionisation constants that affect

the lipophilicity and, consequently, the bioavailability of the API. If a particular drug does not contain a functional group that is ionisable in a given range, it adopts qualities of a non-electrolyte that remains unionised under physiological conditions (Kah and Brown, 2008). The control of pH is critical during dosage form development in order to minimise potential degradation of the API. Furthermore, dosage forms formulated within a pH range of the intended site of application create non-irritant products that can not only improve drug administration, but also patient compliance by improving the adverse effect profile (Wen *et al.*, 2015).

3.9.3.4 Drug content uniformity

Drug content uniformity is an analytical parameter of the quality control of pharmaceutical dosage forms. It ensures that a consistent dose of the active is maintained between batches so that the patient, in turn, receives the correct dose (Slew, 2018).

Mandatory product quality tests for semi-solid topical drug products include the determination of tube uniformity (Ueda *et al.*, 2009). The term 'tube uniformity' can be described as the degree of uniformity of the amount of API amongst tubes containing multiple doses of a given semi-solid dosage form (United States Pharmacopeial Convention, 2013). Ideally, this test should be conducted over a predetermined interval, as some products tend to show physical separation at accelerated storage temperatures due to the nature of the vehicle. The drug uniformity of the topical dosage form is demonstrated by assaying the top, middle and bottom of the sample (Ueda *et al.*, 2009). Drug content uniformity tests will be conducted to ascertain the uniformity of MNZ in the final formulation.

3.9.3.5 Sol-gel transition temperature

Thermoresponsive polymeric hydrogels have been investigated extensively for their potential in sustained drug release and surgical innovations (Bora *et al.*, 2014). The term 'thermoresponsive' implies a critical change due to temperature variation and not progressive thermosensitivity. This thermoresponsive phenomenon is defined by a transition temperature whereby a substance acquires loses due to distinct superconductive properties (Taylor *et al.*, 2017).

Thermoresponsive hydrogels undergo phase transition at temperatures above or below the critical solution temperature (CST). Depending on the mechanism of transition, hydrogels are further classified as positive or negative thermoresponsive polymers (Mah and Ghosh, 2013). Polymers belonging to the positive group swell in H₂O, with an increase in temperature above the CST, and solidify above the upper critical solution temperature (UCST). A subsequent decrease in temperature below the UCST forms a free-flowing solution due to shrinkage of the polymer network (Gandra, 2013). The contrary applies to negative polymers, which demonstrate shrinkage with an increase in temperature above the CST (Klouda and Mikos, 2011).

For vaginally administered products, the sol state is an aqueous solution prior to administration that quickly transforms to a non-flowing gel upon administration in response to the vaginal milieu (Alves *et al.*, 2018). The sol-gel transition can be measured by means of rheology or qualitative assessments (Ponton *et al.*, 2005).

3.9.3.6 *In vitro* drug release studies

In vitro drug release testing (IVDRT) is a measure of the release of the API from the dosage form matrix in a controlled laboratory environment. It is a vital evaluation in drug development and quality control (Brown *et al.*, 2011). The process of IVDRT involves subjecting the dosage form to a set of conditions that could promote drug release, and quantifying the amount of drug released under predetermined conditions (Shen and Burgess, 2013).

For drug development, IVDRT is critical for modelling *in vivo* formulation behaviour and predicting the time-frame of drug release (Stillhart *et al.*, 2017). There are currently no approved compendial methods for the determination of IVDRT of topical products like gels, however, instrumentation, such as flow-through cell apparatus or VDC, have been investigated extensively for their use in the IVDRT of semi-solid preparations. VDCs comprising of FVDC also come highly recommended (Kanfer *et al.*, 2017; Naik *et al.*, 2016). Advantages of the FVDC systems include their simplicity and yield of reliable and reproducible results (Liebenberg *et al.*, 2003).

Pharmaceutical drug delivery systems play a key role in regulating the therapeutic efficacy of APIs by manipulating their toxicity profile, rate of drug release and duration of action at the target site (Upadhyay, 2014). The drug release profiles of various pharmaceutical dosage forms may be described in several ways, including: immediate

release formulations that are designed to allow the release of API instantaneously upon administration; or modified release (MR) formulations that encompass a group of novel pharmaceuticals that facilitate extended or delayed release of API. Examples of MR formulations include delayed, extended, pulsatile and CR dosage forms (Challener, 2018). The focus of this study is limited to CR semi-solid dosage forms.

Controlled release (CR) formulations are designed to maintain drug levels within a desirable range over a sustained period at a constant rate (Ummadi *et al.*, 2013). The main objective of CR formulations is to ensure safety, improve the therapeutic efficacy of many drugs and increase patient compliance by decreasing dosing frequency (Bhowmik *et al.*, 2012; Jalwal *et al.*, 2018). CR formulations are not confined to a specific ROA; therefore, many dosage forms have been developed for, amongst others, transdermal, buccal and vaginal drug delivery (Siegel and Rathborne, 2012). The use of systemically-acting CR formulations are often associated with an increased manifestation of adverse effects and the potential for drug interactions, owing to drug accumulation in tissues not associated with the target site. As a countermeasure, regional or localised drug delivery permits drug administration at lower doses and drug tissue targeting, thereby limiting drug exposure to the affected site (Alomar, 2014)

i. Calculating drug release

IVDRT defines the liberation process of a drug from the dosage form. It is a complex process where, upon contact with an aqueous medium, H₂O penetrates into the dosage form matrix and dissolves the drug (Kakar *et al.*, 2014). The now dissolved drug consequently diffuses out of the matrix due to the presence of a concentration gradient. Moreover, the dosage form may undergo several changes, such as swelling or dissolution in the aqueous medium, thus further contributing to the overall process of drug release (Jug *et al.*, 2017). Once the drug has diffused out of the matrix and into the aqueous medium, minute samples of the medium are withdrawn for analytical quantification of the drug (Nounou *et al.*, 2006). The amount of drug quantified from the analytical assay is then used to determine the cumulative amount of API released per surface area of the membrane, as added by Equation 3.18.

$$Q = \{C_n V + \sum_{i=1}^{n-1} C_i S\} / A$$

Equation 3.18: Calculating cumulative amount (Q) of drug release for IVDRT (Thakker and Chern, 2003).

In the aforementioned equation, Q is the cumulative amount of API released per surface area of the membrane ($\mu\text{g}/\text{cm}^2$), C_n defines the concentration of API at a predetermined sampling interval, V represents the receptor fluid volume in an individual cell, $\sum_{i=1}^{n-1} C_i S$ is the sum of concentrations of API ($\mu\text{g}/\text{ml}$) determined as $n-1$ of the sampling interval, S is the volume of sampling aliquot and A is the surface area of the sample well (Thakker and Chern, 2003). A plot of % cumulative drug release as a function of time is designed to illustrate the drug release kinetic profile over a predetermined period.

The final drug release kinetics from CR semi-solid preparations, such as hydrogels, commonly follow the Higuchi model (Brown *et al.*, 2011; Kanfer *et al.*, 2017). The Higuchi model for the rate of drug release from a matrix is based on the following assumptions:

1. The initial drug concentration in the dosage form matrix is much higher than the drug solubility;
2. Drug diffusion is one dimensional;
3. Drug particles are smaller than system thickness;
4. Drug diffusion is constant;
5. Matrix dissolution and swelling are negligible; and
6. Ideal sink conditions are always attained in the release environment (Dash *et al.*, 2010).

Equation 3.19 further explains the basic principles of the Higuchi model for drug release kinetics.

$$Q = A\sqrt{D(2C_0 - C_s)C_s t}$$

Equation 3.19: Basic Higuchi equation for modelling drug release kinetics.

In this equation, Q is the cumulative amount ($\mu\text{g}/\text{cm}^2$) in time (t) per unit area (A). C_0 represents the initial drug concentration, C_s is the solubility of the drug in the matrix and D denotes the diffusion co-efficient of the drug in the matrix. This mathematical relationship holds true until total drug depletion from the dosage form occurs (Siepmann and Peppas, 2011). In order to study dissolution of dosage forms where drug release occurs through a porous system, the resultant equation is modified slightly (see Equation 3.20).

$$Q = A \sqrt{\left(\frac{D\delta}{\tau}\right) (2C - \delta C_s) C_s t}$$

Equation 3.20: Higuchi model equation for drug dissolution via a planar heterogeneous system.

Here, D is the diffusion co-efficient of API in the solvent, δ denotes the porosity of the matrix, τ is the tortuosity of the dosage form matrix, A and t and C_s are as per Equation 3.19's description. Equation 3.20 can further be simplified to yield Equation 3.21.

$$Q = K_H \times t^{1/2}$$

Equation 3.21: Simplified Higuchi model equation for drug release kinetics

In this equation, the Higuchi constant is denoted by K_H . This final equation (see Equation 3.20) is normally used to define the drug release kinetics of several MR dosage forms.

However, for the purposes of this study various mathematical models, including Higuchi, first order and Korsmeyer-Peppas, were investigated in the determination of release kinetics of MNZ-SLNs and MNZ-Hydrogels respectively.

3.9.4 Experimental

3.9.4.1 Preparation of unloaded hydrogels

For this study, unloaded hydrogels of various compositions were prepared and characterised for their pH and thermoresponsive potential. Table 3.11 gives an overview of the respective ingredient compositions within the given formulations. All formulations were prepared using the CM with minor variations in the process steps.

Table 3.11: Composition of unloaded hydrogel formulations.

Formulation code	Poloxamer 188 (% m/v)	HPMC (% m/v)	Methylcellulose 450 (% m/v)	Chitosan (% m/v)	MNZ (% m/v)
FG1	-	2.0	-	2.0	-
FG2	-	2.0	-	1.0	-
FG3	-	1.0	-	2.0	-
FG4	-	2.0	-	-	-
FG5	18	-	-	1.0	-
FG6	18	2.0	-	2.0	-
FG7	18	1.5	-	-	-

i. Preparation of formulation FG1 to FG4

Due to their likenesses in composition, formulations FG1 to FG4 were prepared in a similar manner. Sufficient quantities of a 2% m/v chitosan solution were prepared by dissolving low-molecular weight chitosan (Sigma-Aldrich™, Steinheim, Germany) in a 1% v/v glacial acetic acid solution (pH 4.5) (Merck™, Dramstadt, Germany) at room temperature under continuous stirring for 60 minutes. Sufficient quantities of a 2% m/v HPMC solution were also prepared concomitantly. HPMC powder (Aspen Pharmacare™, Port Elizabeth, South Africa) was weighed and added to sufficient quantities of H₂O at 80 °C and stirred continuously for 30 minutes in order to yield a transparent homogenous solution. The two individual solutions (chitosan 2% m/v and HPMC 2% m/v) were added together in equal amounts and agitated further under magnetic stirring for 30 minutes, after which the solutions were refrigerated for 24 hours.

ii. Preparation of formulation FG5 to FG7

For the preparation of FG5, sufficient quantities of poloxamer 188 were weighed and gradually dispersed in a 5% v/v glycerol solution. The solution was stirred for 30 minutes in order to yield a colourless and transparent solution that was then refrigerated (at 4 °C) for 24 hours. A 1% m/v chitosan solution was prepared separately by dispersing chitosan in a 1% v/v glacial acetic acid solution so as to yield a transparent, off-yellow solution with a pH of 4.5. The chitosan solution was then mixed proportionally with the poloxamer after 24 hours and refrigerated for a further 24 hours to allow for complete solubilisation.

The preparation of FG6 and FG7 was very similar to the aforementioned method used in FG5. However, here, the adequate quantities of poloxamer 188 were weighed and dispersed in a 5% v/v glycerol solution. Thereafter, individual chitosan solutions and HPMC were added to the poloxamer solution, where applicable.

3.9.4.2 Determination of optimal hydrogel formulation

i. Organoleptic assessments

Descriptive sensory tests for all formulations were undertaken to define the aroma, colour and texture of the hydrogels. For the appearance test, each formulation was assessed visually for colour and homogeneity at an ambient temperature (i.e. 25 ± 2 °C) and at an elevated temperature (i.e. 37 ± 2 °C). Five millilitres of each formulation was transferred to a clear glass tube and placed against a white background, where it was assessed by the operator.

For formulation homogeneity and texture evaluation, stickiness and grittiness assessments of the respective hydrogels were conducted at ambient and elevated temperatures, respectively. Small quantities of the gel were placed between the thumb and index finger and rubbed gently to feel for the presence of any particles.

The aroma test was conducted to define odour characteristics for each formulation. Parametric sensory measurements of each formulation were undertaken by employing the human nose as an odour detector so as to directly determine the properties of odours as experienced by humans (Bratolli *et al.*, 2011). A formulation was deemed ideal for patient use if it demonstrated favourable organoleptic characteristics, such as

colourlessness and odourless (see Section 3.9.3.2).

ii. pH measurements

pH measurements of all formulations were determined by means of a pH meter (MetrOhm™, Herisau, Switzerland). The pH meter was calibrated prior to use by standardised buffer solutions at pH 4, 7 and 9 (Merck™, Dramstadt, Germany). Five millilitres of each respective formulation was placed in a previously cleaned and dried test tube and readings were taken in succession by immersing the electrode in the sample. Each formulation was assessed at ambient and elevated temperatures in triplicates. The electrode tip was submerged in purified H₂O after each reading in order to clean it. A formulation was deemed ideal if its pH was found to be around that of the vaginal milieu (i.e. pH 4.5 ± 2). This process was repeated on the samples after a 12-week storage period at refrigeration temperature.

iii. Viscosity measurements

Temperature-dependent viscosity measurements of the prepared unloaded hydrogels were determined by means of a rheometer (Anton Paar™ MCR 72, Austria) that was equipped with a PP25 parallel plate. Data interpretation was conducted using RheoCompass® software (Anton Paar™ MCR 72, Austria). The shear rate was kept constant within a working temperature range of 25 to 40 °C and a gap width of 1mm. The viscosity properties of each formulation were measured in succession over a temperature range of 25 to 40 °C at a constant shear rate, with intermediate cleaning of the plate. Sufficient quantities of samples were applied carefully to the lower plate of the instrument and allowed to equilibrate for five minutes prior to each analysis. A formulation was deemed ideal if it demonstrated a rapid increase in viscosity over a temperature range of interest (i.e. 35 to 37 °C).

3.9.4.3 *Incorporation of MNZ loaded solid lipid nanoparticles (MNZ-SLNs) into optimal hydrogel formulation*

Due to limited resources, MNZ-SLNs could not be incorporated in all hydrogel formulations for testing. Therefore, unloaded hydrogels were first prepared for the characterisation of rheological, organoleptic and pH properties. The formulation that demonstrated the most favourable characteristics was then selected for MNZ-SLN incorporation. MNZ-SLNs were incorporated into a polymer solution containing a

mucoadhesive and thermoresponsive agent under vigorous stirring. The resultant gel was refrigerated for 24 hours in order to facilitate adequate cross-linking.

3.9.4.4 Characterisation of hydrogel incorporated with MNZ loaded solid lipid nanoparticles (MNZ-SLNs).

i. Measurement of sol-gel transition temperature

A qualitative test tube inversion method was used owing to its cost-efficiency, speed, convenience and simplicity. One millilitre of the prepared hydrogel formulation was placed in a clear glass vial (32 × 11.6 mm, LaPha-Pack™, ThermoFischer Scientific™, Massachusetts, USA). The loaded vial was then submerged in a water bath on a hot plate. The water was gradually heated over a working temperature range of 25 to 40 ± 2 °C. The contents of the tube were allowed to equilibrate over periodic intervals, after which the test tube was inverted and the ability of the gel to flow under its own weight was assessed. The temperature at which the gel would not flow was noted as the sol-gel transition temperature. If the gel continued to flow beyond 40 °C, it was considered that no sufficient gelation for vaginal drug delivery had occurred.

ii. Drug content uniformity

Drug content uniformity assessments of the prepared hydrogel were conducted in order to determine whether the prepared dosage units were within a narrow limit of the label claim. One millilitre (containing 0.2% m/v MNZ) of the prepared hydrogel was dissolved in 7.5 ml of a PBS (pH 4.5) and stirred continuously for five minutes. The resultant solution was transferred to a clean McCartney jar and sealed, where it was then allowed to equilibrate in a bath sonication device for 15 minutes at 37 °C. The final solution was filtered and quantified by means of RP-HPLC under the optimised chromatographic conditions.

iii. *In vitro* drug release testing (IVDRT)

IVDRT of MNZ from the hydrogel through a semi-permeable membrane was evaluated by means of the FVDC method. The FVDC set-up consisted of three replicate samples. A synthetic snake skin membrane (4cm², ThermoFischer™ Scientific, Massachusetts, USA) was hydrated in PBS (pH 4.5) for 30 minutes prior to its use, after which it was placed between the donor and receptor compartments. The receptor compartment contained 15 ml PBS (pH 4.5) under continuous magnetic stirring. The temperature of

the receptor cell was maintained at 37 ± 2 °C by a circulating water jacket. Three millilitres of the prepared hydrogel was carefully measured and placed on the membrane surface side of the donor compartment. Aliquots of 0.5 ml were drawn from the receptor compartment at periodic intervals over a 12-hour period. Equal amounts of fresh PBS were added after each withdrawal to maintain sink conditions. The withdrawn aliquots were diluted with MeOH and H₂O (85:15% v/v) for API quantification via RP-HPLC under optimised chromatographic conditions. The mean cumulative amount of drug permeation per unit surface area of the membrane was plotted versus time.

3.10 ANTIMICROBIAL SUSCEPTIBILITY TESTING (AST)

AST is a process of determining the vulnerability of a microbe to a test compound. Results obtained from AST are useful for the prediction of *in vivo* antimicrobial responses (Balouiri *et al.*, 2016). There are currently a vast majority of AST methods available, ranging from simple diffusion-based methods to more complex broth-based automated systems (Reller *et al.*, 2009). This study, however, limits itself to the investigation of the agar disc diffusion method, owing to its simplicity, low cost and flexible use for a wide spectrum of test compounds. Even though this method possesses many advantages, it does not allow for the differentiation between bactericidal and bacteriostatic test compounds (Mayrhofer *et al.*, 2008). Moreover, it does not provide a direct means for determining test compounds' minimum inhibitory concentrations (MICs) (Balouiri *et al.*, 2016; Luc *et al.*, 2015).

The agar disc diffusion method (commonly referred to as the Kirby-Bauer test) is employed for the testing of microbial susceptibility to antimicrobial agents. An overview of the test involves the inoculation of the agar surface with a test microbe, on which filter discs containing the antimicrobial agents are placed. The resultant sample undergoes incubation under desirable conditions in order to allow for the test compound to diffuse into the agar and inhibit microbial germination (Wheat, 2001; Jorgensen and Ferraro, 1998).

AST is preferred for AST of pharmaceutical products because rapid and reliable identification of microbial susceptibility is critical for optimal clinical efficiency of drug products and resource utilisation (Balouiri *et al.*, 2016). Table 3.12 details factors that influence the generation of accurate and reliable results via the Kirby-Bauer test.

Table 3.12: Factors influencing microbial sensitivity in Kirby-Bauer test (adapted from Lalitha, 2004).

Factor	Comment	Remedy
Moisture	Moisture present in medium counteracts accuracy of AST	Remove excess moisture by incubating (35 ± 2 °C) prior to use Use laminar flow at room temperature with lids ajar until evaporation of excess moisture occurs
pH	Low pH leads to loss of potency of the drugs (e.g. aminoglycosides and macrolides) and excessive activity in others (e.g. tetracycline). These issues are reversed following a high pH.	Test pH of agar to ensure that it is within 7.2 and 7.4 at ambient temperature after solidification
Medium components	Presence of high levels of thymidine or thymine in agar can reverse the effects of some drugs (e.g. sulfonamides) which can lead in inaccurate resistance results Medium with excessive cationic content yields of small zones of inhibition. The converse applies for mediums with low-cation content.	Evaluate efficiency of MHA with <i>E. faecalis</i> using trimethoprim/sulfamethoxazole discs. A zone of inhibition of ≥ 20 mm is indicative of low thymidine levels. Performance test with each match of MHA to be conducted
Types of strains	Certain strains do not germinate in MHA (e.g. <i>N gonorrhoeae</i> , <i>S. pneumonia</i>)	Supplementation of MHA required; or the selection of an alternative media that facilitates growth
Quantity	Amount of organism or antimicrobial concentration has a direct effect on AST	Use a standardised quantity of organisms with a predetermined antimicrobial concentration level

These factors were monitored carefully to ensure that reliable and reproducible results were obtained.

3.10.1 Experimental

3.10.1.1 Modified Kirby-Bauer disc diffusion assay

The AST of the prepared hydrogel, SLNs and controls were conducted by means of a modified Kirby-Bauer disc diffusion assay. This process followed three steps described in the following sub-sections, *viz.* preparation of agar, inoculum preparation and assay.

i. Preparation of Mueller-Hinton Agar (MHA)

MHA was selected as the most suitable medium to facilitate microbial growth, owing to its versatility in different microbes, high-accuracy results and reproducibility in microbiology (Jorgensen *et al.*, 1987). MHA (Merck™, Dramstadt, Germany) comprising of 0.5 g/L meat infusion, 17.5 g/L casein hydrolysate, 1.5 g/L soluble starch and 14.0 g/L agar was prepared in accordance with the manufacturer's instructions. A 1 L solution was prepared by dissolving 38 g of accurately-weighed MHA in purified water over a hot plate under continuous stirring. The resulting agar solution was sterilised in a vertical-type steam autoclave (AlreadyEnterprise Inc™, Model HL-340, Taiwan) at 121 °C for 15 minutes. The sterile agar was allowed to cool to 45 ± 2 °C and immediately transferred into six individual flat-bottomed petri dishes (100 × 20 mm, TPP™, Sigma Aldrich™, Steinheim, Germany) in order to yield uniform depths of ± 4 mm. The agar in the petri dishes was allowed to further cool to ambient temperature and, unless utilised on the same day, they were refrigerated (4 ± 2 °C).

ii. Preparation of inoculum

Candida albicans were utilised for the purposes of this study. The inoculum was prepared by selecting three to five distinct colonies of about 1 mm in diameter from a 24-hour-old culture. The fungal colonies were suspended in 5 ml of freshly-prepared normal saline and vortexed for 30 seconds. The turbidity of suspension was adjusted by the gradual addition of saline solution to a comparable turbidity of a 0.5 McFarland solution.

To inoculate *Candida albicans* onto the MHA test plates, a sterile cotton swab was dipped into the prepared suspension and streaked over the surface of the plates. The process was repeated twice, whilst rotating the plate at ± 60° to facilitate even distribution of the inoculum on the plate surface. The plates were left to dry for 10 minutes so as to remove excess moisture before introducing the test compounds.

iii. Disc diffusion assay

After the surface inoculation of the test plates, the agar was partitioned into six equal segments. Equal quantities of MNZ loaded hydrogels, blank hydrogels, MNZ loaded SLNs, unloaded SLNs and a commercially available MNZ cream were placed onto the surface. The last segment was left blank (i.e. formed the control). The test plates were covered and incubated at 37 ± 2 °C for 24 hours before assessing the respective zones of inhibition. All tests were conducted in triplicates and the mean values of the respective zones were calculated. The findings of this study will be discussed in Chapter 4.

3.11 ETHICAL CONSIDERATIONS

No animal or human subjects were used for the purposes of this study; therefore, no ethical approval was required.

3.12 SUMMARY

The methodology described in this chapter led to the development of a thermoresponsive hydrogel comprising of MNZ-SLNs, for the intended treatment of VVC. A brief overview of this chapter is given in Figure 3.10.

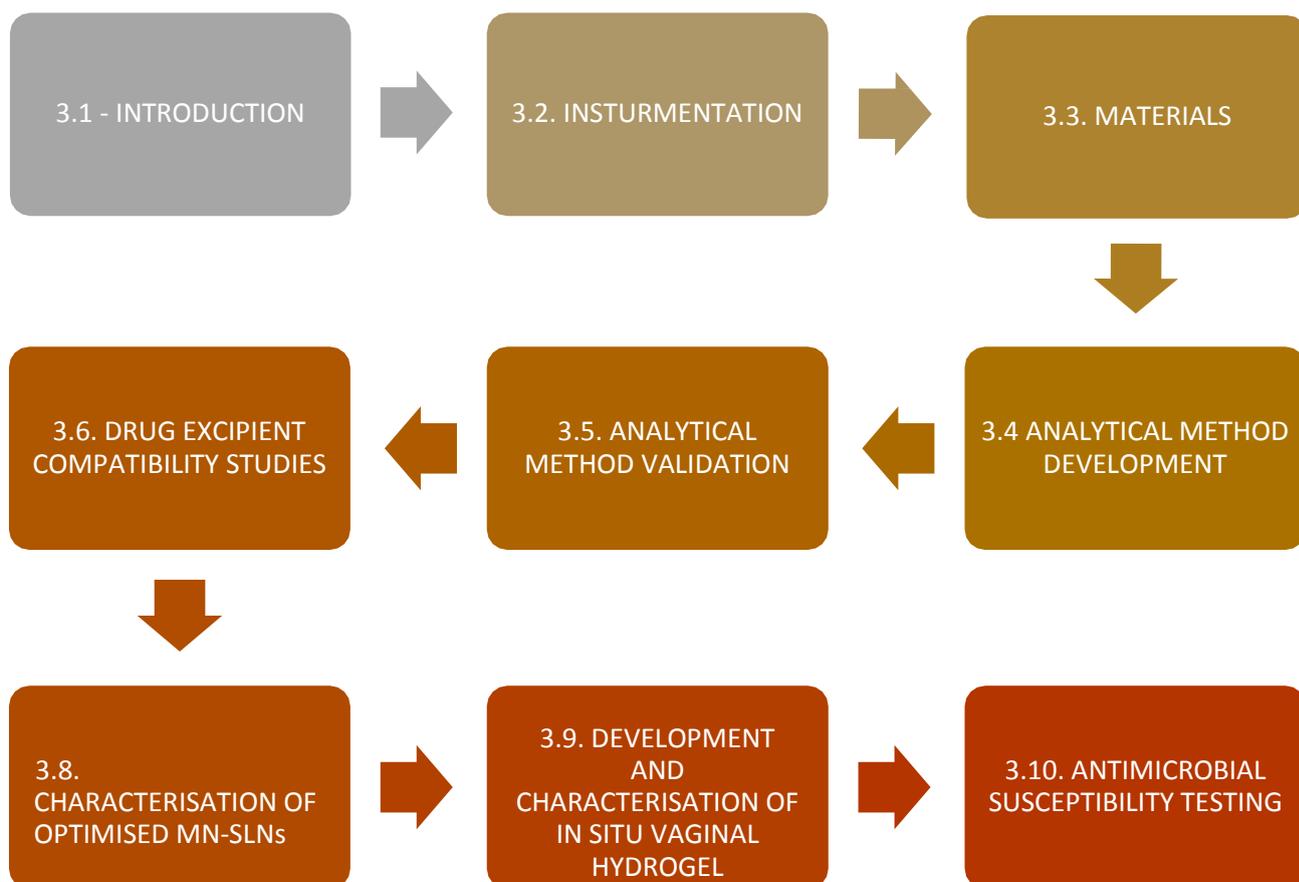

Figure 3.10: Summary of study methodology

The findings of all experimental tests discussed in this chapter will be presented in the following chapter.

CHAPTER 4

RESULTS AND DISCUSSIONS

4.1 INTRODUCTION

Various assessments were conducted for the preparation of the MNZ-SLN loaded vaginal hydrogel. The experimental findings of the development, optimisation and characterisation tests of this novel formulation are discussed in this chapter.

4.2 ANALYTICAL METHOD DEVELOPMENT

An alternative analytical method for the quantification of MNZ in a bulk or complex pharmaceutical product was developed through the use of RP-HPLC. HPLC is a highly selective analytical technique that is capable of identifying, quantifying and purifying isolated ingredients within a complex mixture (Hassan, 2012). It was employed as a means of quantification and subsequent purity assessment of MNZ for the purposes of this study, owing to its accuracy, speed and efficiency.

The use of an already-existing method is ideal, as it is less labour-intensive and time-consuming and is better at generating unbiased results from the operator. There are well-established and documented methods for the quantification of MNZ by means of RP-HPLC available (British Pharmacopeia Commission, 2014). Adopting these methods would have been ideal for this study, however, due to a lack of availability of some of the equipment as well as limited resources, a new method was developed.

4.2.1 Sample preparation

A 2 mg/ml MNZ stock solution was prepared by dissolving MNZ microcrystalline powder in 8.5 ml of MeOH, followed by the addition of H₂O in order to yield a final volume of 10 ml. The resultant solution was colourless and transparent, with a characteristic alcohol odour (see Figure 4.1). No precipitation was observed in the solution suggesting that the API had undergone sufficient dissolution in the solvent.

Figure 4.1: Miconazole nitrate (MNZ) 2 mg/ml stock solution for analytical method development.

Proper sample preparation technique is essential to maintaining RP-HPLC system integrity and to prevent unwarranted chromatographic interference (Moldoveanu, 2004). Furthermore, a homogenous solution that is free of suspended particles is desirable for maintaining RP-HPLC system integrity by preventing blockages and subsequent pressure increase (Shahtaheri *et al.*, 2005; Lim, 1988). Proper sample preparation and a homogenous solution was achieved in this study.

4.2.2 Mobile phase (MP) optimisation

The MP is responsible for the transportation of components in a sample through the column so as to facilitate separation (Kazakevich and Lobrutto, 2007). The quantity and type of organic phase used in a method has a direct influence on selectivity and resolution of the method. Owing to their practicality and availability, MeOH and H₂O were selected as MP components for the purposes of this study.

The experimental results noted in Section 3.4.3.2 are discussed in the following subsections. Most notably, there is a discussion on the effect of the organic phase composition and buffers as components of the MP that were investigated respectively. Various types of MPs and ratios were tested, and the results were compared.

4.2.2.1 Selection of organic phase ratio

Preliminary investigations deemed MeOH as the most favourable organic phase in the MP for the purposes of this study. A sample of 0.25 mg/ml MNZ was prepared by diluting the stock solution with a MeOH:H₂O (85:15) premixed solution. The sample was analysed by means of RP-HPLC under preliminary chromatographic conditions. All variables were kept constant with the exception of the quantity of MeOH in the MP. The MeOH to H₂O ratio in the MP was varied at predetermined ratios. The resultant analyte retention times (R_f) and MNZ peak symmetry factors (A_s) are shown in Table 4.1.

Table 4.1: Implications of varying organic modifier (methanol) in mobile phase (MP).

Sample	MNZ conc. (mg/ml)	H ₂ O (% v/v)	MeOH (% v/v)	Symmetry factor	Retention time (min)
1	0.25	15	85	0.95	5.57
2	0.25	20	80	0.97	6.01
3	0.25	25	75	1.04	8.86
4	0.25	30	70	1.05	10.13
5	0.25	50	50	-	-

As depicted in Table 4.1, MeOH concentration levels of 70 to 85% v/v yielded acceptable peak symmetry and rapid elution times (≤ 10.13 minutes). Figure 4.2 summarises the relationship between MeOH and retention time, where an increase in MeOH concentration caused a gradual decrease in retention time. Further increases in MeOH concentration above 85% v/v resulted in the subsequent loss of resolution, while MeOH concentrations below 70% v/v resulted in very poor resolution with an unstable baseline where no distinct peaks were observed. Minor deviations were noted in the peak symmetry factors, but all results obtained in the MeOH concentration range of 70 to 85% v/v were deemed favourable for method development. All MNZ peaks obtained were also pure, with purity values of ≥ 0.999 .

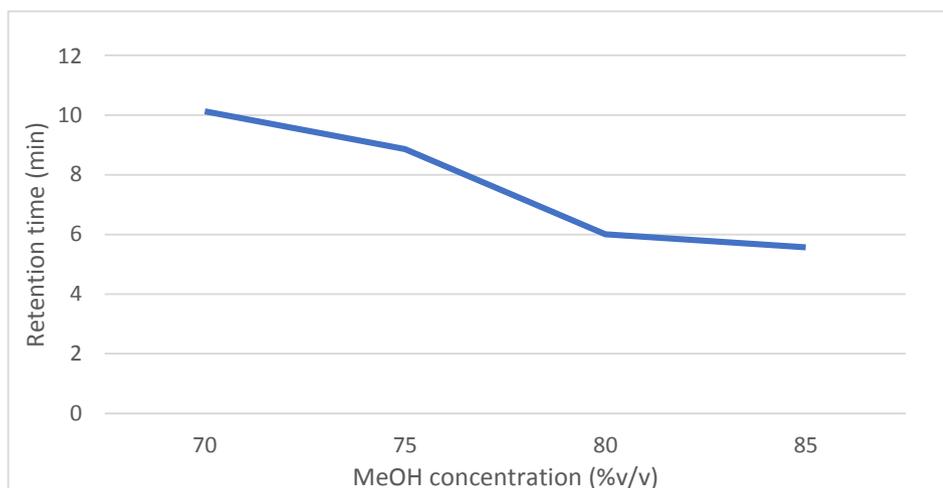

Figure 4.2: Plot of retention time as a function of MeOH concentration for the RP-HPLC analysis of a 0.25 mg/ml miconazole nitrate (MNZ) sample.

High H₂O content in the MP causes the repulsion of lipophilic analytes out of the MP and into the non-polar stationary phase where they remain until they partition into the MP again (Carr *et al.*, 1986). Therefore, the addition of an organic modifier lowers the polarity of H₂O and ensures that the analyte does not repel strongly into the stationary phase. This phenomenon suggests that the use of H₂O reduces the elution strength of the MP and causes a gradual increase of MNZ retention time for the developed method (Joshi *et al.*, 2015).

Through this process, it was also noted that a decrease in MeOH concentration (<70% v/v) led to poor resolution, unstable baselines and the presence of impurities in the MNZ peak. An increase in MP viscosity could possibly explain this phenomenon (Crawford Scientific™, 2017). Solvents of low viscosity are ideal for RP-HPLC, as they reduce the likelihood of dispersion and a build-up of system backpressure (Shalliker and Guichon, 2009). MeOH possesses a viscosity of 0.544 mPa•s at 20 °C, which produces a low-pressure drop at certain flow rates, thereby allowing for rapid analysis due to an increase in mass transfer. A binary mixture of MeOH (60% v/v) and H₂O (40% v/v) produces the maximal acceptable velocity at a pressure of 1.62 mPa•s but, in turn, significantly increases system backpressure (Crawford Scientific™, 2017). Furthermore, the rate of analyte mass transfer is reduced, and the operator runs the risk of system malfunction due to an increase in pressure of the system; therefore, the use of H₂O in the MP above 40% v/v was not advised for the purposes of this study.

Based on these established percentages, the final MP composition was selected at MeOH (85% v/v) and H₂O (15% v/v) because they produced the quickest method for achieving acceptable purity and peak symmetry required in this study.

4.2.2.2 The use of buffers in mobile phase (MP) composition

The potential of buffer use in RP-HPLC has been explored extensively in the literature (Roses *et al.*, 1996; Tindall and Dolan, 2003). For the purposes of this study, the buffer potential was investigated in order to determine whether its use resulted in more favourable selectivity and retention of MNZ when compared to a simple MeOH and H₂O binary mixture.

To that end, an ammonium acetate buffer (pH 4) was freshly prepared and used at 15% v/v (in place of H₂O) with respect to MeOH so as to yield a new MP. Figure 4.3 illustrates a chromatogram of a 0.25 mg/ml MNZ sample recorded at a flow rate of 1.2 ml/min and a temperature of 40 °C using a MeOH (85% v/v):H₂O (15% v/v) MP. Conversely, Figure 4.4 illustrates a chromatogram of a 0.25 mg/ml MNZ sample under similar chromatographic conditions with the exception of an 85% v/v MeOH and 15% v/v ammonium acetate buffer MP.

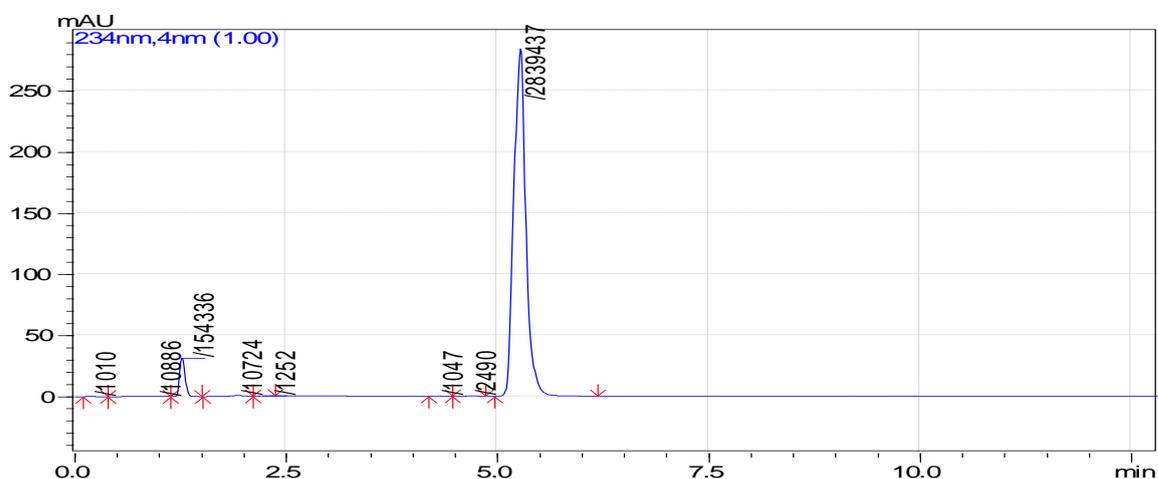

Figure 4.3: Chromatogram of 0.25 mg/ml miconazole nitrate (MNZ) sample at 234 nm (Temp: 40 °C, Flow rate: 1.2 ml/min, MP: MeOH 85% v/v and H₂O 15% v/v).

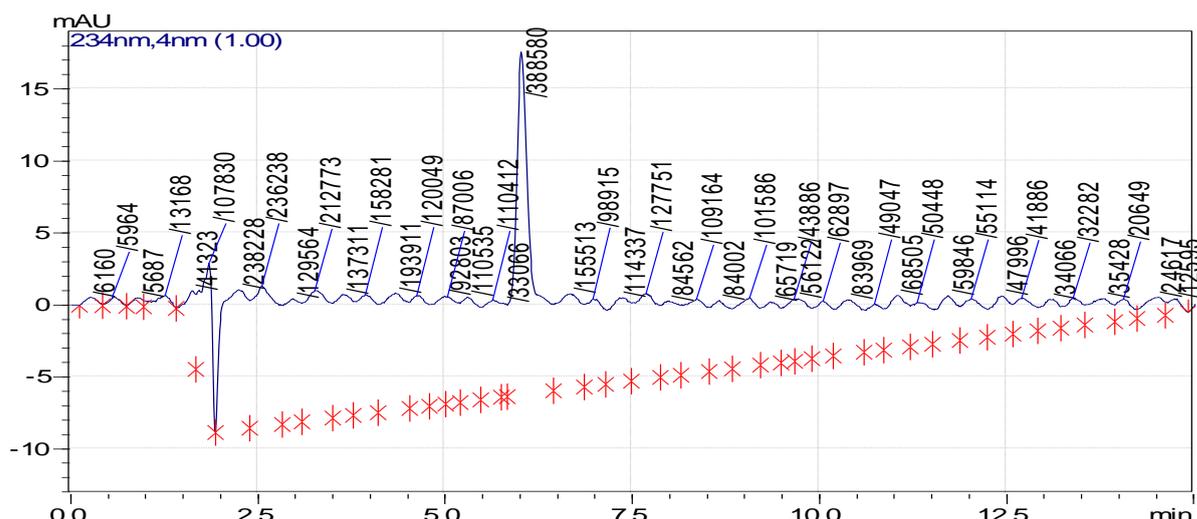

Figure 4.4: Chromatogram of 0.25 mg/ml miconazole nitrate (MNZ) sample at 234 nm (Temp: 40 °C, Flow rate 1.2 ml/min, MP: 85% v/v MeOH and 15% v/v ammonium acetate buffer).

Visual disparities were noted when the two chromatograms were compared. For example, the use of an ammonium acetate buffer resulted in the generation of a smaller miconazole peak, this is possibly attributed to interference by electrolytes from the buffer. Furthermore, a slight increase in retention times of peaks one and two by 30 seconds was observed, with peak one demonstrating a negative protrusion from the baseline.

For ionised compounds, such as MNZ, the use buffer solutions in the MP can improve the selectivity and reproducibility of the method (Roses *et al.*, 1996). It was observed, however, that for this study, the use of a H₂O instead of a buffer solution resulted in improved purity and stability of the baseline. In addition, the method was less time-consuming and more cost-efficient because fewer reagents and materials were consumed. For these reasons, MeOH and H₂O were selected as ideal solvents in the MP for the purposes of this study.

4.2.2.3 Mobile phase (MP) flow rate optimisation

Flow rate is defined as the volume of MP transported through a column per unit time (Bhardwaj *et al.*, 2015). It was believed that the alteration of MP flow rate would have a direct influence on elution time and peak symmetry. To optimise the current chromatographic conditions, the effect of flow rate was investigated. Table 4.2 depicts the measured peak symmetry and retention times of a 0.25 mg/ml MNZ sample at predetermined flow rates.

Table 4.2: Variation of flow rate in the RP-HPLC analysis of a 0.25 mg/ml miconazole nitrate (MNZ) sample at 234 nm (Temp: 40 °C).

Sample	MP MeOH:H ₂ O (% v/v)	MNZ conc. (mg/mL)	Flow rate (mL/min)	Symmetry factor	Retention time (min)
1	85:15	0.25	0.8	1.26	13.15
2	85:15	0.25	1.0	0.97	9.57
3	85:15	0.25	1.2	0.94	6.42
4	85:15	0.25	1.5	0.85	5.02
5	85:15	0.25	2.0	-	-

As depicted in Table 4.2, flow rates of 1.0 to 1.2 ml/min yielded chromatograms with acceptable peak symmetry and retention times. A decrease in flow rates below 1.0 ml/min resulted in lengthy retention times and excessive peak tailing, which were not ideal. Conversely, the gradual increase of flow rate resulted in faster elution of the analyte, which is ideal for producing rapid analytical methods.

However, extreme caution should be taken when increasing the flow rate in order to ensure that the system does not succumb to malfunction as a result of an increased pressure (Carr *et al.*, 2009). In addition, it was noted that subsequent increases in flow rate beyond 1.2 ml/min resulted in the fronting of chromatographic peaks, and a flow rate of ≥ 2 ml/min resulted in column leakages and system malfunction as a result of the excessive pressure build-up.

Figure 4.5 illustrates an indirect proportionality relationship between flow rate and retention time(s), where an increase in flow rate resulted in a decrease of retention time.

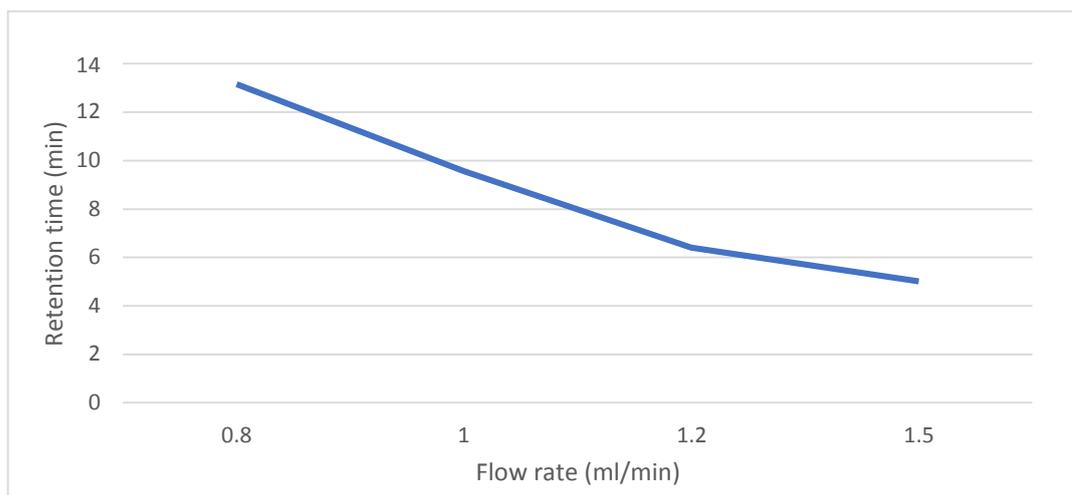

Figure 4.5: Plot of flow rate as a function of retention time for the RP-HPLC analysis of a 0.25 mg/ml miconazole nitrate (MNZ) sample.

Sufficient time must be given for the analyte to interact with the stationary phase; therefore, shorter separation times or rapid methods are not always ideal (Astefanei *et al.*, 2016). As a result, a flow rate of 1.0 ml/min was selected because it allowed for sufficient time for the MNZ to interact with the column packing. It also provided sufficient opportunity to observe the generation of other degradants in the sample whilst producing a Gaussian peak. A reduction of flow rate (<1.0 ml/min) maintained similar peak areas because the concentration of the sample remained unchanged; however, the peaks observed became wider and shorter.

4.2.3 Sample injection volume optimisation

Column overloading, poor retention times and asymmetrical peaks are common issues associated with the poor selection of injection volume (Boonen *et al.*, 2013; Sailaja *et al.*, 2016). Therefore, the effect of the injection volume on the RP-HPLC method for the quantification of MNZ was investigated so as to ensure that symmetrical peaks with sufficient purity and clarity were obtained. Table 4.3 illustrates the values obtained for peak symmetry and retention times at each predetermined injection volume.

Table 4.3: Variation of injection volume for the RP-HPLC analysis of a 0.25 mg/ml miconazole nitrate (MNZ) sample.

Sample	MeOH:H ₂ O	MNZ conc. (mg/mL)	Flow rate (mL/min)	Injection Vol. (μL)	Symmetry factor	Retention Time (min)
1	85:15	0.25	1.0	1	0.98	9.55
2	85:15	0.25	1.0	2	0.98	9.57
3	85:15	0.25	1.0	5	0.97	9.72
4	85:15	0.25	1.0	10	1.03	10.03
5	85:15	0.25	1.0	20	-	-

Injection volumes below 10 μL produced satisfactory MNZ peak symmetry, while the retention times of all analyses remained fairly constant. An increase in injection volume was associated with an increase in the diffusion process time, which translated to more time being used to load the sample on the stationary phase. Larger volumes equated to wider peaks, which took longer to elute and led to significant tailing being observed. Fronting was expressed by a symmetry value (A_s) of <0.8, which indicated possible column overloading (Ornaf and Dong, 2005). As noted previously, the choice of injection solution can affect the retention time. However, in this case, the solution was similar to that of the MP, hence minimal deviations of the retention times were noted. These findings correlate with the findings of Ren and colleagues (2012).

Optimal injection volumes are directly related to the cylindrical volume of the column. The recommended injection volume for the column dimension (4.6 mm × 150 mm) utilised for this study are two to 10 μL. Volumes that exceed this range are only acceptable if the resultant peak is symmetrical (Silicycle, 2018). Based on these parameters, it was observed, experimentally, that volumes exceeding 10 μL produced asymmetrical peaks with significant fronting. Furthermore, an injection volume of 20 μL resulted in column leakage and system malfunction as a direct result of pressure build-up. This was not ideal for the maintenance of system integrity. Conversely, injection volumes of one to 10 μL produced satisfactory peak symmetry and retention times. It should be noted that too low injection volumes are closely linked to a loss of response, especially upon sample dilution (Swartz, 2010). Therefore, 10 μL was selected as the ideal volume for the rapid quantification of MNZ by means of RP-HPLC.

4.2.4 Summary of optimised chromatographic conditions

Carefully optimised chromatographic conditions result in high sensitivity of analyte detection (Montemurro *et al.*, 2016). Method sensitivity is dependent on MP composition and interface parameters, such as temperature and flow rate (McCalley, 2000; Ho and Kim, 2011). Table 4.4 provides a brief summary of optimal chromatographic conditions, as expressed in the British Pharmacopoeia (British Pharmacopoeia Commission, 2014) and current literature (e.g. Hermawan *et al.*, 2017), where differences in each method are contrasted with the experimental conditions of this study.

Table 4.4: Summary of chromatographic conditions in the British Pharmacopoeia (British Pharmacopoeia Commission, 2004), current literature (Hermawan *et al.*, 2017) and the developed method for this study.

Chromatographic variable	British pharmacopoeia	Literature review (Hermawan <i>et al.</i> , 2017)	Experimental conditions
Analyte	MNZ	Miconazole	MNZ
Concentration	10 mg/1ml	0.05 mg/ml	0.25 mg/ml
Sample solvent	MP	MeOH	MP
Injection volume	10 μ L	5 μ L	10 μ L
Column type	Octadecylsilyl C ₁₈ (100 \times 4.6 mm, 3 μ)	Phenomenex C ₈ Luna® (150 \times 4.6 mm, 10 μ)	Phenomenex C ₈ (150 \times 4.6 mm, 5 μ)
Flow	Isocratic	Isocratic	Isocratic
Flow rate	2 ml/min	0.8 ml/min	1.0 ml/min
Temperature	30 $^{\circ}$ C	unspecified	40 $^{\circ}$ C
Wavelength	235 nm	220 nm	234 nm
Mobile phase (MP)	6.0 g ammonium acetate in 300 ml acetonitrile, 320 ml methanol, 380 ml H ₂ O	MeOH:H ₂ O (85:15% v/v)	MeOH:H ₂ O (85:15% v/v)

When compared to the existing pharmacopoeial method, this experimental method

provided comparable results with regard to resolution in the quantification of MNZ. The new method also resulted in the consumption of fewer reagents by simplifying the MP, thereby making it cost-effective. The current method proposed by Hermawan *et al.* (2017) provided faster quantification of MNZ, with a retention time of approximately seven minutes and a drifting baseline. The optimised method for this study, however, provided superior resolution and a steady baseline, with a slight increase in analyte retention time. Table 4.5 summarises the experimental findings for the optimised method in this study.

Table 4.5: Summary of experimental findings for the optimised method.

Parameter	Sample 1	Sample 2	Sample 3	Mean \pm RSD
Peak area	2055001	2053998	2055063	2054687 \pm 0.020
Peak symmetry	0.97000	0.98000	0.97000	0.97000 \pm 0.048
Peak purity	0.99998	0.99999	0.99998	0.99998 \pm 0.000
Retention time (min)	10.6600	10.6900	10.6900	10.6800 \pm 1.253

The mean peak area for an assayed 0.25 mg/ml MNZ sample was 2 054 687 \pm 0.020, with a mean peak symmetry of 0.97 \pm 0.048, which suggested a Gaussian peak. A mean peak purity value of 0.999 suggested that there was no interference from other compounds in the sample. Finally, <15 minutes suggests that a rapid method was developed for the quantification of MNZ.

The benefits of updating existing analytical methods include providing enhanced sensitivity and resolution, rapid elution of the investigated analyte. Moreover, newer solvent-sparing methods provide a cost-effective analysis for resource-limited facilities (Dong and Guillarme, 2017). This study managed to achieve both.

4.3 ANALYTICAL METHOD VALIDATION

A successfully validated method demonstrates that the developed method is indeed suitable for its intended use (Varshosaz *et al.*, 2011). Validation parameters including peak analysis, linearity, precision, accuracy, LoD and LoQ were investigated and their outcomes are discussed in this section.

4.3.1 Peak analysis

The assessment of peak symmetry allows the operator an opportunity to discern the physicochemical process undertaken within the stationary phase (Papai and Pap, 2002). For this study, a chromatogram obtained from the analysis of a 0.5 mg/ml MNZ sample was assessed visually (see Figure 4.6) under the optimised chromatographic conditions, after which the symmetry factor was calculated. Moreover, Equation 4.1 expresses the mathematical calculation of the symmetry factor (A_s) depicted in Figure 4.6.

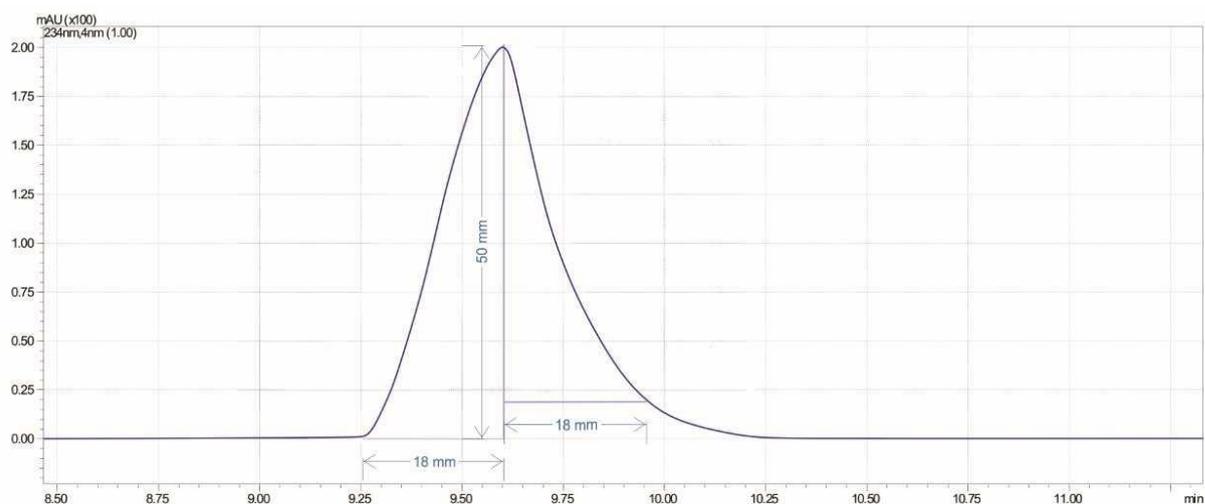

Figure 4.6: RP-HPLC chromatogram of 0.5 mg/ml miconazole nitrate (MNZ) sample (Temperature: 40 °C, Flow rate: 1 ml/min and MP:MeOH 85% v/v:H₂O 15% v/v).

$$A_s = \frac{b}{a} = 1$$

Equation 4.1: Symmetry factor calculation for 0.5 mg/ml miconazole peak under optimised RP-HPLC conditions.

An A_s value of 1 was obtained and was deemed acceptable since it was within the noted range of 0.9 to 1.2. An A_s value in the range of 0.9 to 1.2 is sufficient for indicating a Gaussian peak with negligible tailing or fronting (Kadjo *et al.*, 2017).

4.3.2 Linearity and range

The linearity of the experimental data was determined within a working range of 0.125

to 1.00 mg/ml. Seven ($n=7$) samples at predetermined concentration levels were assayed in triplicates and their experimental results are presented in Table 4.6.

Table 4.6: Calibration data for the quantification of miconazole nitrate (MNZ) in the range of 0.125 to 1.000 mg/ml under optimised chromatographic conditions.

Concentration (mg/ml)	% Target analyte	Peak area (mean of $n=3$)	Peak area % RSD
0.125	25	1110973.557	1.95
0.250	50	2054979.667	0.51
0.400	80	3312895.023	0.82
0.500	100	4164199.890	0.51
0.600	120	4935189.234	1.96
0.750	150	6093138.165	0.26
1.000	200	8210823.447	1.87

Linear regression equation:
 $y = 811214x + 67958$ $r^2: 0.9998$

The mean peak values for each concentration level assayed in triplicate was calculated and utilised in order to generate a plot of mean peak area as a function of concentration. This function was referred to as the calibration curve of MNZ, as illustrated in Figure 4.7.

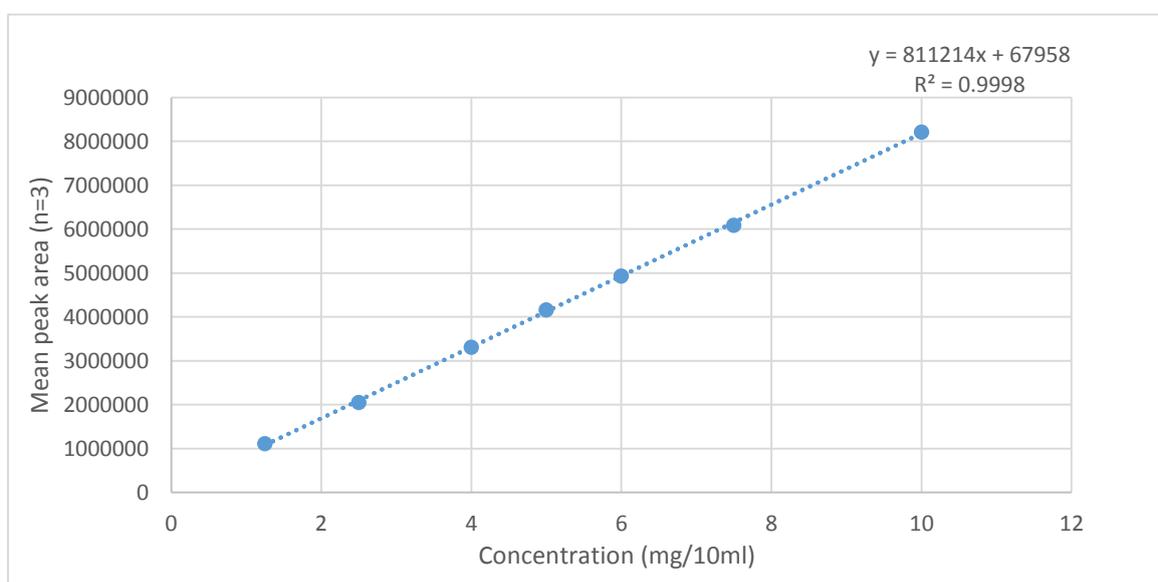

Figure 4.7: Calibration curve of miconazole nitrate (MNZ) in the working range of 0.125 to 1.00 mg/ml.

Data acceptability was judged from the assessment of the correlation co-efficient (r^2) of the regression line. An r^2 value of >0.999 with no curvature of the residual plot is sufficient for the declaration of a linear method (Bakshi *et al.*, 2017). A straight line was obtained with a linear regression equation of $y = 811214x + 67958$ and an r^2 value of 0.9998. Moreover, the % RSD of the mean peak areas was ≤ 2 (see Table 4.6). This indicated a directly proportional relationship between response and concentration, thus deeming the method linear.

The significance of the plot, also referred to as the assessment value (z), was investigated in order to determine whether the plot would cross the line of origin. A z value of $-2 \leq z \leq 2$ is deemed acceptable (Ghasemi and Zahediasi, 2012).

$$\text{Assessment value } (z) = \frac{67958}{4164199.890} \times 100$$

$$z = 1.63$$

Equation 4.2: Assessment value (z) for the calibration plot of miconazole nitrate (MNZ) in the working range of 0.125 to 1.00 mg/ml.

A z value of 1.63 was obtained, which suggested that there would be a high likelihood of the regression line intersecting at zero. This result was favourable.

4.3.3 Accuracy

An accurate method, as defined by the ICH, fulfils the following criteria: the % recovery of the analysed samples does not deviate by a value of $\pm 2\%$ of the theoretical yield with a % RSD of $\leq 2\%$ for the mean concentration (*ICH Harmonised Tripartite Guideline Q2 (R1)*, 1994). Table 4.7 illustrates the % recovery and the mean concentration value obtained from the assay MNZ samples ($n=5$) in triplicates at five concentration levels within the working range.

Table 4.7: Method accuracy data for the quantification of miconazole nitrate (MNZ) within the working range under optimised chromatographic conditions.

Theoretical yield (mg/ml)	Actual yield (mg/ml)		% Recovery
	Mean (n=3)	% RSD	
0.250	0.254	1.76	101.60
0.400	0.402	0.52	100.50
0.500	0.511	1.62	102.00
0.600	0.611	1.90	101.83
1.000	0.983	1.97	98.350

All calculated % RSD were below the acceptance limit of 2% and the % recovery did not deviate more than 2% from theoretical value, thus deeming the method accurate.

4.3.4 Precision

The acceptance criteria for method precision (i.e. repeatability) is very similar to that of accuracy, where a deviation of $\leq 2\%$ is acceptable for recovery and % RSD (*ICH Harmonised Tripartite Guideline Q2 (R1)*, 1994). Table 4.8 illustrates the results obtained from the assay of six samples (n=6 in triplicate at a chosen concentration within the working range).

Table 4.8: Method precision data for the quantification of MNZ within the working range under optimised chromatographic conditions.

Theoretical yield (mg/mL)	Actual yield (mg/mL)		% Recovery
	Mean (n=3)	%RSD	
0.50	0.508	0.83	101.60
0.50	0.506	0.26	101.20
0.50	0.506	0.15	101.20
0.50	0.501	0.12	100.20
0.50	0.509	0.41	101.80
0.50	0.508	0.21	101.60

All calculated % RSD values were below the acceptance limit of 2% and the % recovery did not deviate more than 2% from theoretical value, thus deeming the method precise.

4.3.4.1 Intermediate precision

The acceptance criteria for intermediate precision is the same as that of repeatability (*ICH Harmonised Tripartite Guideline Q2 (R1)*, 1994). The assay results obtained on the different working days should have a statistical significance of $\leq 2\%$ RSD (Little, 2016). The findings of this study's assay of six samples ($n=6$) at 0.5 mg/ml in triplicates on two separate days by the same operator and on the same machine are depicted in Table 4.9.

Table 4.9: Intermediate precision data for the quantification of miconazole nitrate (MNZ) within the working range under optimised chromatographic conditions.

Theoretical yield (mg/mL)	Actual yield (mg/mL)					
	Day 1		Day 7		Day 1	Day 7
	Mean ($n=3$)	% RSD	Mean ($n=3$)	% RSD	% Recovery	
0.50	0.508	0.83	0.491	0.58	101.60	98.13
0.50	0.506	0.26	0.494	0.06	101.20	98.74
0.50	0.506	0.15	0.492	0.07	101.20	98.40
0.50	0.501	0.12	0.492	0.18	100.20	98.40
0.50	0.509	0.41	0.490	0.23	101.80	98.00
0.50	0.508	0.21	0.494	0.12	101.60	98.86

All calculated % RSD were below the acceptance limit of 2% and the % recovery did not deviate more than 2% from theoretical values, thus deeming the method precise. However, while the intermediate precision was deemed acceptable, a slight deviation in % recovery was observed. This deviation may have been as a result of human error during the preparatory steps, such as the weighing of the MNZ, dilution of the stock solution or transfer into the sample vials. This deviation was not deemed significant since all results were maintained within the limit of acceptability.

4.3.5 Limit of detection (LoD)

A signal-to-noise ratio of 3:1 was considered as the LoD (Tamilsevan *et al.*, 2014; Sun *et al.*, 2012). Table 4.10 illustrates the calculated data for LoD for MNZ quantification under optimised chromatographic conditions.

Table 4.10: Limit of detection (LoD) data for the quantification of miconazole nitrate (MNZ) under optimised chromatographic conditions.

Sample no.	Active ingredient	Peak purity	Concentration (mg/ml)	Concentration (% w/v)	% RSD
1	MNN	0.9999	0.015	1.5	0.62
2	MNZ	0.9999	0.015	1.5	0.80
3	MNZ	0.9998	0.016	1.6	0.56

It was determined that the LoD was 0.015 mg/ml, where MNZ could be accurately detected under the optimised chromatographic conditions.

4.3.6 Limit of quantitation (LoQ)

A signal-to-noise ratio of 10:1 was considered as the LoQ (Tamilsevan *et al.*, 2014; Sun *et al.*, 2012). Table 4.11 illustrates the calculated data for LoQ for MNZ quantification under the optimised chromatographic conditions.

Table 4.11: Limit of quantitation (LoQ) data for the quantification of miconazole nitrate (MNZ) under optimised chromatographic conditions.

Sample no.	Active ingredient	Peak purity	Concentration (mg/mL)	Concentration (%w/v)	% RSD
1	MNZ	0.9999	0.052	5.2	0.96
2	MNZ	0.9999	0.052	5.2	0.80
3	MNZ	0.9999	0.052	5.2	0.83

The LoQ was determined to be 0.052 mg/ml, where MNZ could be accurately quantified under the optimised chromatographic conditions.

4.3.7 Specificity

Peak purity tests were conducted utilising PDA detection. These tests were useful in displaying that analyte responses were not associated with the presence of other components in the sample. Similarly, chromatograms were evaluated for the presence of compounds which may cause potential interference or co-elution with the MNZ peak.

Figure 4.8 depicts a chromatogram of a 0.5 mg/ml MNZ sample under optimised chromatographic conditions.

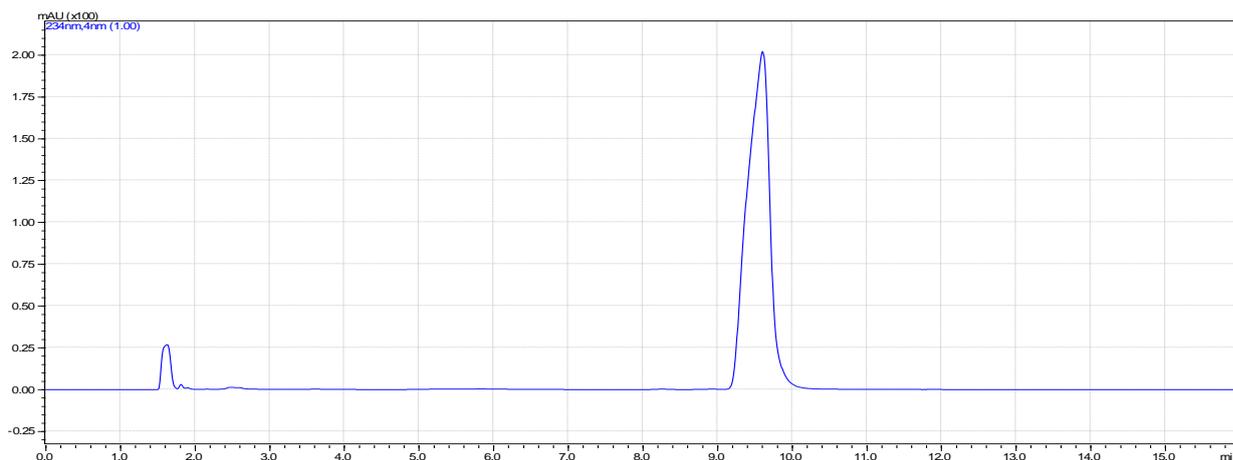

Figure 4.8: Chromatogram of a 0.5 mg/ml miconazole nitrate (MNZ) sample under optimised chromatographic conditions (Temperature: 40 °C, Flow rate: 1 ml/min and MP:MeOH 85% v/v:H₂O 15% v/v).

Two peaks were generated at 1.23 and 10.03 minutes, respectively, with good resolution and no obvious interference noted. Peak symmetry and baseline noise were satisfactory. The initial peak observed may be attributed to the partitioning of the nitrate ion upon dissolution in solvent. The second peak indicates the detection of miconazole at 0.9999 purity (see Figure 4.9).

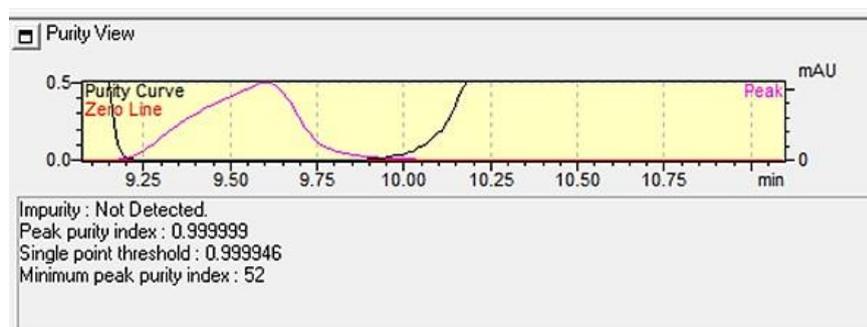

Figure 4.9: Peak purity profile of MNZ assayed under optimised chromatographic conditions (Temperature: 40 °C, Flow rate: 1 ml/min and MP:MeOH 85% v/v:H₂O 15% v/v).

A negative control in the form a blank injection of the MP was investigated under optimised chromatographic conditions (see Figure 4.10), where no obvious peaks that may cause potential interference with MNZ were observed. There was, however, a peak observed at ± 1.63 minutes. This may be attributed to the solvent front, which represents unretained material in the column.

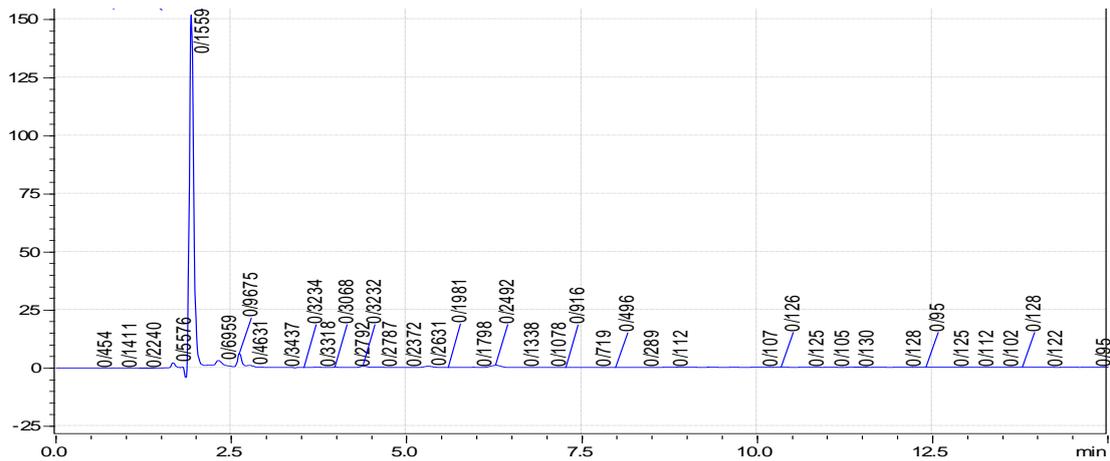

Figure 4.10: Blank injection of MP under optimised chromatographic conditions (Temperature: 40 °C, Flow rate: 1 ml/min and MP:MeOH 85% v/v:H₂O 15% v/v).

A positive control (in the form of a MNZ-SLNs) was investigated under the optimised conditions. Figure 4.11 depicts the generated chromatogram, where no additional peaks were observed. This lack of peaks suggested that the method was suitable for the analysis of MNZ in bulk, or within a complex pharmaceutical mixture. However, there was a noted shift in the retention time to 12.25 minutes. This shift could possibly be attributed to the complex composition of the MNZ-SLN formulation, such as the presence of lipids.

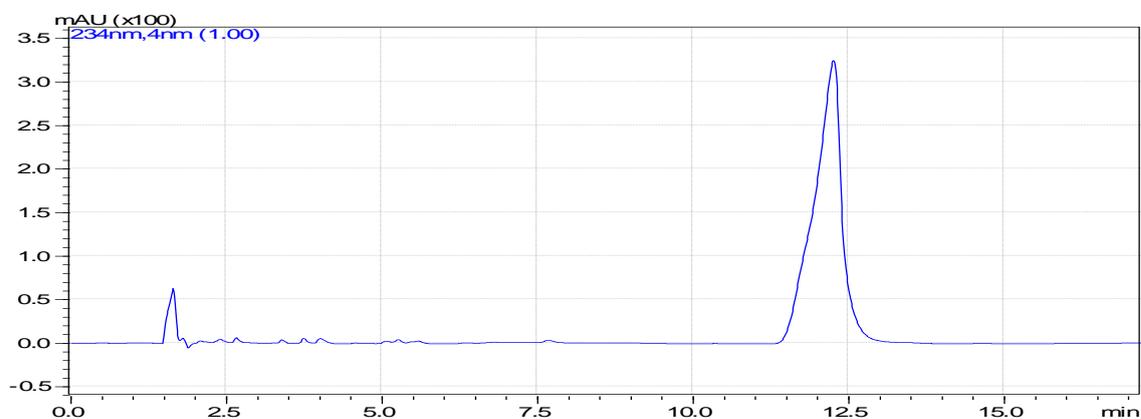

Figure 4.11: Chromatogram of 0.5 mg/ml MNZ-SLNs under the optimised conditions (Temperature: 40 °C, Flow rate: 1 ml/min and MP:MeOH 85% v/v:H₂O 15% v/v).

4.3.7.1 Acid/Alkali hydrolysis

Freshly-prepared samples were subjected to extreme acid/base conditions in order to generate chromatographic profiles of MNZ under these stress conditions. Figure 4.12 depicts a chromatogram of a 0.5 mg/ml MNZ sample under acidic stress conditions.

The peak area value, here, was significantly smaller than that found in Figure 4.8 (standard solution). This finding indicated that MNZ underwent significant degradation. Additional peaks were formed (marked 2 to 10 in Figure 4.12), which indicated the presence of degradation products within the sample.

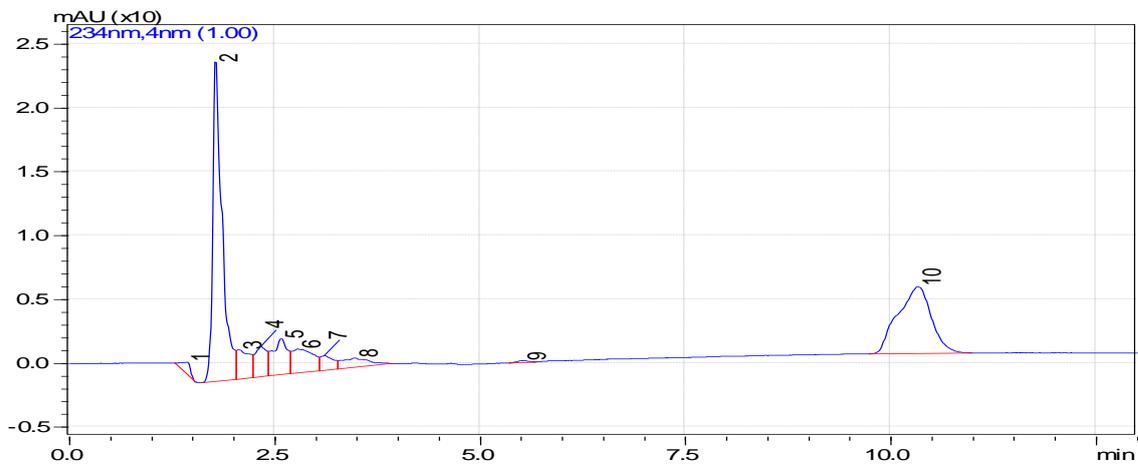

Figure 4.12: Chromatogram of a 0.5 mg/ml miconazole nitrate (MNZ) sample under acidic stress conditions.

The peak purity profile (depicted in Figure 4.13) was also assessed. It revealed a good factor of 0.999, which indicated that the detected analyte was, indeed, MNZ. The retention time of the analyte was consistent with that of the standard sample under the optimised conditions.

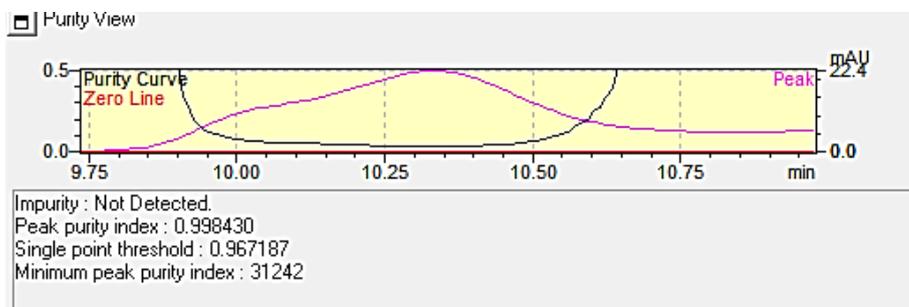

Figure 4.13: Peak purity profile of 0.5 mg/ml miconazole nitrate (MNZ) under acidic stress conditions.

The results from the alkali stress testing of a MNZ 0.5 mg/ml sample is depicted in Figure 4.14. The peak values obtained are much smaller than that of the standard solution, which indicated that significant degradation of the analyte took place. Additional peaks, labelled 2 to 9 in Figure 4.14, further indicated the presence of degradation products.

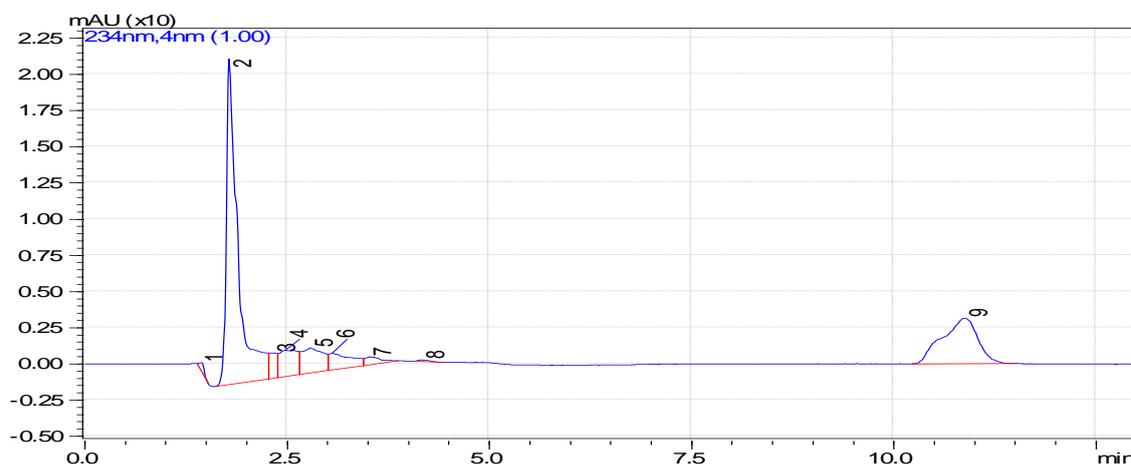

Figure 4.14: Chromatogram of a 0.5 mg/ml miconazole (MNZ) sample under alkali stress conditions

The peak purity of the resultant MNZ peak was investigated (see Figure 4.15). A purity index of 0.9962 was obtained, which demonstrated the absence of other by-products at that elution time, and concluded that MNZ had eluted at 10.00 minutes.

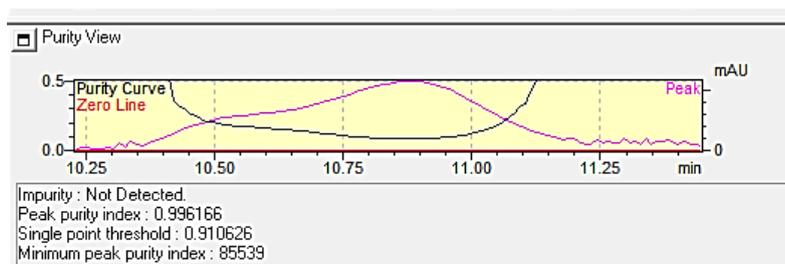

Figure 4.15: Peak purity profile of 0.5 mg/ml miconazole nitrate (MNZ) under alkali stress conditions.

An overview of the acid/alkali force degradation study is provided in Table 4.12. The rate of degradation under acidic conditions was much less than that of alkali conditions. MNZ was found to be labile under both hydrolytic conditions. The respective chromatograms indicated the presence of additional peaks, which correlated with degradation products and impurities. A reduction of peak height and the broadening of peak bases were observed, which indicated that MNZ underwent hydrolysis to degrade chromophoric groups.

Table 4.12: Overview of acidic/alkali stress testing of a 0.5 mg/ml miconazole nitrate (MNZ) sample.

	Acid hydrolysis			Alkali hydrolysis		
Sample	1	2	3	1	2	3
Purity profile	0.9989	0.9999	0.9999	0.9973	0.9972	0.9962
Peak area	147989	148101	148025	105760	105800	105782
Mean peak area (<i>n</i> =3) + SD	148038.3 ± 0.21			105780.7 ± 0.04		
Mean conc.	0.099 mg/ml			0.047 mg/ml		
Retention factor	10.75	10.70	10.71	10.82	10.79	10.80
Mean retention time	10.72 ± 0.03			10.80 ± 0.02		
% Degradation	80.2%			90.6%		

4.3.7.2 Oxidation

Freshly-prepared samples were subjected to extreme oxidative conditions so as to generate chromatographic profiles of MNZ under stress conditions. Figure 4.16 demonstrates a chromatogram of a 0.5 mg/ml MNZ sample under oxidative stress using a 3% H₂O₂ solution.

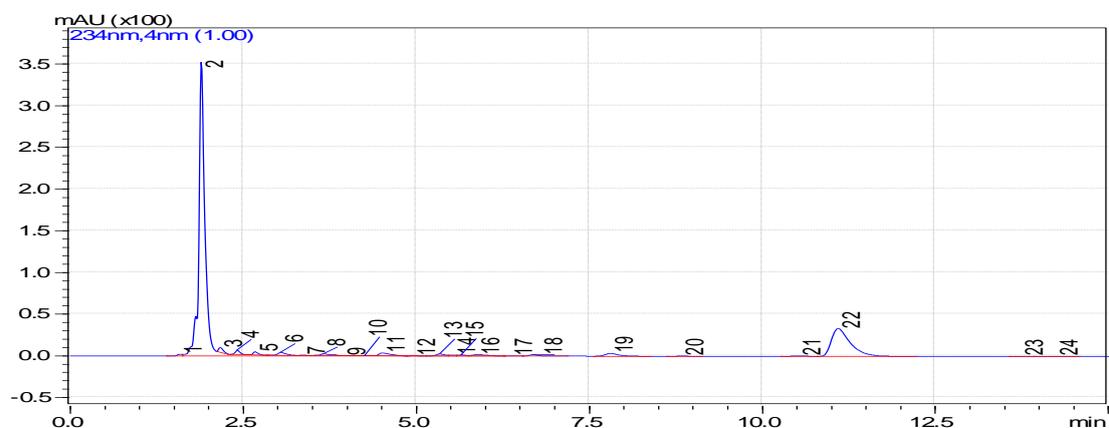

Figure 4.16: Chromatogram of 0.5mg/ml miconazole nitrate (MNZ) sample under oxidative stress conditions (3% hydrogen peroxide solution).

The MNZ peak values obtained were significantly smaller than those of the standard sample, which suggested that MNZ underwent oxidative degradation. Additional peaks, labelled 2 to 22 in the aforementioned figure, were observed, which further indicated the presence of degradation products. There was also a slight shift in retention time of the analyte.

A control in the form a blank sample (MeOH 85% v/v and H₂O 15% v/v) was also investigated under oxidative stress in order to determine whether there was the presence of degradation products as a result of the oxidising agent (see Figure 4.17). One peak was observed before two-and-a-half minutes; this represented the solvent front. The baseline was stable, with the presence of degradation products. Thus, the findings indicated that the presence of degradation product was due to the MNZ sample analysis and not due to the 3% H₂O₂ solution.

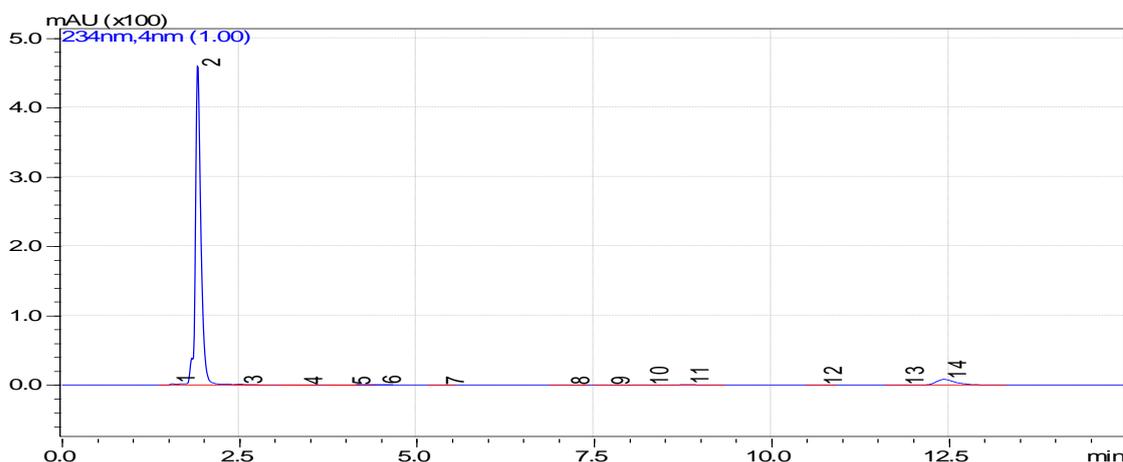

Figure 4.17: Chromatogram of a blank injection (MeOH 85% v/v and H₂O 15% v/v) under oxidative stress conditions.

The analysis of the peak purity profile indicated a good correlation of 0.999927 (see Figure 4.18). This finding concluded that there was an absence of impurities within the observed peak. The symmetry of the peak, however, suggested significant tailing.

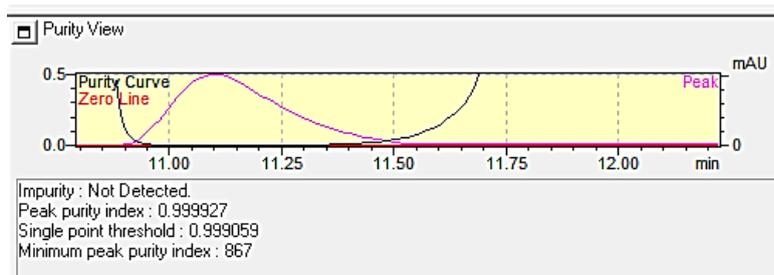

Figure 4.18: Peak purity profile of 0.5 mg/ml miconazole nitrate (MNZ) sample under oxidative stress.

A summary of the oxidative stress results of a 0.5mg/ml MNZ sample is illustrated in Table 4.13. It was observed that MNZ was labile under oxidation when using a 3% H₂O₂ solution, with a slight increase in retention time.

Table 4.13: Summary of oxidative stress results for the assay of a 0.5mg/ml miconazole nitrate (MNZ) sample.

Sample	0.5mg/ml MNZ sample			Blank sample (MeOH 85% v/v:H ₂ O 15% v/v)		
	1	2	3	1	2	3
Purity profile	0.99995	0.99993	0.99997	-	-	-
Peak area	98230	97657	98823	No peak	No peak	No peak
Mean peak area (n=3) + SD	98239.67 ± 0.15			-		
Mean conc.	0.037 mg/ml			-		
Retention factor	11.85	11.60	11.73	-	-	-
Mean retention time	11.73 ± 0.03			-		
% Degradation	92.6%			-		

4.3.7.3 Photolytic degradation

Samples were subjected to photolytic exposure so as to generate chromatographic profiles of MNZ under photolytic stress conditions. Analyte degradation was monitored over a period of seven days. The first reading was taken after 48 hours, then 96 hours and, lastly, after 144 hours. Figure 4.19 illustrates an example of a 0.5 mg/ml sample under photolytic stress after 48 hours. The peak area was slightly smaller than that of the standard solution, which indicated that degradation of MNZ occurred. Additional degradation products, marked 2 to 19 in the figure, were also observed. A slight shift in retention time was also noted.

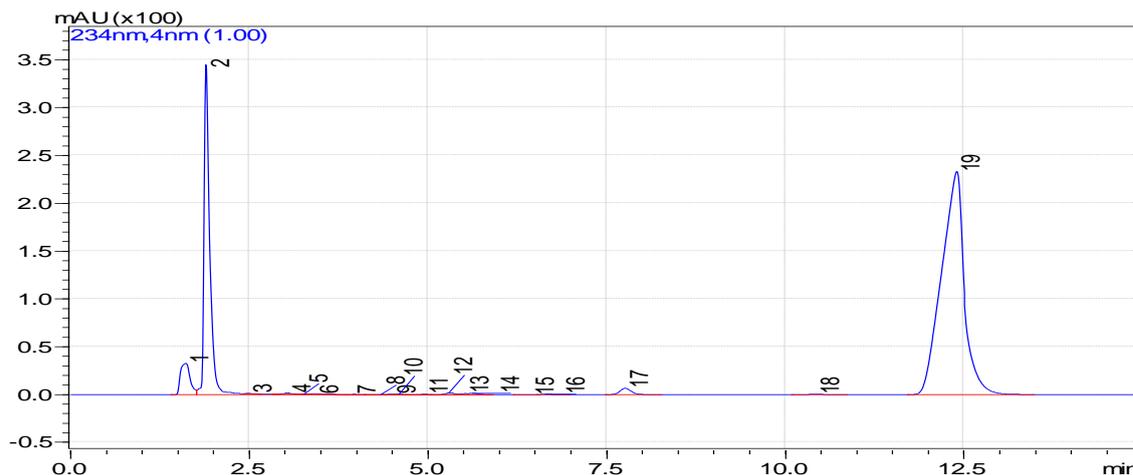

Figure 4.19: Chromatogram of 0.5mg/ml miconazole nitrate (MNZ) sample under photolytic stress at 48 hours.

The assessment of peak purity indicated a good correlation of 0.9999, which suggested the absence of impurities in the observed peak. Good symmetry was also noted (see Figure 4.20).

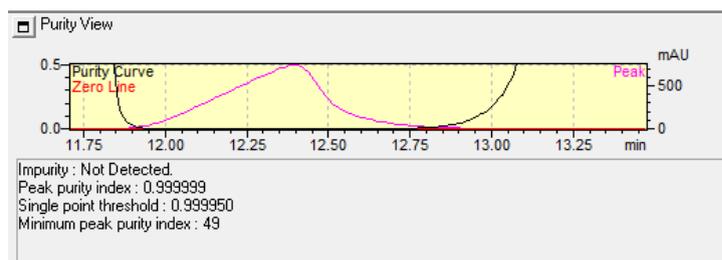

Figure 4.20: Peak purity profile of 0.5 mg/ml miconazole nitrate (MNZ) sample under photolytic stress at 48 hours.

A control test was conducted by placing a 0.5 mg/ml MNZ sample in a dark room. Periodic assays were then conducted at 48, 96 and 144 hours. Figure 4.21 illustrates an example of a chromatogram generated under these conditions at 48 hours. The peak area observed was slightly less than that of the standard sample, which suggested that the analyte had undergone some degradation. Minor degradation products (peaks 2 to 9) were also noted, with an increased retention time.

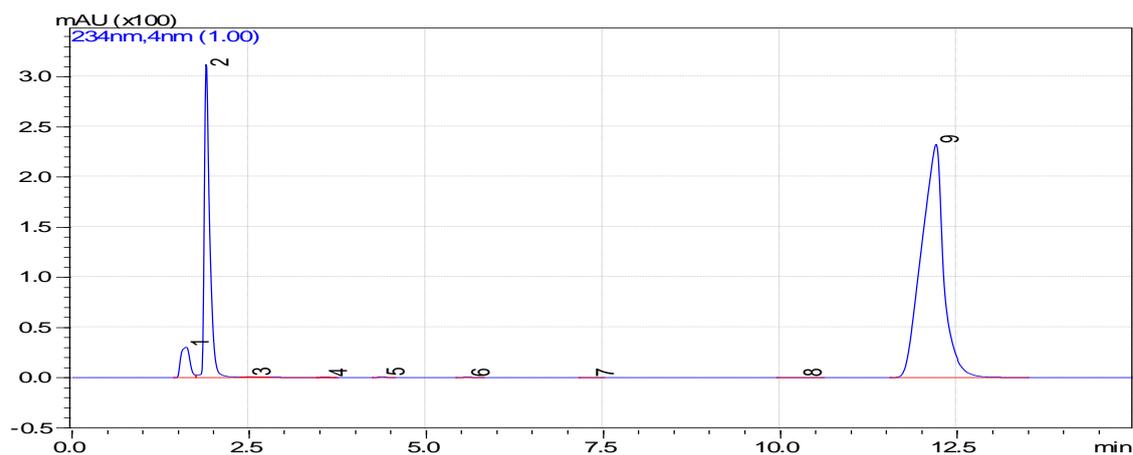

Figure 4.21: Chromatogram of 0.5 mg/ml miconazole nitrate (MNZ) sample stored in a dark room at 48 hours.

The peak purity profile investigation revealed an acceptable index of 0.99999, which suggested the absence of by-products or impurities in the peak.

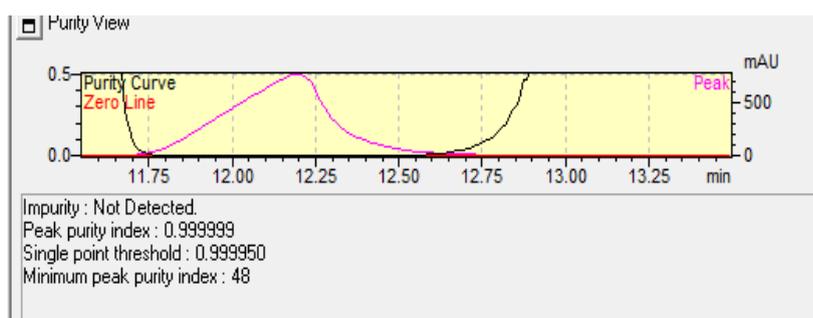

Figure 4.22: Peak purity profile of a 0.5 mg/ml miconazole nitrate (MNZ) sample in a dark room at 48 hours.

A summary of the outcomes from the photolytic stress testing of a 0.5 mg/ml MNZ sample is provided in Table 4.14.

Table 4.14: Summary of photolytic stress testing on a 0.5 mg/ml miconazole nitrate (MNZ) sample.

	Time		
	48 hours	96 hours	144 hours
1 × ICH photo exposure			
- R _f	12.39 min	12.35 min	12.41 min
- Mean area	4102433 ± 0.24	2981567 ± 1.02	998756 ± 0.15
- Mean conc.	0.48 mg/ml	0.36 mg/ml	0.11 mg/ml
- Purity profile	0.99999	0.99997	0.99998
- % deg.	4%	28%	77%
Darkroom			
- R _f	12.19 min	12.23 min	12.19 min
- Mean area	5019559 ± 0.51	3920126 ± 0.13	2005987 ± 0.12
- Mean conc.	0.61 mg/ml	0.47 mg/ml	0.24 mg/ml
- Purity profile	0.99999	0.99999	0.9999
- % deg.	+0.2%	6%	52%

From the information presented in the aforementioned table, MNZ was susceptible to photolytic degradation under both test and control conditions. Light conditions, however, facilitated greater and faster degradation when compared to storage in a dark room. The extent of degradation was greatly increased with prolonged storage and exposure to light. Degradation was also observed in the control sample that was kept in the dark, but this could be attributed to other mechanisms like oxidation upon storage. Moreover, the rate of degradation in the control was relatively high. It should be noted that these tests were conducted at ambient temperature (25 ± 2 °C), which suggested the possibility of MNZ thermal degradation in cases of prolonged storage.

4.3.7.4 Thermal degradation

Freshly-prepared samples were exposed to various temperatures to generate chromatographic profiles of MNZ under thermal stress conditions. The temperatures ranged between four, 25, 60 and 80 °C over a period of 120 hours. Figure 4.23

illustrates an example of a chromatogram of a 0.5 mg/ml MNZ sample under thermal stress at 60 °C after 24 hours. The observed peak area was significantly smaller than that of the standard sample, which indicated that the analyte underwent degradation. Furthermore, additional degradation compounds (marked 2 to 6 in Figure 4.23) were noted.

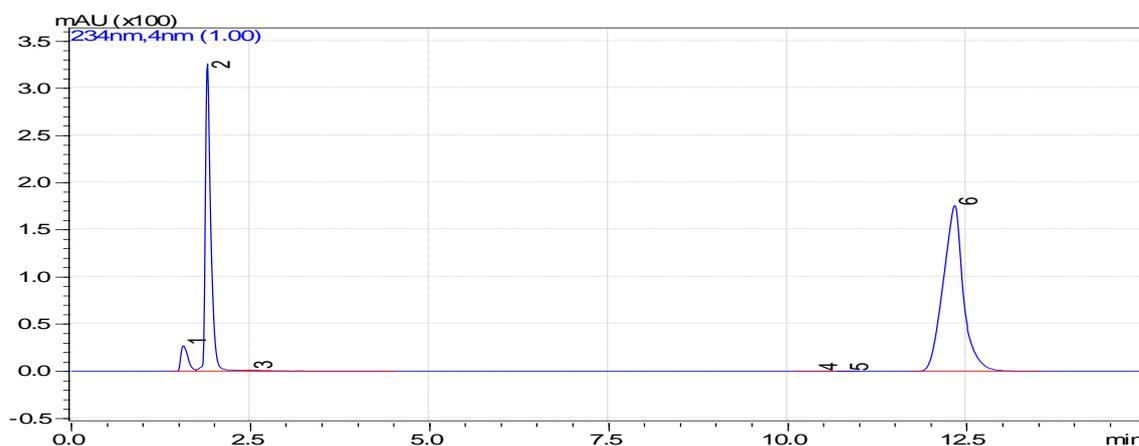

Figure 4.23: Chromatogram of 0.5 mg/ml miconazole nitrate (MNZ) sample at 60 °C after 24 hours.

Peak purity profile assessments revealed an acceptable index of 0.99999, which suggested the absence of by-products or impurities in the peak (see Figure 4.24).

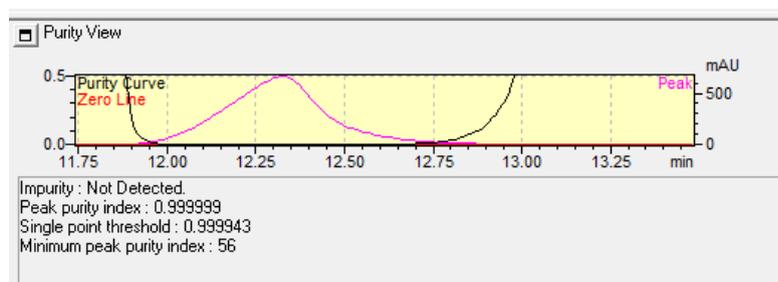

Figure 4.24: Peak purity profile of a 0.5 mg/ml miconazole nitrate (MNZ) sample at 60 °C after 24 hours.

A summary of the chromatographic findings under the respective thermal conditions at each time interval are depicted in Table 4.15.

Table 4.15: Summary of thermal stress testing of a 0.5 mg/ml miconazole nitrate (MNZ) sample(s) over a 24-hour period.

Temperature	Time		
	24 hours	72 hours	120 hours
4 ± 2°C			
- R _f	12.12 min	12.10 min	12.11 min
- Mean area	4042068 ± 0.21	3825164 ± 0.15	3569817 ± 1.25
- Mean conc.	0.49 mg/ml	0.46 mg/ml	0.43 mg/ml
- Purity profile	0.99999	0.99999	0.99999
- % deg.	3%	8%	14%
25 ± 2°C			
- R _f	12.10 min	12.13 min	12.15 min
- Mean area	3681054 ± 1.54	3109687 ± 1.56	1975264 ± 0.42
- Mean conc.	0.46 mg/ml	0.37 mg/ml	0.24 mg/ml
- Purity profile	0.99999	0.99999	0.99999
- % deg.	8%	26%	52%
60 ± 2°C			
- R _f	12.32 min	12.15 min	12.20 min
- Mean area	3 444 884 ± 2.52	2389675 ± 0.19	1426973 ± 0.52
- Mean conc.	0.41 mg/ml	0.29 mg/ml	0.17 mg/ml
- Purity profile	0.99999	0.99999	0.9999
- % deg.	18%	42%	66%
80 ± 2°C			
- R _f	12.18 min	12.20 min	12.20 min
- Mean area	2765478 ± 1.23	1095231 ± 0.12	862341 ± 1.54
- Mean conc.	0.33 mg/ml	0.13 mg/ml	0.09 mg/ml
- Purity profile	0.99998	0.99999	0.99998
- % deg.	34%	74%	82%

The rate and extent of degradation increased with an increase of temperature and prolonged exposure to thermal conditions. Samples stored at 4 °C were characterised by a larger peak area when compared to the rest, suggesting a slower rate of degradation of the analyte. A shift in retention time was also noted for all samples, which suggested possible oxidative degradation upon storage.

4.3.8. Summary of method validation parameters

An isocratic RP-HPLC stability-indicating method was developed by utilising an octyl stationary phase for the quantification of MNZ in bulk or complex pharmaceutical products. The reliability of the method was statistically validated for linearity, accuracy, precision and specificity within a working range of 0.125 to 1.000 mg/ml. The LoD and LoQ were calculated to be 0.015 and 0.052 mg/ml, respectively. The standard calibration curve was linear within the working range, with a correlation co-efficient of >0.999. A summary of the validation parameters is provided in Table 4.16.

Table 4.16: Summary of method validation parameters.

Parameter	Experimental data
Working range	0.125 to 1.000 mg/ml
Calibration curve	$Y = 811214 + 67958$
LoD ($n=3$)	0.015 mg/ml
LoQ ($n=3$)	0.052 mg/ml
Accuracy	Recovery = $0.50 \pm 2\%$; % RSD $\leq 2\%$
Precision	
- Intra-day	Recovery = $0.50 \pm 2\%$; % RSD $\leq 2\%$
- Inter-day	
Specificity	Chromatogram with Gaussian peak Peak purity >0.999 Sufficient degradation under stress conditions

MNZ samples were subjected to stress conditions of hydrolysis, oxidative, thermal and photolytic degradation. The results are summarised in Table 4.17.

Table 4.17: Summary of forced degradation testing parameters.

Parameters	Conditions	Extent of degradation			
Acid/alkali hydrolysis	Acid: in 1M HCl refluxed for 120 min at 80 °C	Acid: 80.2%			
	Alkali: in 1M NaOH refluxed for 120 min at 80 °C	Alkali: 90.6%			
Oxidative	In 3% H ₂ O ₂ refluxed for 120min at 80 °C	92.6%			
Photolytic					
Dark room	0.5 mg/ml stored in a dark cupboard; sampling done at periodic intervals at ± 25 °C				
- 48 hrs					0.2%
- 96 hrs					6%
- 144 hrs					52%
1 × ICH guidelines	0.5 mg/ml samples stored in an incubator, sampling done at periodic intervals at ± 25 °C				
- 48 hrs					4%
- 96 hrs					28%
- 144 hrs					77%
Thermal	Conditions	24 hrs	72 hrs	120 hrs	
4 ± 2°C	0.5 mg/ml samples stored in an incubator at the various temperatures	3%	8%	14%	
25 ± 2°C		8%	26%	52%	
60 ± 2°C		18%	42%	66%	
80 ± 2°C		34%	74%	82%	

The forced degradation studies proved that MNZ was labile under photolytic, oxidative, hydrolytic and thermal stress. Oxidative stress demonstrated the greatest degradation of 92.6%, whilst thermal stress at 4 °C facilitated the least degradation. Based on these findings it was concluded that, even under extreme stress conditions no degradation products would interfere/interact with the analyte during analysis. Thus deeming the method specific.

4.4 DRUG-EXCIPIENT COMPATIBILITY STUDIES

Simultaneous thermal analysis (SDT) is a highly useful technique for detecting possible incompatibilities between API and excipients in a formulation (Julio *et al.*, 2013) and was, therefore, employed for the determination of drug-exciipient compatibility in this study. To that end, bulk materials and binary mixtures of cholesterol and MNZ were investigated.

4.4.1 Thermograms of bulk materials

The thermal behaviour of MNZ (API) in the formulation was investigated. It was observed that MNZ crystalline powder underwent a rapid two-step endothermic degradation. The melting point was recorded at 184.39 °C (see Figure 4.25). Complete degradation occurred by 400 °C with a $\pm 10\%$ residue.

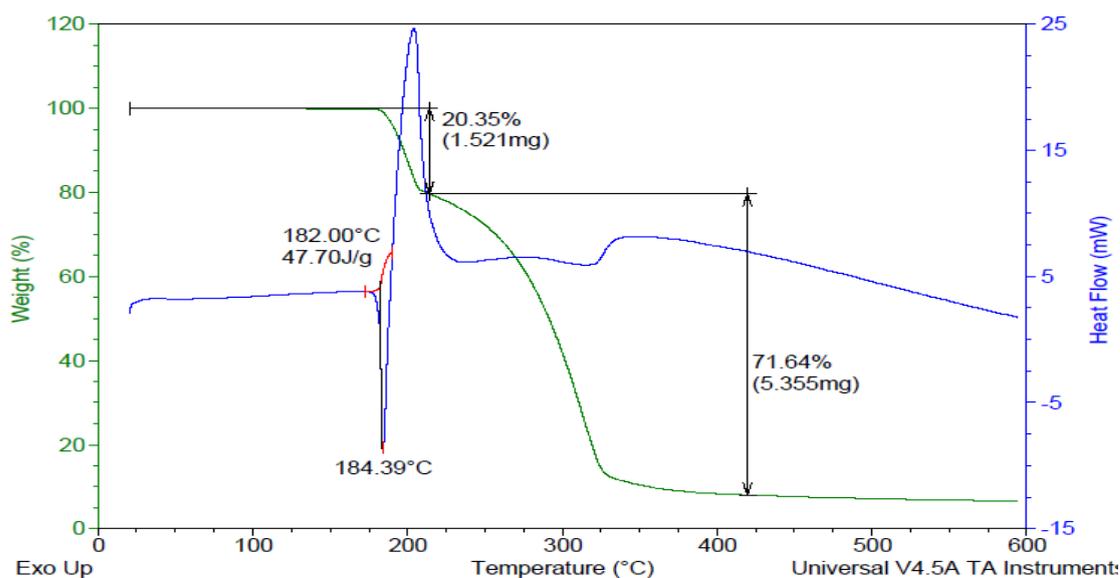

Figure 4.25: Thermogram of bulk miconazole nitrate (MNZ) microcrystalline powder (blue curve indicates the heat flow (mW) as a function of temperature; green curve indicates the % mass of sample as a function of temperature).

For the bulk material of cholesterol, a rapid single-step degradation was observed. The onset of degradation occurred at 143.94 °C with actual melting taking place at 146.7 °C. This melting is indicated by the sharp downward peak in Figure 4.26.

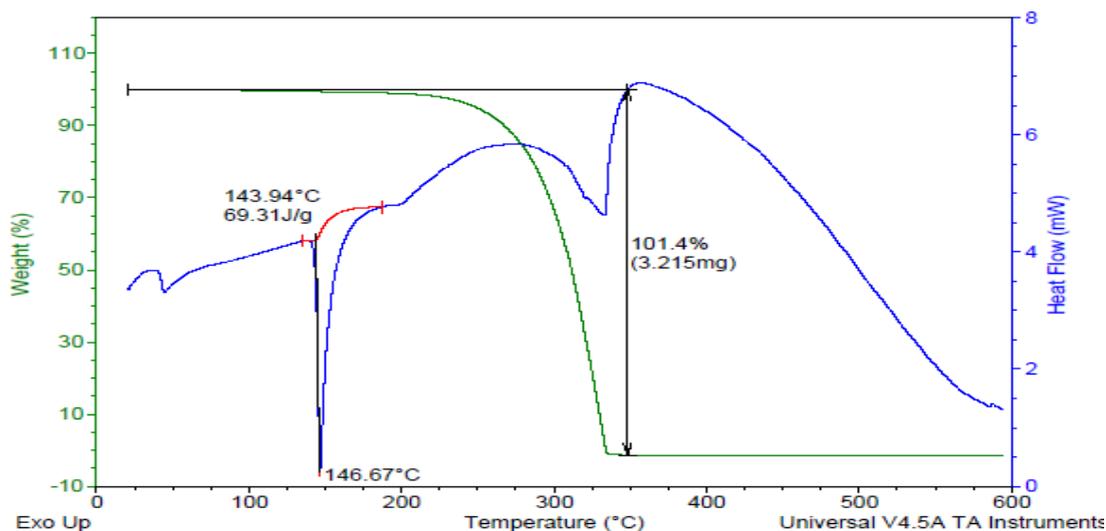

Figure 4.26: Thermogram of bulk cholesterol (blue curve indicates the heat flow (mW) as a function of temperature; green curve indicates the % mass of sample as a function of temperature).

4.4.2 Thermogram of binary mixture

The thermal characteristics of a MNZ and cholesterol binary mixture were investigated in order to determine the possible interaction between the two components. Interactions may be expressed by a shift or broadening of the thermogram. A two-step degradation process was noted for the mixture. The melting range was between 141.6 °C to 155.97 °C, with actual melting taking place at 145.88 °C (see Figure 4.27).

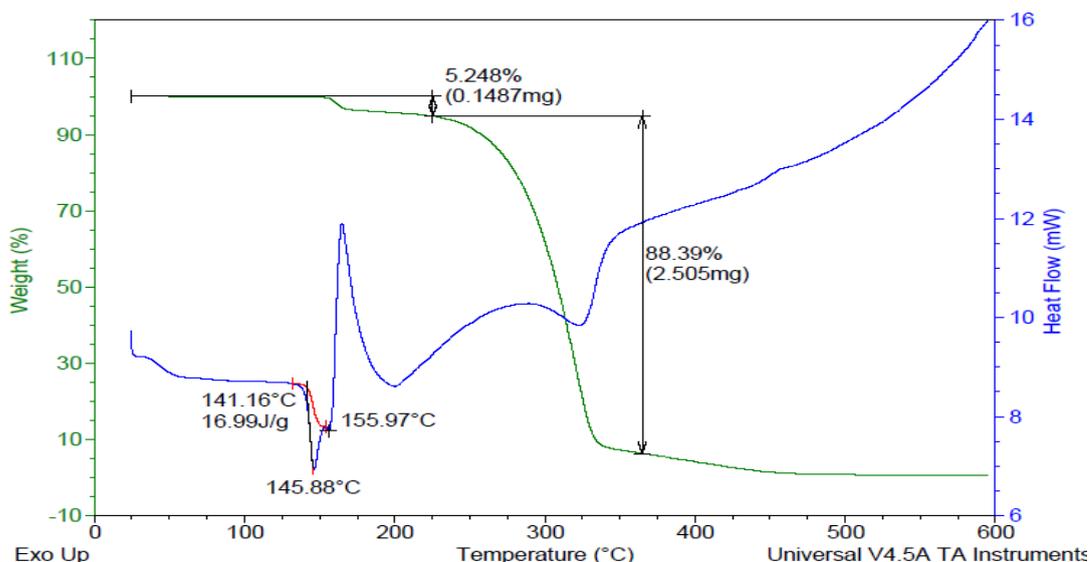

Figure 4.27: Thermogram of dried mixture of miconazole nitrate (MNZ) (35% m/m) and cholesterol (65% m/m).

4.4.3 Summary of drug-excipient compatibility studies

Based on the findings of the SDT, it can be concluded that there is a clear distinction in the thermal behaviours of MNZ and cholesterol, respectively. MNZ demonstrated a much higher melting point (184.39 °C) than cholesterol (146.74 °C). It should be noted that the two-step degradation process observed may have been as a direct result of the dissociation of N_3O_4^- from $\text{C}_{18}\text{H}_{14}\text{Cl}_4^+$ in the MNZ molecule. The molecular mass (M_r) of N_3O_4^- accounted for 22.12% of the total M_r of MNZ (highlighted in Figure 4.28). This number correlates with the 1.52 mg (20.35%) change in mass accounted for in the initial degradation of MNZ.

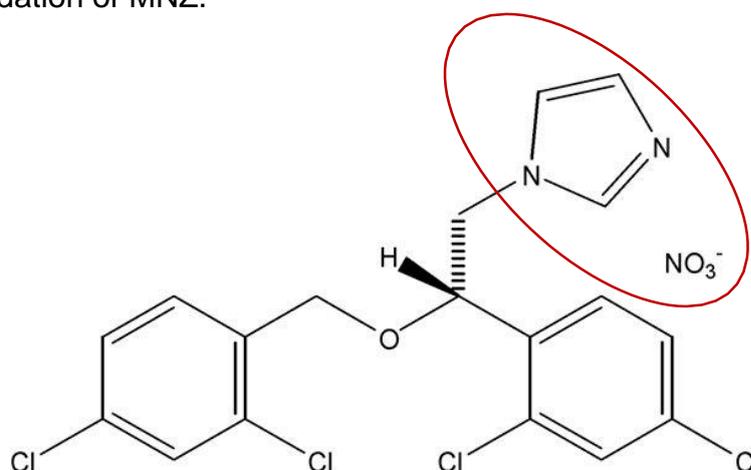

Figure 4.28: Chemical structure of miconazole nitrate (MNZ) demonstrating N_3O_4^- molecule circled in red (De Zan *et al.*, 2009).

A summary of the changes in thermal behaviour of MNZ and cholesterol in bulk and binary mixtures is illustrated in Figure 4.29. The thermogram depicts a shift to a lower temperature from 185 ± 2 °C to 157 ± 2 °C for MNZ in the mixture. The higher melting point of MNZ in the bulk formulation may be indicative of a highly ordered crystal lattice structure. For a less ordered structure, the melting of materials requires less energy than that of highly ordered structures. It is of great importance to note the change in melting point and broadening of the peak as these were associated with lattice defects and the formation of amorphous regions in which a drug can be located. Less order was preferential, as it allowed for greater accommodation of API in the lipid vesicle. Conversely, cholesterol maintained its thermal properties, with negligible shifts in its melting point from 146.06 °C to 146.19 °C.

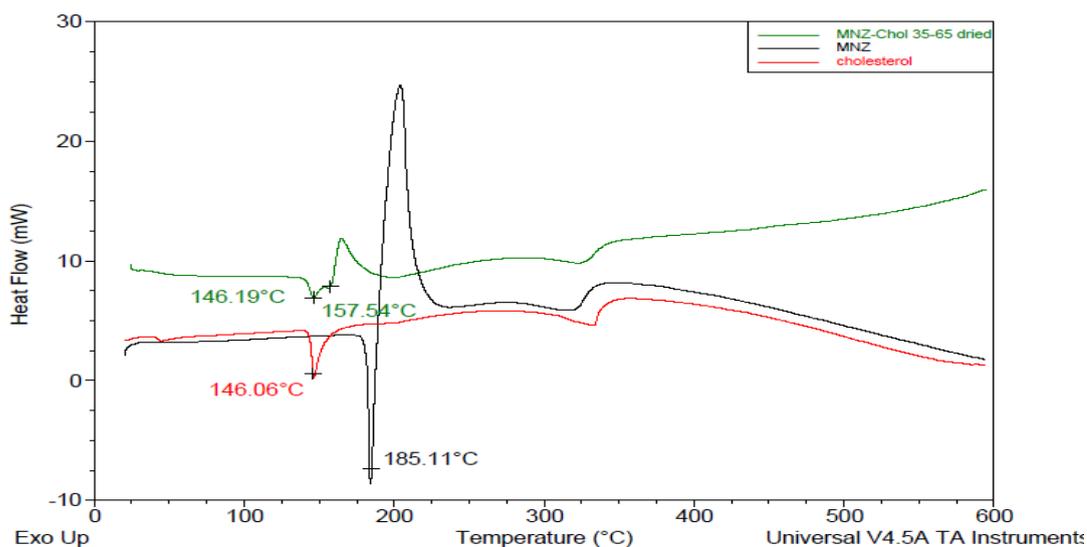

Figure 4.29: Thermogram of cholesterol (red), miconazole nitrate (MNZ) (black) and MNZ (35% v/v) and cholesterol (65% v/v) binary mixture (green).

Figure 4.30 illustrates the thermal degradation of MNZ and cholesterol in bulk and binary mixtures by analysis of % weight as a function of temperature.

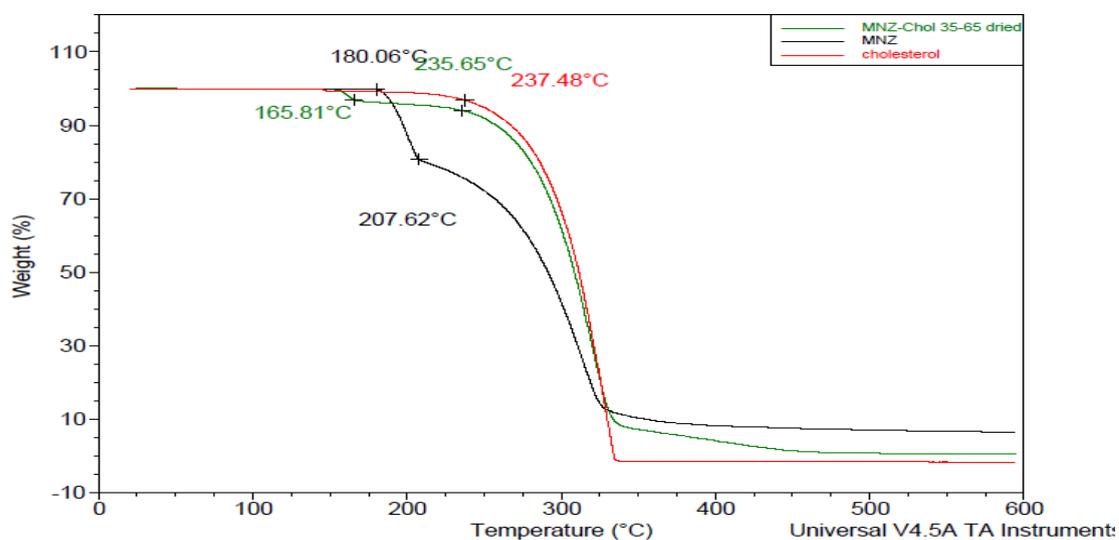

Figure 4.30: Function of % weight versus temperature of miconazole nitrate (MNZ) (black), cholesterol (red) and MNZ (35% v/v) and cholesterol (65% v/v) binary mixture (green).

It was observed that the degradation of cholesterol changed from a single- to a two-step process when placed in a binary mixture, with a shift in melting point from 237.48 °C to 165.81 and 235.65 °C, respectively. This is possibly owing to the presence of the API in the mixture.

Furthermore, the degradation of MNZ followed a two-step process in both the bulk and binary mixture formulations. Its respective melting points went from 180.06 °C and 207.62 °C to 165.81 °C and 235.65 °C, respectively. It was also noted that bulk cholesterol left no residue upon degradation, but MNZ left a residue of $7.0 \pm 1\%$. This residual value of MNZ was, however, decreased to 3.67% when combined in a binary mixture.

MNZ demonstrated satisfactory dissolution with cholesterol and rapid degradation of $N_3O_4^-$ at 165.81°C, thus leaving miconazole alone in the lipid mix. The combination of MNZ and cholesterol resulted in the formation of a distinct chromatogram that assumed the entrapment of the API in the lipid. These findings were deemed favourable as it was expected that cholesterol would modify the thermal behaviour of MNZ so as to facilitate adequate entrapment in the formulation of MNZ-SLNs.

4.5 DEVELOPMENT AND OPTIMISATION OF MNZ LOADED SOLID NANOPARTICLES (MNZ-SLNs)

4.5.1 Preparation of MNZ loaded solid lipid nanoparticles (MNZ-SLNs)

Two techniques, namely bath sonication and PUS, were investigated for the preparation of MNZ-SLNs. A 2% MNZ-SLN formulation was prepared by using a novel melt-emulsification, low-temperature solidification method. The resultant coarse suspension was divided into two equal portions. One portion was subjected to sonication by means of a probe-tip device for four minutes, whilst the other underwent bath sonication for four minutes.

Table 4.18 depicts the respective particle size measurements obtained from PCS analysis of a 2% m/v MNZ-SLN formulation using the two respective techniques.

Table 4.18: Photon correlation spectroscopy (PCS) characteristics of 2% MNZ loaded solid lipid nanoparticles (MNZ- SLNs) formulated via bath and Probe-tip ultrasound sonication (PUS), respectively.

Run	Bath Sonication		PUS	
	z-avg. (d.nm)	PDI	z-avg. (d.nm)	PDI
1	156.90	0.479	51.21	0.191
2	150.23	0.461	52.06	0.193
3	152.60	0.465	52.17	0.193
Mean ± SD	153.24 ± 2.76	0.46 ± 0.01	51.81 ± 0.43	0.192 ± 0.001

Larger particle agglomerates scatter more light, and cause rapid sedimentation when compared to their smaller counterparts (Pradhan *et al.*, 2016). Furthermore, both techniques yielded particles within the nano-size range; however, MNZ-SLN preparation via bath sonication yielded bigger particles with a mean z-avg. value of 153.2 nm. Figure 4.31 illustrates a comparison between observed particle size distributions in nano-dispersions prepared by ultrasonic bath versus PUS.

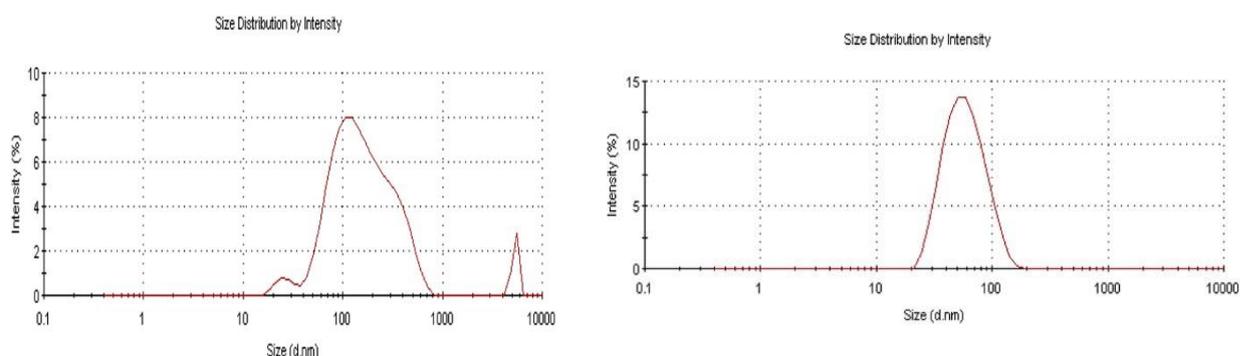

Figure 4.31: Comparison of particle size (z-avg.) distribution in prepared 2% m/v MNZ loaded solid lipid nanoparticles (MNZ-SLNs) via ultrasonic bath device (left) and probe-tip ultrasound sonication PUS (right).

Nanoparticle formation via bath sonication produced an unacceptably high PDI, which suggested sample absorbance and fluorescence due to poor dilution or the presence of large sedimenting particles. PDI values exceeding 0.3 suggest an unstable and non-homogenous suspension that may result in the instability of the final formulation (He *et al.*, 2017). Based on the PCS characterisation results, it can be concluded that the

use of PUS facilitated superior disintegration of particle agglomerates into smaller and mono-dispersed units in the coarse dispersion. These findings motivated PUS as a tool for the preparation of MNZ-SLNs.

4.5.2 Statistical optimisation of prepared MNZ loaded solid lipid nanoparticles (MNZ-SLNs)

DesignExpert® software (v7.0.0. StatEase™. Minneapolis, USA) was used for the statistical optimisation of the prepared MNZ-SLNs. Thirteen experimental runs were generated through a CCRD. These runs were prepared and characterised respectively. An appropriate empirical model was then selected to statistically validate the data input by analysis of variance (ANOVA). A lack-of-fit test was then conducted to evaluate the significance of the chosen model. This process was employed for each measured response. Model desirability was then assessed in order to ascertain optimal conditions that facilitated the maximal entrapment efficiency of MNZ with minimal deviations in particle diameter upon storage.

4.5.2.1 Central composite rotatable design (CCRD)

A CCRD was employed as a RSM tool for the optimisation of particle characteristics of MNZ-SLNs. Thirteen individual nanodispersions were prepared by means of a melt-emulsion, low temperature PUS method in accordance with the specifications of the experimental design sheet (see Table 3.10). Each formulation was divided into two halves, where one half was stored at ambient temperature (25 ± 2 °C) and the other at refrigerated temperatures (4 ± 2 °C). Individual characterisation tests for z-avg., PDI, ZP and %EE were conducted on each formulation at days zero, 14 and 28 of storage.

The overall effects of lipid concentration and sonication time on %EE were assessed by an indirect method. Particle characteristics, such as z-avg., ZP and PDI were determined by means of PCS. The results obtained from these investigations are summarised in Tables 4.19 and 4.20, respectively. Ideal formulations were deemed acceptable if they possessed good uniformity within the nanometre range, and when they had a high ZP value with minimal deviations in characteristics upon storage.

Table 4.19: Characterisation of MNZ loaded solid lipid nanoparticles (MNZ-SLNs) stored at ambient temperature (25 ± 2 °C).

Run	Day 0 (t_0)				Day 14 (t_1)				Day 28 (t_2)

All formulations demonstrated desirable characteristics upon analysis at day zero. With prolonged storage, however, changes in particle size and entrapment efficiency were observed in most formulations. From the results tabulated in Table 4.20, changes in particle characteristics (especially PDI and z-avg.) were comparable for samples stored at fridge and ambient temperature. Figure 4.32 depicts the change in particle size of individual formulations under ambient versus fridge conditions over a 28-day period.

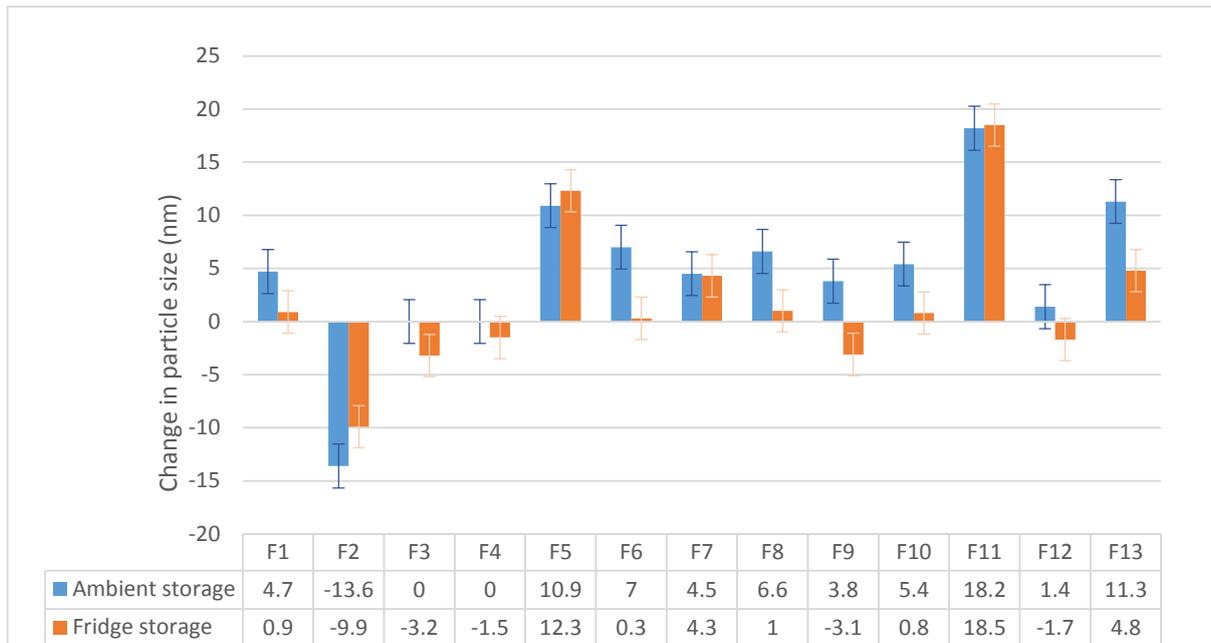

Figure 4.32: Graph depicting the change in particle size (z-avg.) on prepared MNZ solid lipid nanoparticles (MNZ-SLNs) after 28 days at fridge (orange) and ambient (blue) storage.

The majority of formulations demonstrated an increase in particle size over the 28-day period, irrespective of the storage temperature. Only one formulation (F2) demonstrated a decrease in size when stored at ambient temperature. This finding is significantly less than that of the five formulations (F2, F3, F4, F9 and F12) that demonstrated a decrease in particle size upon storage in the fridge. The mean particle size growth was calculated as 6.15 ± 5.04 nm and 5.33 ± 6.23 nm for ambient ($n=12$) and fridge ($n=8$) storage, respectively. The mean particle size shrinkage was calculated as -13.6 ± 00 nm and -3.88 ± 3.09 nm for ambient ($n=1$) and fridge ($n=5$) storage, respectively. Based on these findings, it was concluded that fridge storage facilitated the lowest mean particle growth and shrinkage.

The use of an emulsifier (surfactant) in MNZ-SLN formulations prevents the aggregation of particles through its microviscosity properties (Bynan *et al.*, 2018; Emami *et al.*, 2015). Microviscosity defines the friction experienced by a particle undergoing diffusion due to its interactions with its environment on a microscopic scale (Goins *et al.*, 2008). Higher temperatures, however, induce destabilisation of the colloidal system by reducing the microviscosity of the emulsifier. Furthermore, high temperatures increase the kinetic energy of the colloidal system, which is sufficient for overcoming repulsive forces within the dispersion to form agglomerates (Shah *et al.*,

2014). The consequences of agglomeration include colloidal system instability and drug expulsion. Hence, all forthcoming investigations and assessments were conducted solely on the aforementioned refrigerated samples.

4.5.3 Statistical data analysis

Five output factors (responses), viz. ZP, %EE, z-avg., change in z-avg. and %EE upon storage (in a 28-day period) were investigated. The PDI for all formulations were acceptable and, therefore, not investigated further for the purposes of the optimisation studies. Response models were utilised to diagnose and illustrate a relationship(s) between the input variables and the measured responses. Furthermore, statistical data was depicted graphically through the use of 3D plots. Normal plots of residuals were constructed to assess the significance of the proposed model and its suitability in the assumption of normality.

4.5.3.1 Analysis of variance (ANOVA) and normal plots of residuals

ANOVA is a statistical tool used for the prediction of input variable effects on measured responses (Kao and Green, 2008). Where p-values (Prob>F) of less than 0.05 indicate significant model terms, those > 0.1000 are not statistically significant model terms (Ogee *et al.*, 2016). Using ANOVA, normal plots of residuals were generated to determine the data normality. The representation of the generated data by means of these plots allowed for adequate visualisation to discern points that lay close to the straight line, thus confirming that the data were normally distributed. The ideal pattern for distribution points should follow a straight line. However, mild scatter can be expected (Bewick *et al.*, 2005; Schneider *et al.*, 2010).

i. Analysis of variance (ANOVA) and normal plot of residuals for zeta potential (ZP)

An f-value of 0.67 was obtained, which indicated that the model was not significant relative to the noise, with a 65.92% probability that this value would occur due to noise. The lack of a fit p-value of 0.648 was advantageous, as it suggested that there were no significant model terms relative to pure error. Table 4.21 provides a summary of the ANOVA test response for ZP.

Table 4.21: Analysis of variance (ANOVA) test for response surface quadratic model for zeta potential (ZP).

Source	Sum of squares	Degree of freedom	Mean square	f-value	p-value	
Model	96.01	5	19.20	0.67	0.659	not significant
Lipid conc. (A)	44.78	1	44.78	1.56	0.2514	
Sonication time (B)	46.02	1	46.02	1.61	0.246	
AB	0.01	1	0.01	0.000349	0.986	
A²	0.37	1	0.37	0.013	0.9125	
B²	5.10	1	5.10	0.18	0.686	
Residual	200.56	7	28.65	-	-	
Lack-of-fit	62.34	3	20.78	0.60	0.648	not significant
Pure error	138.22	4	34.56	-	-	
Cor. total	296.57	12	-	-	-	

Based on the statistical data provided, it can be concluded that there were no significant model terms that influenced the measured ZP for the prepared formulations. The use of a linear response surface model was recommended for the ANOVA test of ZP because it demonstrated the greatest potential of maximising the predicted and adjusted r^2 values. The normal plot of residuals for ZP, illustrated in Figure 4.33, depicts a fairly linear pattern of the plotted points. This suggests a normal distribution of the points of externally studentised residuals versus normal % probability.

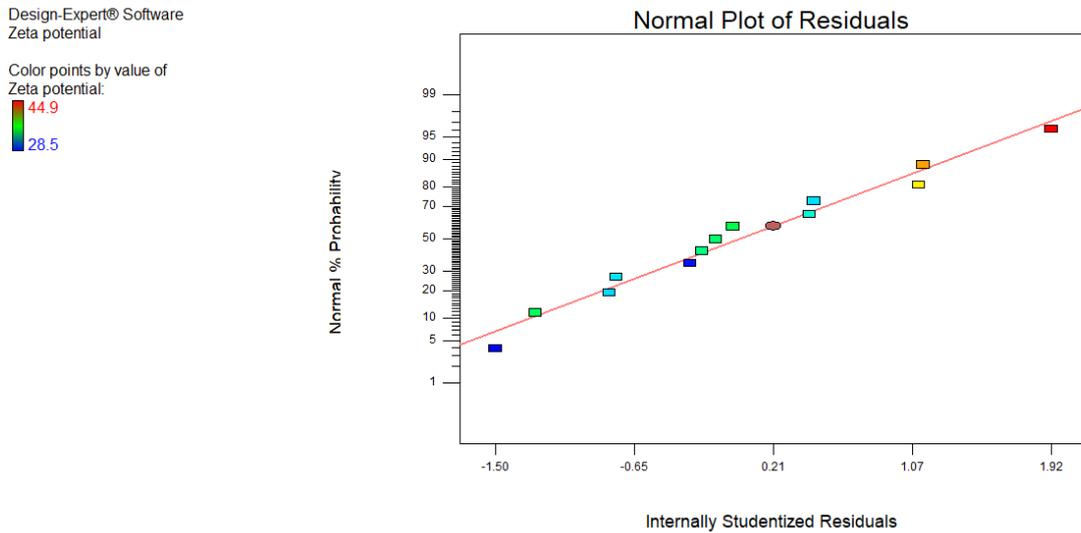

Figure 4.33: Normal probability plot of residuals for zeta potential (ZP) displaying a linear relationship of normal % probability as a function of externally studentised residuals.

The statistical data indicated that there was no relationship between the input variables (i.e. lipid concentration and sonication time) on the measured response (i.e. the ZP). Nanodispersion components that demonstrated the greatest influence on surface charge and particle stability (i.e. surfactants) were kept constant in all formulations; therefore, a significant effect on ZP from the two input variables, respectively, was not anticipated. This phenomenon was supported by the statistical findings and concurs with other findings that the effect of sonication parameters on ZP is negligible (Siddiqui *et al.*, 2014).

ii. Analysis of variance (ANOVA) and normal plot of residuals for entrapment efficiency (%EE)

A series of models were proposed in the ANOVA test of %EE. None were deemed significant; however, the quadratic empirical model resulted in the generation of the highest f-values (0.75) with a high probability that this value would occur due to noise. A lack of f-value of 4.41 with a p-value of 0.0928 favoured a non-significant response, which was ideal. A summary of the ANOVA test response values for %EE is depicted in Table 4.22.

Table 4.22: Analysis of variance (ANOVA) test for response surface quadratic model for entrapment efficiency (%EE).

Source	Sum of squares	Degree of freedom	Mean square	f-value	p-value	
Model	774.36	5	154.87	0.75	0.6133	not significant
Lipid conc. (A)	4.55	1	4.55	0.022	0.8865	
Sonication time (B)	169.71	1	169.71	0.82	0.3957	
AB	56.55	1	56.55	0.27	0.6176	
A²	198.17	1	198.17	0.96	0.3609	
B²	410.55	1	410.55	1.98	0.2022	
Residual	1451.69	7	207.38	-	-	
Lack-of-fit	1114.72	3	371.57	4.41	0.0928	not significant
Pure error	336.97	4	84.24	-	-	
Cor. total	2226.05	12	-	-	-	

The results summarised in Table 4.22 concluded that no significant model terms influenced the measured response (%EE).

The plot of internally studentised residuals versus normal % probability is depicted by Figure 4.34. This figure presents a fairly linear trend of all the plotted data points, thus suggesting a normal distribution.

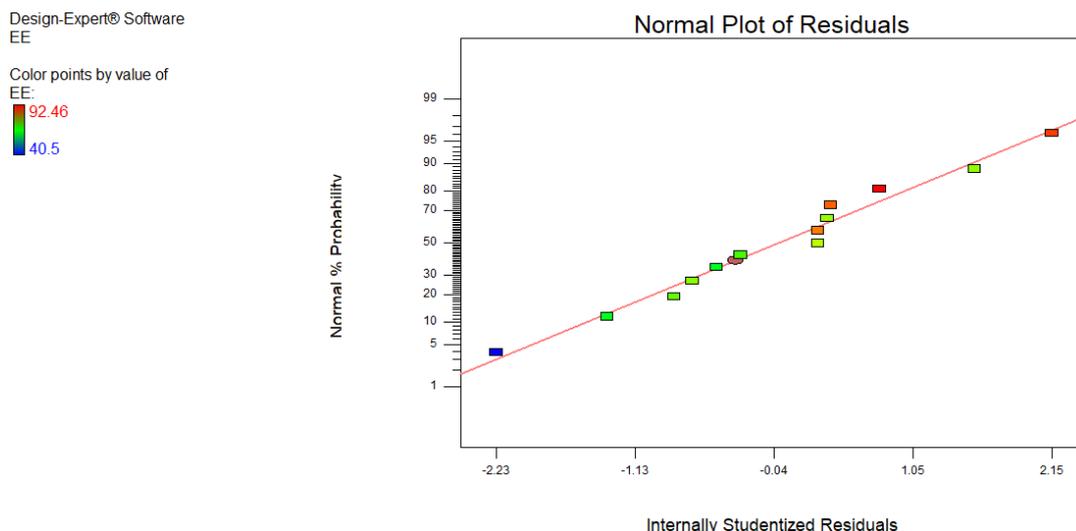

Figure 4.34: Normal probability plot of residuals for entrapment efficiency (%EE) displaying a linear relationship of normal % probability as a function of externally studentised residuals.

The statistical data suggested that no relationship between the input variables on the measured response (%EE) was observed. SLN components that demonstrate the greatest influence on DL and consequently %EE (i.e. lipid type and drug-lipid ratio concentration) were kept constant in all formulations. Generally, changing the drug-lipid ratio allows for the incorporation of more drug into the vesicle until maximal saturation is reached (Emami *et al.*, 2015; Lakshmi *et al.*, 2012). Emami *et al.* (2015) proposed that increasing the amount of lipid concentration can facilitate an improvement of %EE by improving the dissolution of highly lipophilic drugs in vesicles which allows for more space to accommodate the API. Furthermore, Soma and colleagues (2017) noted that lipid concentrations beyond 3% did not facilitate significant increase to %EE. This latter phenomenon was observed in this study, possibly owing to the narrow-working lipid concentration range of 3 to 4% m/v, where no statistically significant changes to %EE were noted.

iii. Analysis of variance (ANOVA) and normal plot of residuals for mean particle size (z-avg.)

Various models were constructed for the ANOVA test of z-avg.; however, none were deemed significant. The use of a quadratic empirical model generated the highest f-values (0.75) but with a high probability that it would occur due to noise. A lack-of-fit value (1.64) with a p-value of 0.3156 favoured a non-significant response, which was

ideal. A summary of the ANOVA test response values for z-avg. are depicted in Table 4.23.

Table 4.23: Analysis of variance (ANOVA) test for response surface quadratic model for mean particle size (z-avg.).

Source	Sum of squares	Degree of freedom	Mean square	f-value	p-value	
Model	508.94	5	101.79	0.75	0.6133	not significant
Lipid conc. (A)	64.46	1	64.46	0.47	0.5138	
Sonication time (B)	43.51	1	43.51	0.32	0.5897	
AB	169.00	1	169.00	1.24	0.3022	
A²	74.41	1	74.41	0.55	0.4840	
B²	128.14	1	128.14	0.94	0.3645	
Residual	953.97	7	136.28	-	-	
Lack-of-fit	525.56	3	175.19	1.64	0.3156	not significant
Pure error	428.41	4	107.10	-	-	
Cor. total	1462.91	12	-	-	-	

The normal plot of residuals for mean particle size (z-avg.) is illustrated by Figure 4.35. A fairly linear trend was observed, with a minor scattering of the points. This suggested a normal distribution of the points of externally studentised residuals versus normal % probability.

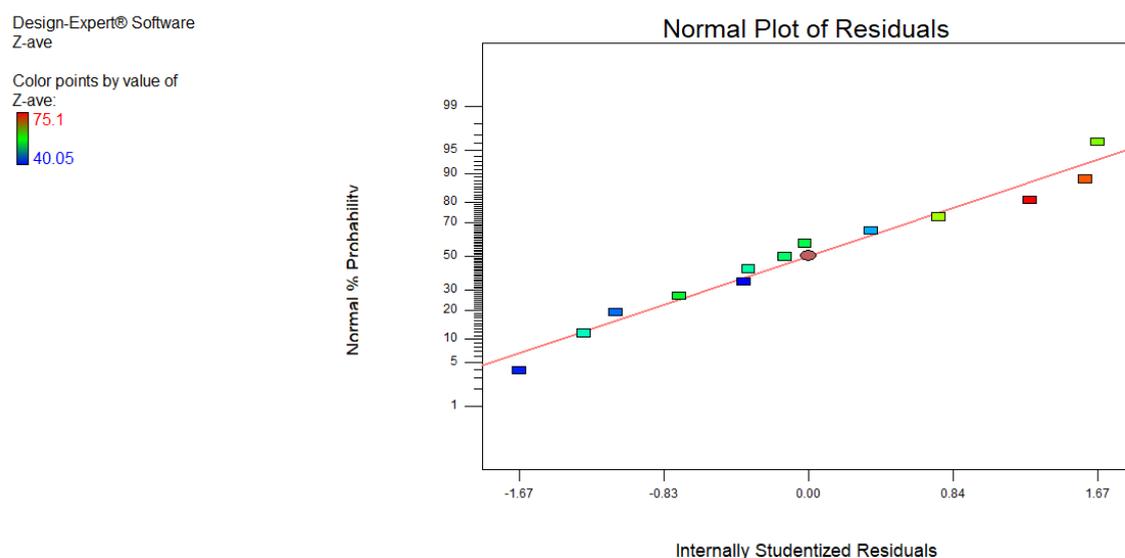

Figure 4.35: Normal probability plot of residuals for mean particle size (z-avg.) displaying a linear relationship of normal % probability as a function of externally studentised residuals.

The statistical data suggest that there was no relationship between the input variables on the measured response (z-avg.) SLN components, which demonstrated an influence on z-avg.; including the likes of surfactant and lipid concentration and method of SLN preparation. The surfactant concentration was kept constant in all formulation and was not expected to have a significant influence on the measured response. Ali and Singh (2018) recommend that an increase in lipid concentration within the formulation has a directly proportional effect on z-avg. This phenomenon was not observed statistically within this study, possibly owing to the narrow-working concentration range used for the statistical investigation.

The effect of sonication time on SLNs z-avg. is complex but can be summarised as an increase in sonication time that results in the reduction of particle size (Gupta *et al.*, 2017). Literature on sonication time effects is conflicting, with some studies suggesting that sonication time increases particle size until a critical point is reached, after which size reduction occurs (Pardhan *et al.*, 2016; Wang *et al.*, 2013). The working range for this study was narrow in order to allow for sufficient observation of this phenomenon. Furthermore, factors such as amplitude, need to be taken into account when sonication effects are investigated. For the purposes of this study, amplitude was kept constant and was, thus, not expected to have a statistically significant effect. This finding was

in agreement with a study conducted by Esmailzadeh-Gharedaghi and colleagues 2017.

iv. Analysis of variance (ANOVA) and normal plot of residuals for change in mean particle size (Δz -avg.)

A modified quadratic model derived from backward elimination regression with an α exit value of 0.100 was used to produce an f-value of 4.72, which indicated a significant model. A p-value of 0.0359 indicated a small probability of 3.59%, where the f-value this vast would occur as a result of noise. A summary of the ANOVA test response values of sonication times with respect to Δz -avg. over a 28-day period at refrigeration temperature is depicted in Table 4.24. The lack-of-fit p-value of 0.14 was favourable, as it indicated that the lack-of-fit was not significant relative to pure error, with a 98.10% probability that this value would occur due to noise.

Table 4.24: Analysis of variance (ANOVA) test for modified quadratic model for change in mean particle size (Δz -avg.).

Source	Sum of squares	Degree of freedom	Mean square	f-value	p-value	
Model	299.6	2	149.98	4.72	0.0359	significant
B-sonication time	136.42	1	136.42	4.30	0.0649	
B²	163.54	1	163.54	5.15	0.0466	
Residual	317.43	10	31.74	-	-	
Lack-of-fit	55.95	6	9.33	0.14	0.9810	not significant
Pure error	261.48	4	63.37	-	-	
Cor. total	617.40	12	-	-	-	

A normal plot of residuals that depicted a fairly linear trend is illustrated in Figure 4.36. Here, nearly all the points within the minimum and maximum range lie close to the depicted line.

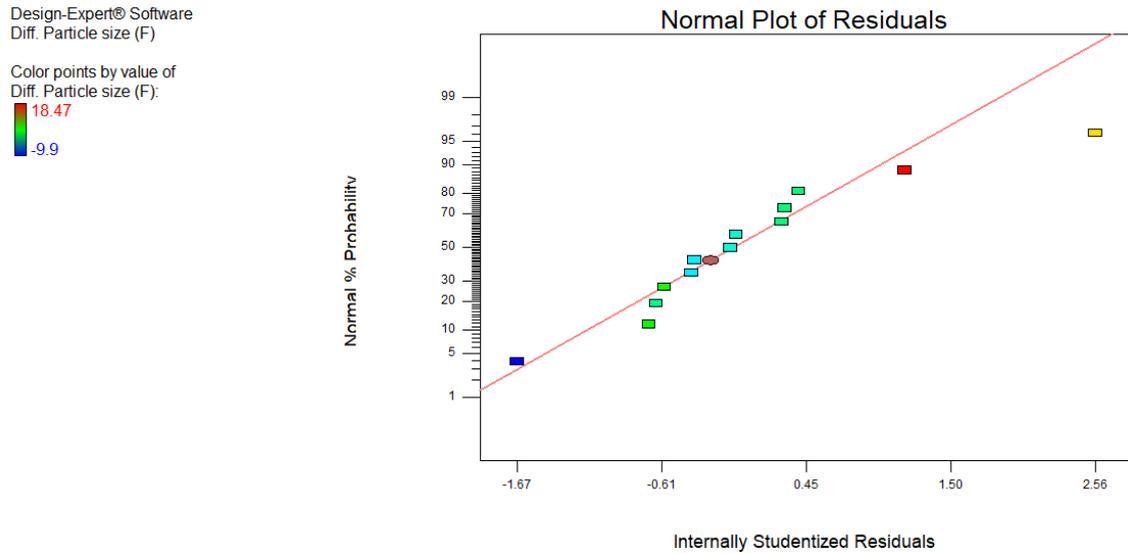

Figure 4.36: Normal probability plot of residuals for change in mean particle size (Δz -avg.) displaying a linear relationship of normal % probability as a function of externally studentised residuals.

Of the two variables that were investigated, sonication time demonstrated a statistically significant effect with respect to change in particle size upon storage. Therefore, by optimising the sonication parameters effectively, minor changes in MNZ-SLNs z -avg. upon storage could be observed.

v. Analysis of variance (ANOVA) and normal plot of residuals for change in % entrapment efficiency ($\Delta \%EE$)

A series of models were constructed for the ANOVA test of the $\Delta \%EE$ of the formulated MNZ-SLNs upon storage ($\pm 4^\circ C$) over a 28-day period. None of the models obtained were deemed significant, and the quadratic model yielded the highest f - and p -values of 0.56 and 0.7259, respectively. Attempts were made to remove insignificant terms with the hope of improving the overall predictor of response. These attempts proved to be unsuccessful.

Table 4.25 summarises the ANOVA test results of lipid concentration and sonication time with respect to the change in SLNs entrapment efficiency upon storage throughout a 28-day period. The lack-of-fit p -value of 0.069 was favourable, which indicated that the lack-of-fit was not significant relative to pure error, with a 97.37% probability that this value would occur due to noise.

Table 4.25: Analysis of variance ANOVA test for response surface quadratic model for change in % entrapment efficiency (Δ %EE.).

Source	Sum of squares	Degree of freedom	Mean square	f-value	p-value	
Model	93.44	5	18.69	0.56	0.7259	not significant
Lipid conc. (A)	0.19	1	0.19	5.83E-003	0.9412	
Sonication time (B)	3.85	1	3.85	0.12	0.7430	
AB	7.24	1	7.24	0.22	0.6542	
A²	29.76	1	29.76	0.90	0.3744	
B²	62.23	1	62.23	1.88	0.2125	
Residual	231.54	7	33.08	-	-	
Lack-of-fit	11.34	3	3.78	0.069	0.9737	not significant
Pure error	220.20	4	55.05	-	-	
Cor. total	324.98	12	-	-	-	

The normal % probability versus internally studentised plot of residuals (illustrated in Figure 4.37) indicated a fairly linear plot for all the distribution points within the minimum and maximum range. This suggested a normal distribution of the generated data.

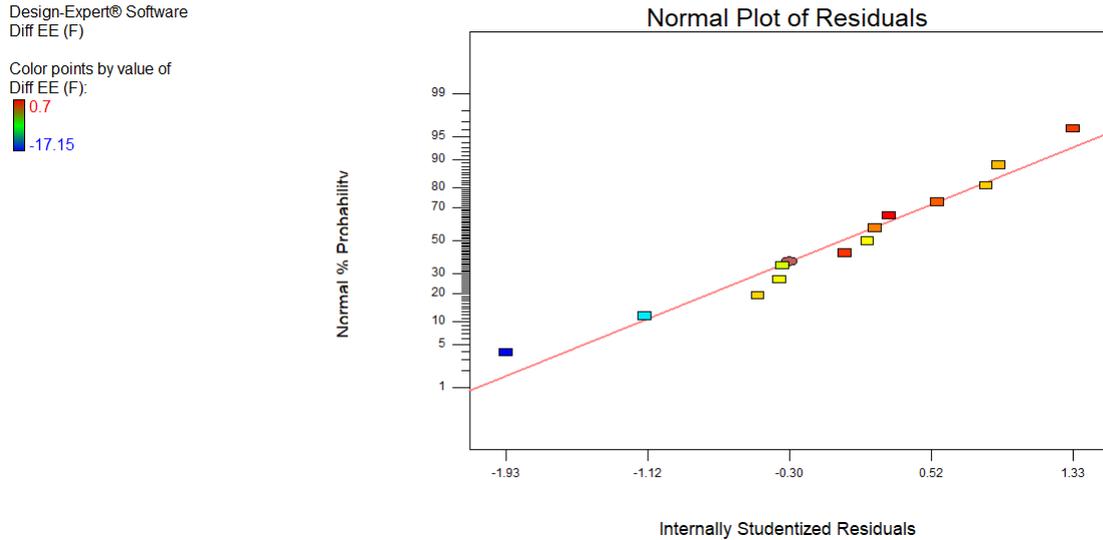

Figure 4.37: Normal probability plot of residuals for change in % entrapment efficiency (Δ %EE) displaying a linear relationship of normal % probability as a function of externally studentised residuals.

The statistical data indicated that there was no relationship between the input variables (i.e. lipid concentration and sonication time) on the measured response (i.e. Δ %EE). Changes in Δ %EE were observed upon storage as a result of configuration changes in the lipid crystalline structure. The period for analysis was kept constant for all formulations tested, but it was not sufficient enough to allow for the observation of statistically significant changes to %EE in the MNZ-SLNs formulations.

vi. Summary of polynomial equations and co-efficient of coded factors

The ultimate empirical model of the coded factors for the responses (Y_1 to Y_5) are depicted by Equations 4.3 to 4.7. The results are based on the analysis of 13 MNZ-SLNs preparations designed in accordance with Table 4.20, stored at $4 \pm 2^\circ\text{C}$ for a period of 28 days.

$$Y_1 = 35.70 + 2.37a - 2.40b + 0.050ab - 0.23a^2 - 0.86b^2$$

Equation 4.3: Empirical model for analysis of variance (ANOVA) test of zeta potential.

$$Y_2 = 82.26 - 0.75a - 4.61b + 3.76ab - 5.34a^2 - 7.68b^2$$

Equation 4.4: Empirical model for analysis of variance (ANOVA) test of % entrapment efficiency (%EE).

Equation 4.7: Empirical model for analysis of variance (ANOVA) test of change in % entrapment efficiency (Δ %EE.).

A summary of the statistics for the evaluated surface response models is presented in Table 4.26.

Table 4.26: Summary statistics for evaluated response surface models (SD = standard deviation, r^2 = regression co-efficient, Adj r^2 = adjusted r^2 , Pred r^2 = predicted r^2 , Adeq prec = adequate precision, C.V% = co-efficient of variation).

Response	SD	f-value	p-value	r^2	Adj r^2	Pred r^2	Adeq. Prec.	C.V%
Y ₁	5.35	0.67	0.66	0.324	-0.159	-1.223	2.620	15.98
Y ₂	14.40	0.75	0.6133	0.348	-0.118	-2.798	2.263	19.40
Y ₃	11.67	0.75	0.6133	0.348	-0.118	-2.012	2.931	21.32
Y ₄	5.63	4.72	0.036	0.485	0.383	0.128	5.71	311.28
Y ₅	5.75	0.56	0.726	0.288	-0.224	-0.307	1.782	140.80

ZP (Y₁): The negative value obtained for the predicted r^2 implied that the overall mean would be a better predictor than the current suggested response model. The signal-to-noise ratio indicated by the adequate r^2 is 2.62, which suggested that the model was not sufficient for the navigation of the design space. By removing insignificant model

terms (i.e. AB, A², B²), a linear model was obtained, which was deemed sufficient for the navigation of the design space.

%EE (Y₂): The use of the mean as a predictor of response was likely suitable, due to the negative value of the predicted r². This model was unlikely to produce sufficient signal (Adeq. Prec. = 2.263), indicating that this model should not be used in the navigation of the design space.

Z-avg. (Y₃): The negative value obtained for the predicted r² implied that the current model was not suitable, and the use of the overall mean would be a better predictor of response. Additionally, a ratio of 2.931 obtained for the adequate precision implied an insufficient signal to allow for the use of this model to navigate the design space.

Δ z-avg. (Y₄): There was a noticeable difference of 0.2553 between the predicted r² value and its adjusted value. This was not ideal, and could possibly be explained by the large block effect or a problematic data or model. Possible remedies for correction could come from the transformation of data, model reduction or the exclusion of outliers. The adequate precision value of >4 suggested the sufficiency of the signal for the navigation of the design space.

Δ %EE (Y₅): A negative value obtained for the predicted r² implied that the overall mean could be used as a predictor of response. However, the model would not be ideal, since an adequate precision value of 1.78 was obtained.

4.5.3.2 Predicted versus actual plots

Scatter plots of the predicted versus actual response values for each of the measured responses are illustrated in Figure 4.38. These plots serve as an aid to detect values that are not easily predicted by the model (Steyerberg *et al.*, 2010). The actual value is the measured response presented for a particular run and the predicted value was generated by using a prediction equation that included block and centre point corrections, as expressed in Equation 4.8.

$$\hat{y} = X\beta$$

Equation 4.8: Response surface methodology (RSM) prediction value equation.

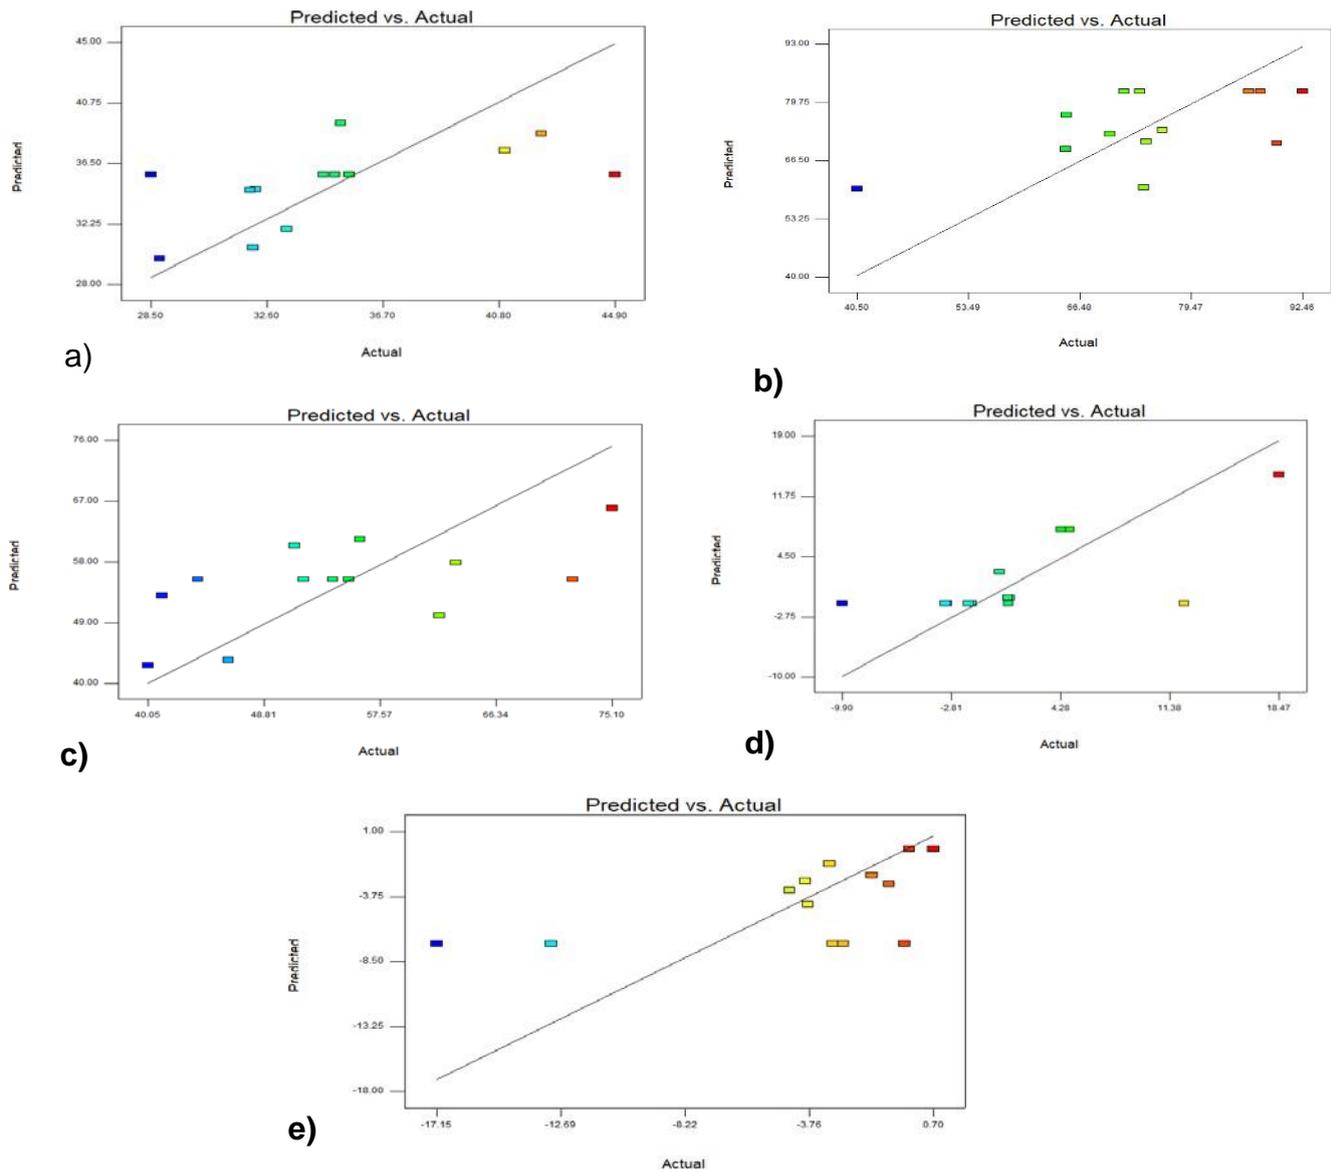

Figure 4.38: Predicted versus actual point prediction plots for (a) zeta potential (ZP) (b) % entrapment efficiency (%EE) (c) mean particle size (z-avg.) (d) change in mean particle size (Δ z-avg.) and (e) change in % entrapment efficiency (Δ %EE).

The distance of a point from an ideal regression line drawn at a 45° angle demonstrates how well or poorly a prediction is performed. Ideally, all the points should lie close to the regressed diagonal line (Field, 2016). A weak correlation between the model prediction and actual results was noted for all the scatter plots in this study. A model possessing a high r^2 value most likely yields points that lie closer to the diagonal line (Steyerberg *et al.*, 2010). Sub-figures a, c and e in Figure 4.38 show a weak correlation, as the points are loosely scattered in specific zones.

4.5.3.3 Residual versus run plots

The residual versus experimental run plots are useful for checking lurking variables that may have affected the response during the experiment. This plot consists of a random scatter (Anderson and Whittcomb, 2003). The trends in this study's plots show a time-related variable lurking in the experiment (see Figure 4.39).

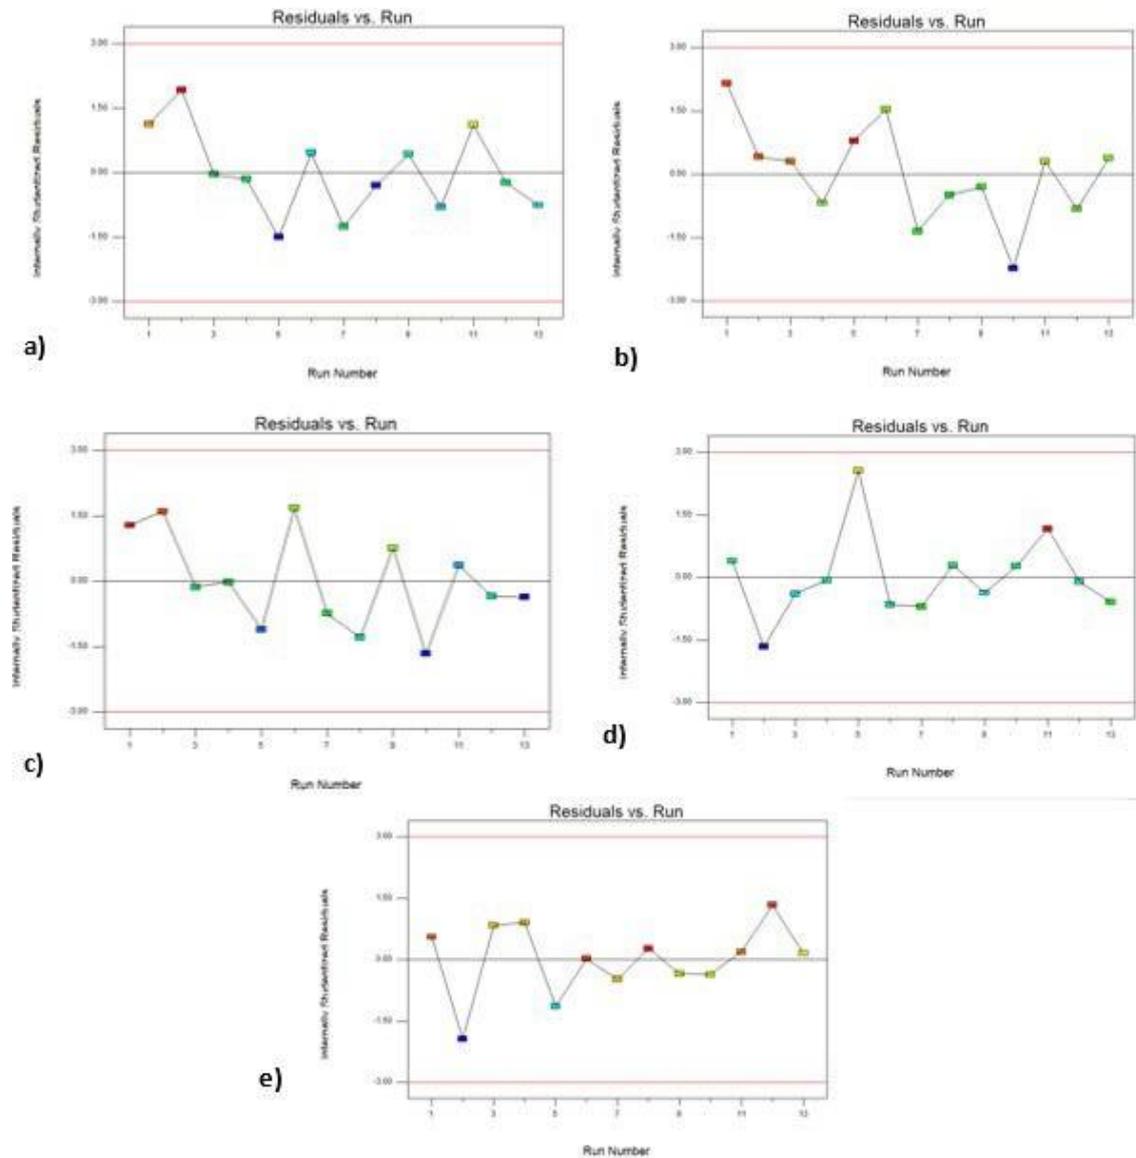

Figure 4.39: Residual versus run plots for (a) zeta potential (ZP) (b) % entrapment efficiency (%EE) (c) mean particle size (z-avg.) (d) change in mean particle size (Δ z-avg.) and (e) change in % entrapment efficiency (Δ %EE).

4.5.3.4 Interaction plots

Interaction plots display average values for the levels of one factor on the x-axis and a separate line for each level of another factor (Anderson and Whittcomb, 2003). Interaction plots are used to demonstrate the relationship between one categorical factor and a continuous response dependent on the value of a second categorical factor. Figure 4.40 illustrates interaction plots for the CCRD used in the optimisation of the prepared MNZ-SLNs.

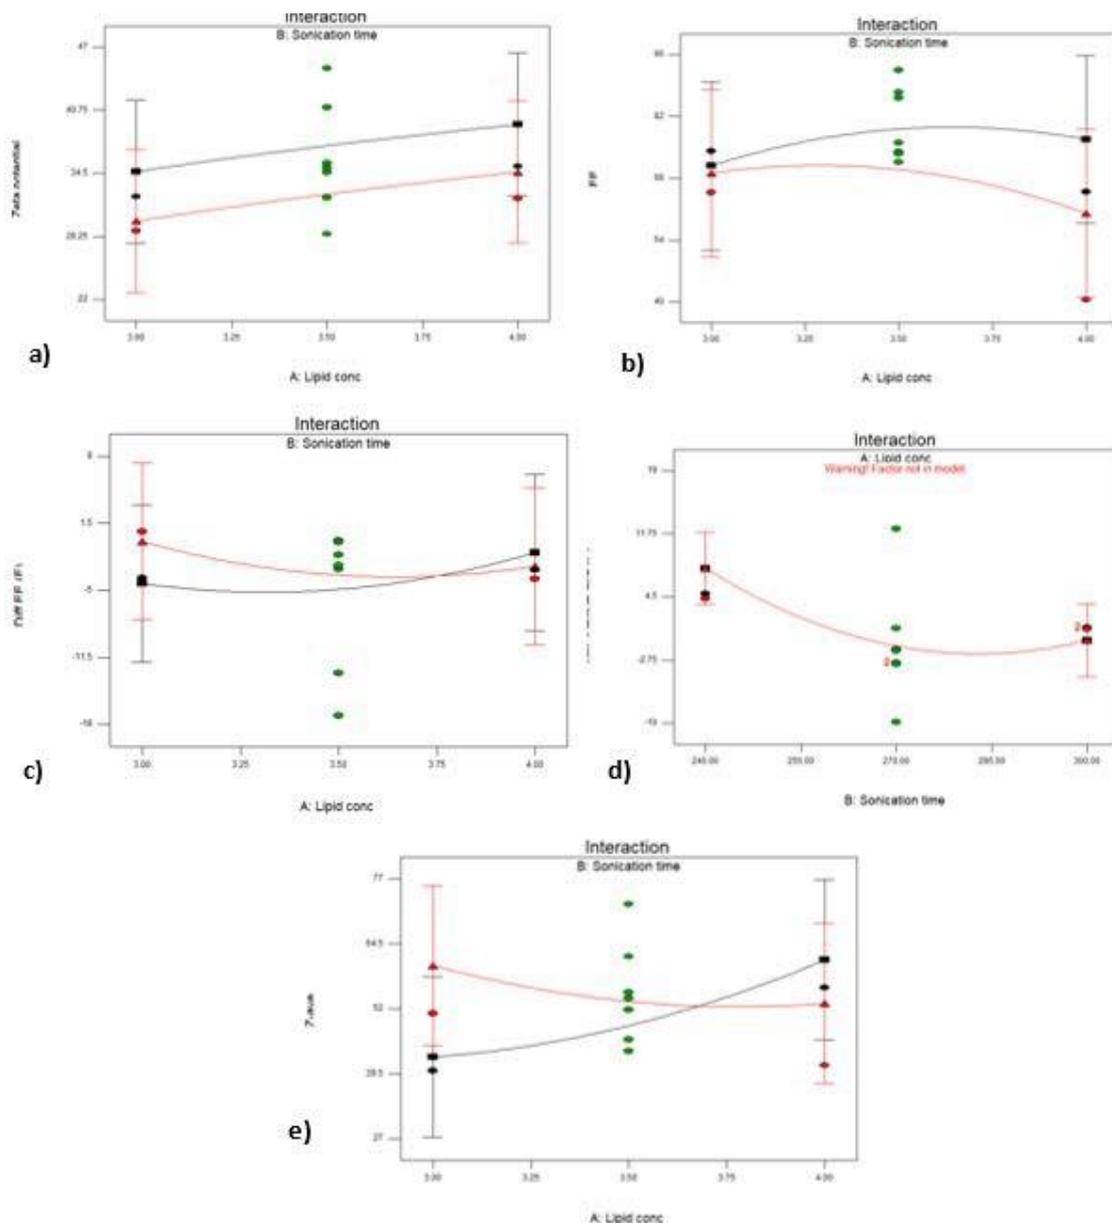

Figure 4.40: Interaction plots for (a) zeta potential (ZP) (b) % entrapment efficiency (%EE) (c) mean particle size (z-avg.) (d) change in mean particle size (Δ z-avg.) (e) change in % entrapment efficiency (Δ %EE).

In order to understand how the interactions affect the relationship between factors and the measured response, the lines of these plots were evaluated. Parallel lines suggest that no interaction occurred, whilst non-parallel lines suggest an interaction between the factors. It was noted that interactions between the input and output variables occurred in all measured responses except for ZP. Although these plots display interactive effects, it was necessary to perform a further evaluation of the statistical significance of these effects. This further evaluation is presented in the following sub-section.

4.5.3.5 Contour and response surface plots

Three dimensional (3D) surface plots were constructed so as to facilitate the understanding of the relationship between the input variables and the measured response(s).

i. Zeta potential (ZP)

Figure 4.41 is a 3D graphical depiction of ZP measurements for 13 experimental runs, as generated by the CCRD. This surface plot was formed by a horizontal axis of lipid concentration (% m/v) and a vertical axis of sonication time (seconds). The lines represent iso-responsive values where no significant interaction in terms of ZP were noted.

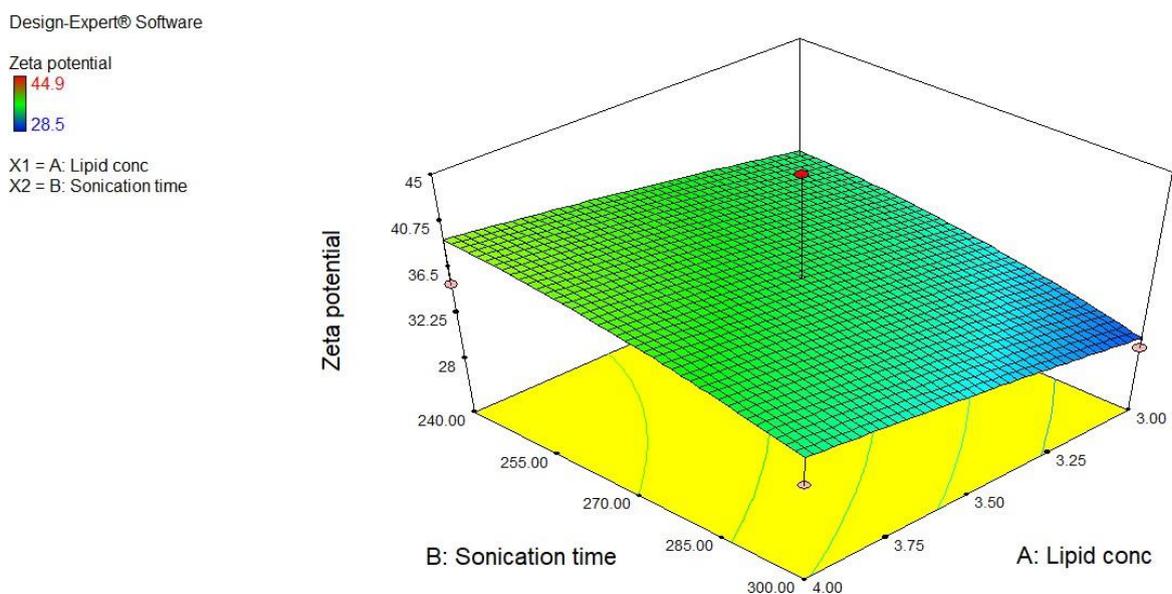

Figure 4.41: 3D response surface plot of lipid concentration (% m/v) and sonication time (seconds) with respect to zeta potential (ZP).

Based on the empirical model quadratic equation, lipid concentration (A) demonstrated a positive effect on ZP, whilst sonication time had a negative effect. This suggests that negative co-efficient values of sonication time result in an indirectly proportional relationship between sonication time and ZP. This effect was, however, not considered to be significant (by the statistical model) for the determination of ZP and, consequently, MNZ-SLNs stability.

ii. % Entrapment efficiency (%EE)

Figure 4.42 provides a 3D graphical depiction of %EE measurements for 13 experimental runs generated by the CCRD. The surface plot was formed by a horizontal axis (lipid concentration % m/v) and a vertical axis (sonication time in seconds). The region of maximal encapsulation was quite large, spanning from 240 to ± 280 seconds in sonication time between 3.5 to 3.8% m/v lipid concentrations.

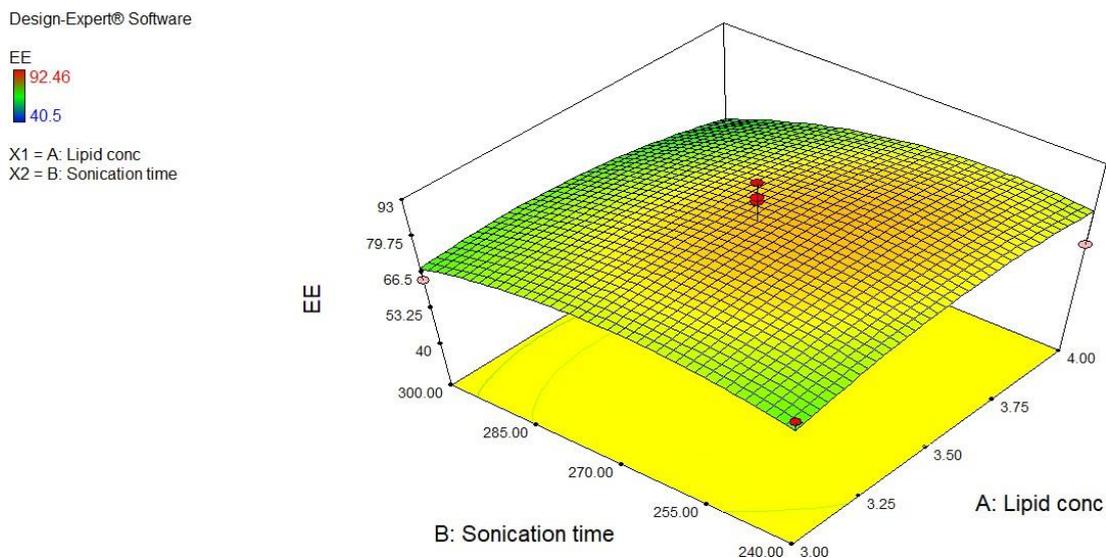

Figure 4.42: 3D response surface plot of lipid concentration (% m/v) and sonication time (seconds) with respect to entrapment efficiency (%EE).

Based on the quadratic model equation for the measured response (%EE), both input variables demonstrated a negative effect on %EE. This suggests that a decrease in lipid concentration and sonication time resulted in increased entrapment of MNZ within the lipid matrix. This effect, however, was not deemed significant by the statistical model.

iii. Mean particle size (z-avg.)

Figure 4.43 offers a 3D graphical depiction of mean particle size (z-avg.) of 13 experimental runs produced by the CCRD. Maximal z-avg. was observed in the region of lower lipid concentration (3% m/v) in the sonication time range of 285 to 300 seconds. Alternatively, maximal particle size was observed with lipid concentrations >3.75 between the sonication time ranges of 240 to 285 seconds.

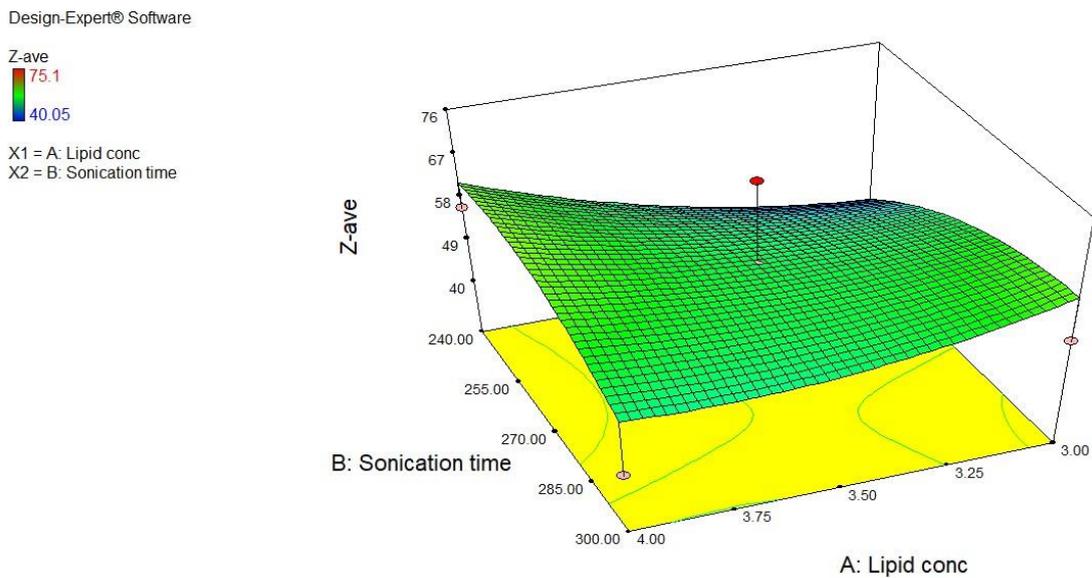

Figure 4.43: 3D response surface plot of lipid concentration (% m/v) and sonication time (seconds) with respect to mean particle size (z-avg.).

Based on the quadratic model equation for the measured response, both input variables demonstrated a positive effect on mean particle size, which suggested that an increase in lipid concentration and sonication time results in increased mean particle size of the developed MNZ-SLNs. This effect, however, was not deemed significant by the statistical model.

iv. Change in particle size (Δ z-avg.)

Figure 4.44 provides a 3D graphical depiction of Δ z-avg. of 13 experimental runs produced by the CCRD. Maximal Δ z-avg. was observed in the regions below 270 seconds of sonication time.

Based on the empirical statistical model for the measured response, lipid concentration did not demonstrate an effect on particle size upon storage. Sonication time does, however, seem to have an inversely proportional relationship with change in particle size, where an increase in sonication time results in statistically significant Δz -avg. upon storage.

Design-Expert® Software

Diff. Particle size (F)

X1 = B: Sonication time

X2 = A: Lipid conc

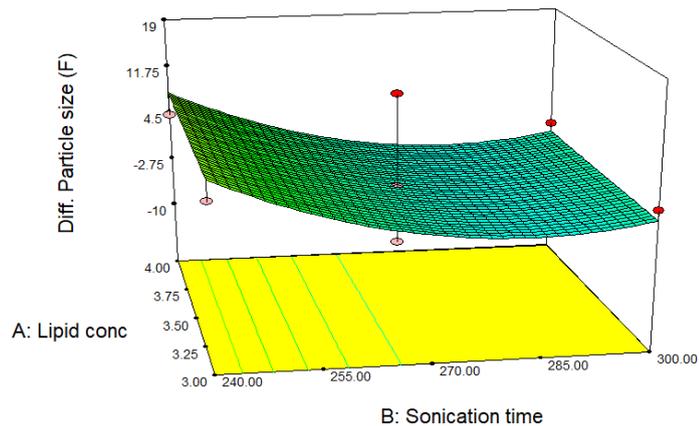

Figure 4.44: 3D response surface plot of lipid concentration (% m/v) and sonication time (seconds) with respect to change in mean particle size (Δz -avg.) upon storage at fridge temperature ($4 \pm 2^\circ\text{C}$).

v. Change in % entrapment efficiency ($\Delta \%EE$)

Figure 4.45 provides a graphical depiction of $\Delta \%EE$ measurements upon storage for 13 experimental runs generated by the CCRD. The surface plot was formed by a horizontal axis (lipid concentration % m/v) and a vertical axis (sonication time in seconds). The region of maximal encapsulation was quite large, spanning from 245 to ± 280 seconds in sonication time between 3.10 to 3.8 % m/v lipid concentrations.

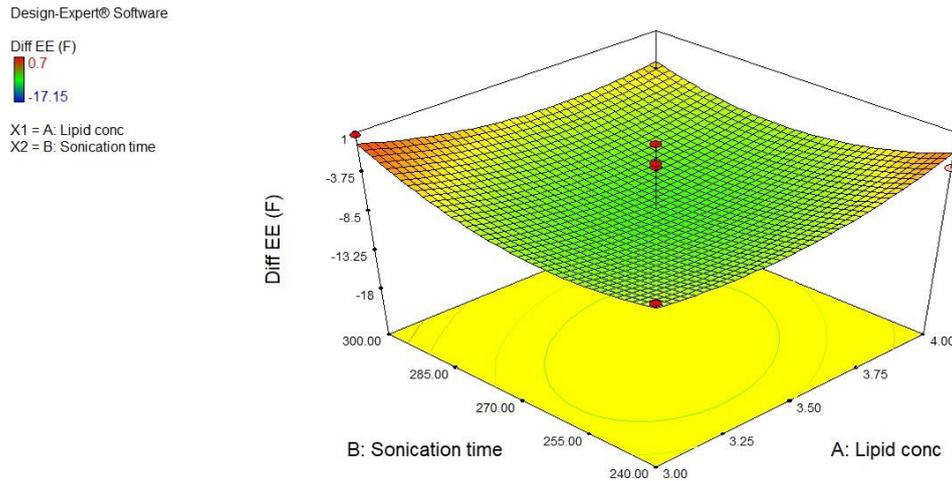

Figure 4.45: 3D response surface plot of lipid concentration (% m/v) and sonication time (seconds) with respect to change in % entrapment efficiency (Δ %EE.) upon storage at fridge temperature ($4 \pm 2^\circ\text{C}$).

Based on the quadratic model equation for the measured response, both input variables demonstrated a positive effect on Δ %EE upon storage, which suggested that an increase in lipid concentration and sonication time results in greater changes to particle size in the prepared MNZ-SLNs upon storage. This effect was, however, not deemed significant by the statistical model.

4.5.3.6 Statistical model validation

Table 4.26 provides a summary of the set goals for each response used to generate optimal conditions. From the data gathered by the CCRD and ANOVA testing, the predicted response optimisation parameters were a maximum lipid concentration of 4% m/v with a sonication time of 260.94 seconds.

Table 4.27: Summary of set goals for each measured response, where lipid con = lipid concentration, sonic. = sonication time, ZP = zeta potential, %EE = % entrapment efficiency, z-avg. = mean particle size, diff size = change in particle size upon storage, diff. %EE = change in entrapment efficiency upon storage.

Name	Goal	Lower limit	Upper limit	Lower weight	Upper weight	Importance
Lipid conc.	In range	3.00	4.00	1	1	3
Sonic.	In range	240.00	300.00	1	1	3
ZP	In range	30.00	44.9.0	1	1	1
%EE	Maximise	40.50	92.46	1	1	4
Z-avg.	In range	40.05	75.10	1	1	1
Diff. size	Target = 0	-9.90	18.47	1	1	3
Diff %EE	Target = 0	-17.50	0.70	1	1	4

Three batches of MNZ-SLNs were prepared under the suggested optimisation parameters and characterised in order to validate the predicted response. The predicted response and mean values of the measured response are shown in Table 4.27. In this table, the confidence interval (CI) is defined as a range of values associated with a population parameter. A prediction interval (PI) is a type of CI used in regression analysis, and is defined by the range of values that predicts the value of a new observation, based on an existing model (Pang *et al.*, 2018).

Table 4.28: Predicted response and mean values of measured response (Response \pm SD = measured response from validation batches \pm standard deviation, Pred. = predicted response, SE mean = mean standard error, CI = confidence intervals, PI = prediction intervals and SE Pred. predicted standard error).

Response	Response \pm SD	Pred.	SE Mean	95% CI low	95% CI High	SE Pred.	95% PI Low	95% PI High
ZP	38.43 \pm 0.86	38.47	2.88	31.66	45.27	6.08	24.09	52.84
%EE	75.24	77.99	7.75	59.68	96.31	16.35	39.33	116.66
Z-avg.	73.03 \pm 0.78	62.36	6.28	47.51	77.20	13.26	31.01	93.70
Diff. size	11.57	0.54	2.01	-3.94	5.01	5.98	-12.79	13.86
Diff %EE	-6.80	-4.51	3.09	-11.82	2.81	6.53	-19.95	10.94

The measured response was compared against the confidence and predicted interval values so as to ascertain the reliability of the model. CI is concerned with the centre of population distribution, whilst PI accounts for the centre as well as the tails of distribution; thus, PI demonstrates greater sensitivity in the assumption of normality (Levin and Robbins, 1981).

The mean values for the ZP, %EE, Z-avg., Δ z-avg. and Δ %EE of the prepared MNZ-SLN formulations were determined as 38.70, 75.24 and 73.03 nm, 11.57 nm and -6.80, respectively, by means of PCS and ultracentrifugation. By employing ANOVA statistical testing, the PI range for the generated model was established between 24.09 and 52.84 for ZP, 39.33 and 116.66 for %EE and 31.10 and 93.70 for z-avg., -2.79 and 13.86 for Δ z-avg and -19.95 and 10.94 Δ %EE (see Table 4.27). Therefore, based on the predicted model, it can be concluded that the measured responses for the validation batches fell within the predicted range of optimised response.

4.6 CHARACTERISATION OF OPTIMISED MNZ LOADED SOLID LIPID NANOPARTICLES (MNZ-SLNS)

Three unloaded and MNZ loaded SLN formulations ($n=3$) were prepared, respectively, under the optimised conditions. Various techniques were then employed for their characterisation. These techniques are discussed in the following sub-sections.

4.6.1 Photon correlation spectroscopy (PCS)

PCS was employed in the determination of z-avg., PDI and ZP characteristics of the prepared formulations.

4.6.1.1 Mean particle size (z-avg.) and polydispersity index (PDI)

Each formulation of (MNZ loaded and unloaded) was analysed in triplicates by means of PCS (Malvern Zetasizer Nano-ZS™, Malvern Instruments™, United Kingdom). Table 4.28 provides an overview of the PCS results for PDI and z-avg. determination.

Table 4.29: Summary of mean particle size (z-avg.) and PDI measurements of optimised unloaded and MNZ loaded solid lipid nanoparticles (MNZ-SLNs) batches.

	Particle size (nm)			PDI		
	Sample 1	Sample 2	Sample 3	Sample 1	Sample 2	Sample 3
Unloaded SLNs	88.54	89.02	87.90	0.264	0.255	0.266
Mean (n=3)	88.49 ± 0.56			0.262 ± 0.005		
2% MNZ-loaded SLNs	72.80	72.40	73.79	0.256	0.253	0.255
Mean (n=3)	73.03 ± 0.78			0.254 ± 0.001		

The results obtained from the PCS analysis of 2% MNZ-SLNs demonstrated a mean population size of 73.03 ± 0.78 nm with a narrow size distribution (PDI = 0.254), thus depicting a homogenous dispersion with good size measurements that fall within the acceptable size range for SLNs. It should be noted that the analysis of unloaded SLNs demonstrated a uniform dispersion within an nm range; however, the measured particle size was slightly bigger than that of the 2% MNZ loaded SLN. Under normal circumstances, the incorporation of drugs within SLNs would cause an increase in particle size (Stella *et al.*, 2018). Therefore, it was expected that the 2% MNZ-loaded SLNs would possess a larger z-avg. value than the unloaded SLNs. This phenomenon was, however, not observed in this study, as the introduction of MNZ

resulted in a subsequent decrease of free lipid content, thereby decreasing the overall z-avg. of the loaded SLNs. These results were in agreement with a study conducted by Shafique and colleagues (2017).

An illustration of the size distribution by intensity for an analysed 2% MNZ loaded SLN formulation is displayed in Figure 4.46. A good correlation between intensity and volume can be noted in this figure by the single distribution peak without additional contaminating peaks. A mean particle hydrodynamic diameter (d.nm) of 73.79 nm was observed, which falls into an acceptable nm range for SLNs.

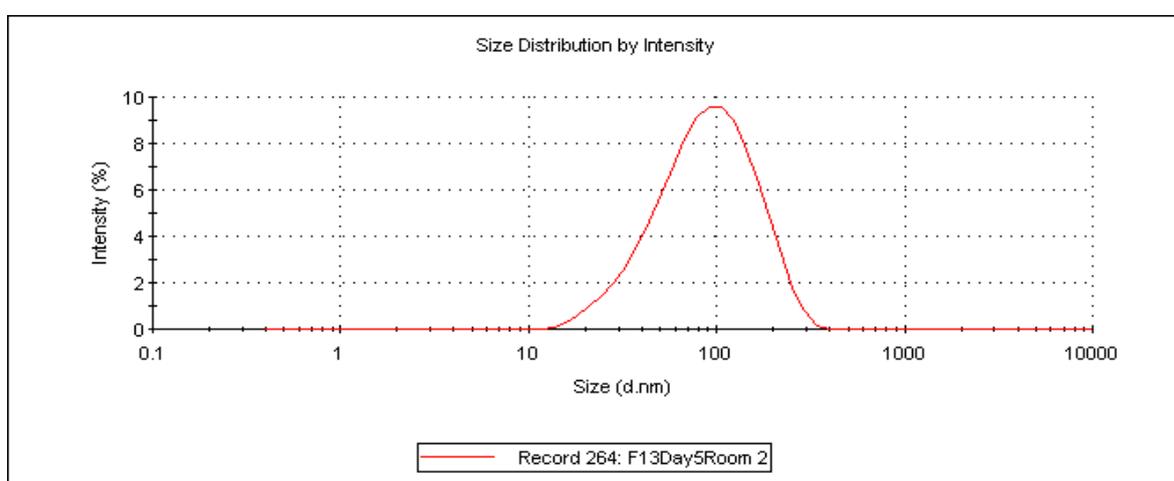

Figure 4.46: Peak of 2% MNZ loaded solid lipid nanoparticle (MNZ-SLN) size distribution by intensity.

4.6.1.2 Zeta potential (ZP)

Each formulation of MNZ loaded and unloaded batches was analysed in triplicates by means of PCS (Malvern Zetasizer Nano-ZS™, Malvern Instruments™, United Kingdom). Table 4.30 provides an overview of the PCS results for ZP determination.

Table 4.30: Summary of zeta potential (ZP) measurements of unloaded and optimised MNZ loaded solid lipid nanoparticles (MNZ-SLNs) batches.

	ZP (mV)			
	Sample 1	Sample 2	Sample 3	Mean ($n=3$)
unloaded SLNs	-16.7	-17.7	-16.7	-17.03 ± 0.58
2% MNZ SLNs	37.5	38.6	39.2	38.43 ± 0.86

The mean ZP values for the unloaded SLNs and 2% MNZ-loaded SLNs were -17.03 and 38.43 mV, respectively. The negative surface charge observed on the unloaded SLNs is possibly owing to the chemical nature of the lipid matrix. Naturally, an electrophoretic mobility of less than ± 30 mV would indicate instability (Mendez *et al.*, 2018); however, the use of non-ionic surfactants, such as polysorbate 80 and poloxamer 188, tend to stabilise the nanomolecules, irrespective of the lowered ZP. Surface coverage with these surfactants also lowers ZP by causing a reduction of its electrophoretic mobility; therefore, these molecules rely more on steric stabilisation and less electrostatic stabilisation (Shah *et al.*, 2014).

It should be noted that, in this study, the loading of MNZ into the SLN resulted in a significant increase of ZP. This is possibly due to the presence of cationic nitrogen atoms in the structure of the MNZ moiety, where this charge dominated over the lipids and neutral charge of the surfactants. This finding suggests that the drug molecule coats the surface of the loaded SLN, thus contributing to the reversal of surface charge. This finding was similar to a study by Qushawy *et al.*, 2018 and Shah *et al.*, 2016. The magnitude of the mean measured electrophoretic mobility (38.43 ± 0.86 mV) is sufficient for the prevention of particle agglomerates, thus facilitating adequate stability (Mendez *et al.*, 2018). The ZP value fell within the statistically approximated 95% CI value of 38.47 mV and, again, validated the statistical model.

4.6.2 Transmission electron microscopy (TEM)

The microstructure analysis of statistically optimised MNZ-SLNs was undertaken by TEM. The macroscopic appearance of the MNZ-SLN preparation resembled a milky solution immediately after production and upon storage. TEM analysis was then

employed for microscopic visualisation of the preparation. The findings are represented in Figure 4.47.

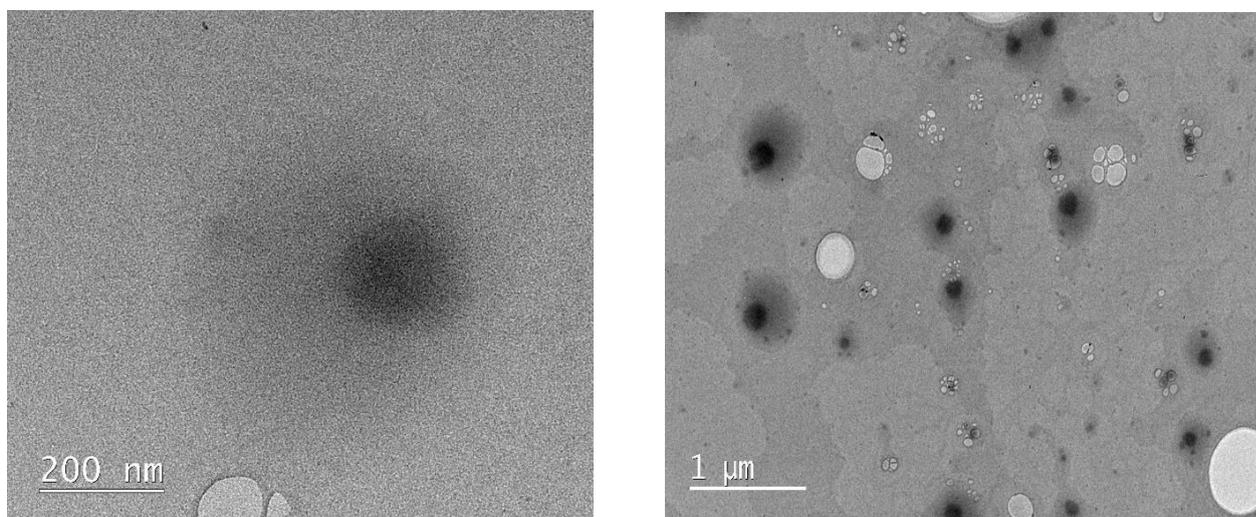

Figure 4.47: Transmission electron microscope (TEM) image of optimised MNZ loaded solid lipid nanoparticles (MNZ-SLNs) preparation.

The size measurements agreed with the data obtained from the PCS analysis of 2% MNZ loaded SLNs. The minor difference between the two measurements may be attributed to the effect of particle dehydration and poor storage conditions prior to analysis resulting in its expansion. Roughly spherical particles were observed and particle size in the nm range (i.e. 10-1000 nm). The periphery of the particles was well-defined, but no clear internal visualisation was possible, which demonstrated the susceptibility of the lipid to the electronic beam. The surface appeared smooth, with no obvious protrusions. No agglomeration of particles was noted, which suggested that the colloidal system was well dispersed. Moreover, TEM analysis served as a size validation tool for the statistically optimised MNZ-SLN preparation, where it fell within the 95% PI range of 31.09 to 93.70 nm.

4.6.3 Calculating % drug entrapment efficiency (%EE)

The %EE of the optimised MNZ-SLN formulation was determined through an indirect method. The dispersion was first centrifuged, after which the quantity of free drug in the supernatant was determined by means of RP-HPLC (see conditions in Section 4.2.4). These results were employed in the calculation of %EE with the aid of Equation 3.15. A summary of the results is provided in Table 4.31

Table 4.31: Summary of calculated % entrapment efficiency (%EE) for optimised 2% MNZ loaded solid lipid nanoparticles (MNZ-SLNs) batches.

Sample	Assayed mass (MNZ-SLN preparation)	Assayed mass (supernatant)	% Entrapment efficiency \pm RSD
1	0.27 mg	0.06 mg	76.14
2	0.25 mg	0.07 mg	73.65
3	0.25 mg	0.06 mg	74.32
Mean (n=3)	0.26 \pm 3.67	0.06 \pm 7.44	74.70 \pm 1.42

The amount of drug incorporated in a colloidal system is dependent on the physicochemical properties of the drug and its preparation process. The mean %EE for the optimised MNZ-SLNs was relatively high. The overall %EE was reflective of the high solubility of MNZ in the melted lipid. The lipid:drug weight ratio of 2:3 cholesterol to MNZ contributed to an increased DL which, in turn, related to good entrapment of the drug within the lipid. The higher lipid content also provided more space for drug accommodation. Furthermore, the drug:lipid ratio demonstrated an increase in viscosity of the lipid phase, which caused faster solidification of the nano-dispersion and, consequently, entrapping more drug. This phenomenon was in line with previous research that established how solidification prevents the diffusion of drugs to the external aqueous medium and results in the higher entrapment of APIs (Joseprakash *et al.*, 2011; Nandini *et al.*, 2015). The calculated mean %EE fell near the 95% CI of 77.99%, thus validating the statistical model.

4.6.4 Accelerated stability studies

Storage stability tests were conducted to establish a shelf-life profile and label storage instructions applicable to all future batches and batches manufactured under similar conditions. The stability of the prepared MNZ-SLNs was investigated under accelerated storage conditions, as advised by the WHO (2009). Three samples ($n=3$) were kept at ambient temperature and their organoleptic properties, z-avg. and %EE were assessed at predetermined intervals, as was presented in Table 4.32.

ZP is a function of surface coverage by charged species at a specific pH. It is used as an indicator for dispersion stability (Shah *et al.*, 2014). It should be noted, however, that ZP values were not included for the purposes of this study because characterisation assessments by means of PCS revealed sufficient particle stability. Table 4.32 below depicts a summary of MNZ-SLNs characteristics under the accelerated storage conditions.

Table 4.32: Overview of optimised 2% MNZ-solid lipid nanoparticles (MNZ-SLNs) characteristics under accelerated stability storage conditions for WHO zone IVb.

Product name: Optimised 2% MNZ loaded solid lipid nanodispersion.	Packaging material: 10 ml McCartney glass jars			
Batch size: 10 ml	Storage conditions: 40 ± 2 °C/ 75 ± 5 % RH			
Date of manufacture: 14 May 2017	Manufacturer of API: Acros Organics, ThermoFischer Scientific™, Massachusetts, USA.			
Date of commencement of stability study	14 May 2017			
Specification Limits	Mean particles size <1000 nm			
Time intervals (months)	Sample 1: Z-avg. %EE	Sample 2: Z-avg. %EE	Sample 3: Z-avg. %EE	Mean (<i>n</i> =3) Z-avg. %EE
0	72.80 nm 74.32	72.45 nm 73.65	73.79 nm 76.14	73.01 ± 0.77 nm 74.70 ± 1.41
1	83.81 nm 69.87	83.61 nm 68.51	83.52 nm 70.24	83.65 ± 1.57 nm 69.54 ± 1.07
3	82.65 nm 68.59	83.92 nm 69.02	85.58 nm 70.36	84.13 ± 1.43 nm 69.32 ± 1.09
6	95.21 nm 64.47	94.86 nm 65.41	95.63 nm 65.98	95.23 ± 0.33 nm 65.29 ± 0.95
% Total drug loss	13.25	11.19	13.45	12.63 ± 8.09

The relation between the two measured responses against time are illustrated in Figure 4.48. In this figure, it is evident that as time progressed, the z-avg. (depicted in blue) gradually increased. Simultaneously, the %EE (depicted in orange) gradually decreased upon storage.

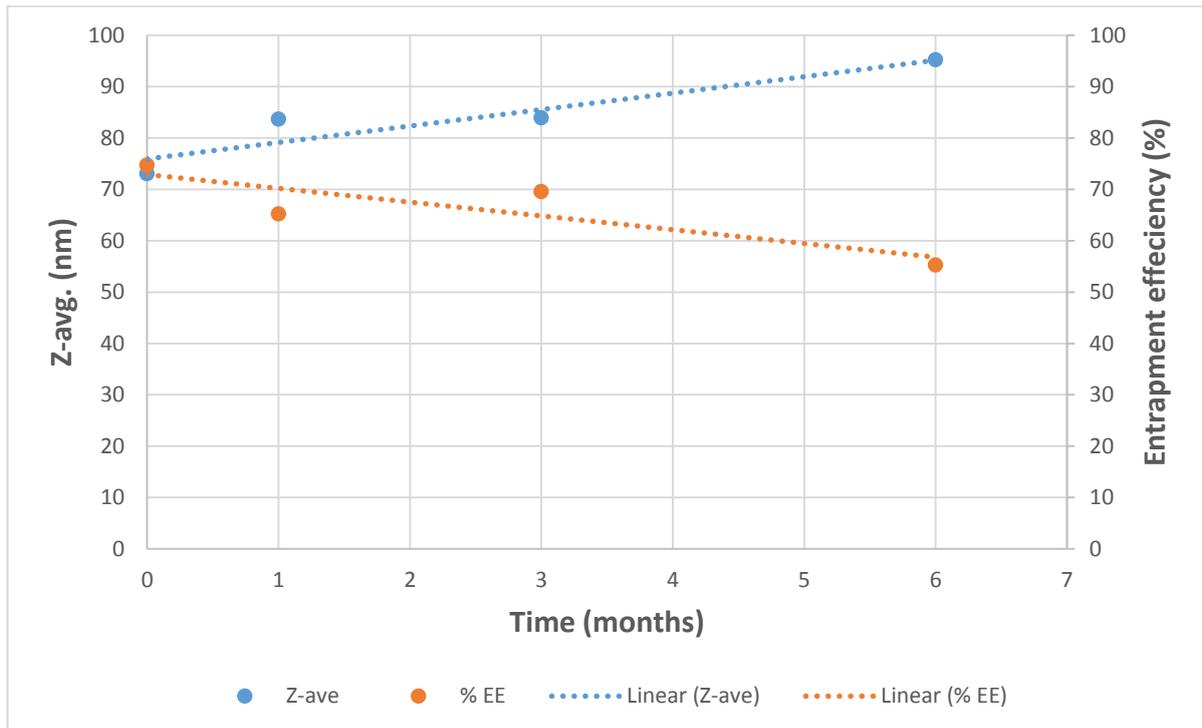

Figure 4.48: Change in particle size (z-avg.) and entrapment efficiency (%EE) under WHO Zone IVb accelerated stability test conditions.

No obvious visual changes to the dispersions were noted over the predefined storage period. However, significant changes to z-avg. were noted upon storage, which were accompanied with a decrease in %EE of the nanoparticles. This phenomenon may be accounted for due to the use of heat in the preparation steps of the nanoparticles. The use of heat during the formulation process causes particle crystallisation in higher energy modifications (α), but upon storage, these modifications are transformed to low-energy and more ordered (β) crystal lattice structure. As a result, this degree of order conferred on the stored nanoparticle can lead to the expulsion of drugs, as less space is available for drug accommodation (Das and Chaudhury, 2010).

These findings imply that, under the accelerated stability conditions, the transition of the optimised SLN dispersions from a high-energy α or β' form to a more stable β form occurred at a slightly rapid rate, which resulted in a mean drug loss of 12.63% over a period of six months under the WHO-accelerated stability storage conditions. A significant change at accelerated storage conditions is defined as 5% loss of potency from the initial assay, degradation exceeding the specification limit, exceeded pH limits and a failure to meet specifications for organoleptic properties (WHO, 2009). Where a significant change is noted under these storage conditions, a minimum of six month's data should be included from an ongoing one-year study at $30 \pm 2^\circ\text{C}/65\% \pm 5\% \text{RH}$ where the same significance criteria is applied (Hela, 2012). Due to time constraints in this study, such practices were not feasible and, therefore, are discussed in the recommendations section of the next chapter.

Additionally, there are many factors that influence the stability of a pharmaceutical product. A loss in %EE from the SLNs does not necessarily equate to the loss of potency from the product. The API may still be stable in the continuous phase of the lipid dispersion (Harde *et al.*, 2014), and further investigation tests by means of an X-Ray powder diffraction are recommended to determine lipid crystalline phase structures and, consequently, lipid vesicle stability. Moreover, storage conditions need to be taken into account, as the current recommended conditions were not suitable for this novel dosage form. There are also many formulations that require refrigerated conditions due to stability issues; therefore, it is recommended that all prepared MNZ-SLN formulations be stored in a fridge.

4.7 DEVELOPMENT AND CHARACTERISATION OF IN SITU VAGINAL HYDROGELS

Hydrogel formulations of various compositions were prepared and characterised for their organoleptic properties, pH and sol-gel transitioning abilities. The formulation which displayed the most favourable characteristics underwent incorporation with an optimised 2% MNZ-SLN preparation.

4.7.1 Preparation of unloaded hydrogels

The CM of gel production was employed for the preparation of seven hydrogel formulations of various compositions (see Table 3.11). All prepared formulations were transparent and free-flowing at ambient temperature upon production.

The physical appearance of all formulations was aesthetically pleasing, which suggested adequate dissolution of the polymer in the aqueous solvent with no suspending particles.

4.7.2 Determination of optimal hydrogel formulation

Sensory, pH and rheological tests were employed in the determination of the optimal hydrogel formulation that would undergo incorporation with the prepared MNZ-SLNs formulation. These tests are discussed in more detail in the following sub-sections.

4.7.2.1 Organoleptic assessments

Descriptive sensory tests were undertaken to define the organoleptic characteristics of the prepared unloaded hydrogel formulations. The knowledge of product preferences ensured product acceptability. Organoleptic property assessments are critical for determining sensory characteristics of a product, with the aim of improving patient compliance by facilitating dosage form acceptability (Morrow *et al.*, 2014; Joglekar *et al.*, 2008). Formulations FG1 to FG7 were assessed for their physical appearance, colour, homogeneity, texture, skin feel and odour. The results obtained are summarised in Table 4.33.

Table 4.33: Summary of organoleptic evaluations of prepared unloaded hydrogel formulations (FG1 to FG7).

Code	Physical appearance	Colour	Texture	Skin feel	Homogeneity	Odour
FG1	Slightly transparent	Off-yellow	Smooth	Cool, refreshing, moisturising, non-greasy	No phase separation, no particles observed, homogenous	Strong characteristic chemical odour
FG2	Slightly transparent	Off-yellow	Smooth	Cool, refreshing, moisturising, non-greasy	Cool, refreshing, moisturising	Mild characteristic chemical smell
FG3	Slightly transparent	Off-yellow	Smooth	Cool, refreshing, non-greasy	Single phase, homogenous	Mild characteristic chemical odour
FG4	Transparent	Colourless	Smooth	Cool, light, non-greasy	Single homogenous phase	Odourless
FG5	Slightly transparent	Off-yellow	Smooth	Cool, light, non-greasy	Single homogenous phase	Mild characteristic chemical odour
FG6	Slightly transparent	Off-yellow	Smooth	Cool, non-greasy, refreshing	Single homogenous phase	Characteristic chemical odour
FG7	Transparent	Clear	Smooth	Non-greasy, light, refreshing	Single homogenous phase	Odourless

The findings demonstrate that all formulations displayed cosmetically appealing appearances and a smooth texture, with acceptable homogeneity and no signs of phase separation. Chitosan-containing formulations (FG1, FG2, FG3, FG5 and FG6) had a characteristic chemical odour, which is possibly attributed to the fact that the natural polymer is derived from the marine environment (Muxika *et al.*, 2017). Furthermore, minor concentrations of glacial acetic acid were utilised in the preparation of all chitosan-containing formulations, thus giving them a mild characteristic vinegar smell.

FG4 and FG7 were formulated in the absence of acetic acid and chitosan and were found to possess no characteristic odour or colour. These results are more favourable because many women have indicated their preference towards odourless and colourless products intended for intravaginal use (Plameira-de-Oliveira *et al.*, 2014; Li *et al.*, 2013; Vermani and Garg, 2000).

4.7.2.2 pH measurements

pH is a measure of the acidic or basic nature of a solution. This value can impact the flavour, consistency and stability of a dosage form (Bajaj, 2012). The pH measurements for Day 0 and 84 of the formulated unloaded hydrogel preparations are summarised in Table 4.34.

Table 4.34: Summary of pH measurements of prepared unloaded hydrogel formulations (FG1 to FG7).

	Day 0				Day 84			
	Sample 1	Sample 2	Sample 3	Mean (n=3)	Sample 1	Sample 2	Sample 3	Mean (n=3)
FG1	4.51	4.51	4.52	4.51 ± 0.01	4.50	4.50	4.51	4.50 ± 0.01
FG2	4.65	4.65	4.65	4.65 ± 0.00	4.62	4.63	4.63	4.63 ± 0.01
FG3	4.51	4.53	4.53	4.52 ± 0.01	4.51	4.52	4.52	4.52 ± 0.01
FG4	6.80	6.81	6.82	6.81 ± 0.01	6.81	6.83	6.83	6.82 ± 0.01
FG5	4.51	4.51	4.50	4.51 ± 0.01	4.51	4.52	4.51	4.52 ± 0.01
FG6	4.51	4.51	4.53	4.52 ± 0.01	4.51	4.52	4.52	4.52 ± 0.01
FG7	6.80	6.80	6.81	6.80 ± 0.01	6.81	6.81	6.81	6.81 ± 0.00

Low pH values were noted in all chitosan-containing formulations. This is attributed to the use of small concentrations of glacial acetic acid in the preparation process. The remaining formulations were close-to-neutral in pH. The pH values of hydrogel

formulations containing poloxamer 188 and HPMC, only, were more basic, with an average pH range of 6.82 ± 0.01 . Due to the logarithmic nature of the pH scale, even the slightest changes have a significant impact on a formulation (Munhoven, 2013). However, in this study, over a period of 12 weeks, no significant changes in pH for all formulations were noted.

The natural pH of the vaginal environment is in the acidic range (4.5). This low pH acts as a defence mechanism and facilitates a healthy vaginal microflora (Keshwani *et al.*, 2014; Ashok *et al.*, 2014). In order to maintain this environment, the WHO (2012) recommends the use of vaginal lubricating products in a pH of ± 4.5 and osmolality of less than 1200mOsm/kg (Edwards and Panay, 2016).

Furthermore, site-specific drug delivery can be maintained through the creation of an acidic formulation. In such cases, the majority of drug candidates are either weak acids or bases, thereby inferring that drugs can be ionised to a certain extent, depending on their pKa and the pH of the vaginal fluid (Rohan and Sassi, 2009).

The unionised form of a drug with a large pKa is better absorbed from the vagina than its ionised form. Therefore, a slightly acidic vaginal environment favours better pharmacokinetics of acidic formulations, where the $\text{pH} < \text{pKa}$ of the drug (Kale and Ubgade, 2013). In addition, the likelihood of certain infections (i.e. bacterial vaginosis, in particular) increases with an increase in vaginal pH. Therefore, it is advantageous to use products that maintain the vaginal pH within its physiological range (Haya *et al.*, 2014). Lowered pH (<3) increases the severity of vagina mucosa irritation, whilst higher pH values (>5) compromise the mucosa's natural barrier function, making it feel dry and vulnerable to irritation and infections (Kaminsky and Willigan, 1982). Formulations (i.e. chitosan-based hydrogels) that demonstrated a pH measurement of less than 5 were, therefore, considered ideal for the purposes of this study.

Due to their unfavourable organoleptic characteristics, further manipulation of FG1 and FG8 was also considered. The use of a PBS ($\text{pH } 4.5 \pm 2$) to dissolve the respective mucoadhesive polymer was employed as the aqueous phase during the preparation process to reduce the overall pH of the formulation.

4.7.2.3 Viscosity measurements

Viscosity studies of all formulations were conducted to aid with the prediction of their *in situ* gelling behaviour. Flow characteristics of vaginal formulations not only affect their 'spreadability', but also their residence time at the site of application (Almomen *et al.*, 2015). Figure 4.50 depicts a relationship of shear stress versus shear rate for the formulation of FG1 to FG7, with a commercially available vaginal cream as a control.

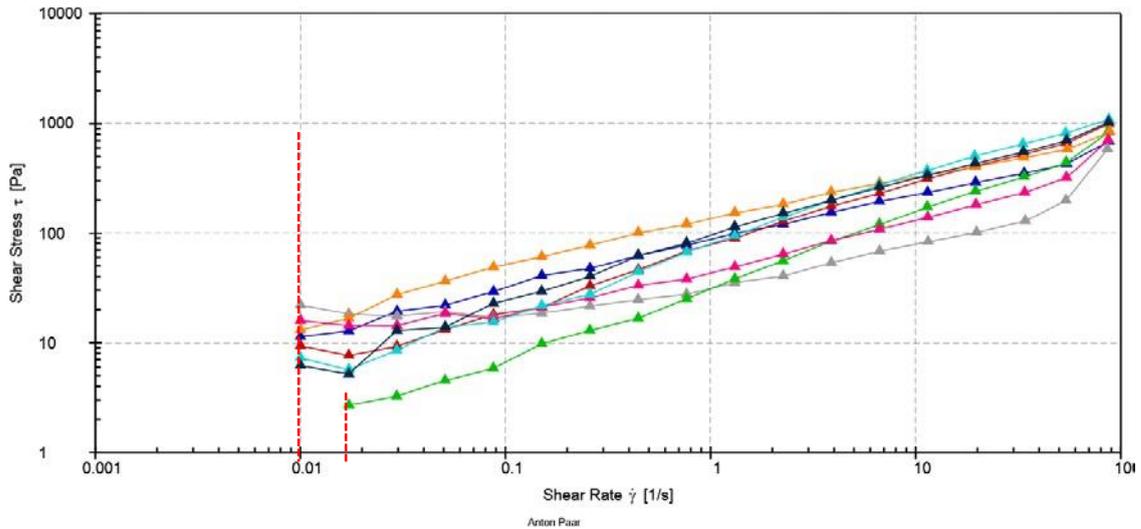

Figure 4.49: Shear stress (Pa) versus shear rate (1/s) of prepared unloaded hydrogels and a commercial vaginal cream, where ▲=FG1, ▲=FG2, ▲=FG3, ▲=FG4, ▲=FG5, ▲=FG6, ▲=FG7, ▲=control, --- =yield stress at $37 \pm 2^\circ\text{C}$.

A non-Newtonian fluid's flow curve is non-linear and does not cross through the origin. Moreover, its viscosity does not remain constant at a given temperature but is dependent on conditions like shear rate and flow geometry (Chhabra, 2010). Based on this definition, all the tested formulations in this study can be deemed non-Newtonian fluids. The point at which the formulations began to flow was indicated by the yield stress. FG4 possessed a slightly higher yield stress than the other formulations, which suggested that higher shear rates were required to induce flow of the hydrogel.

The flow behaviour of the prepared hydrogels and control were assessed by monitoring the variation of viscosity with respect to the change in their shear rates. A summary of these observations is given in Figure 4.51.

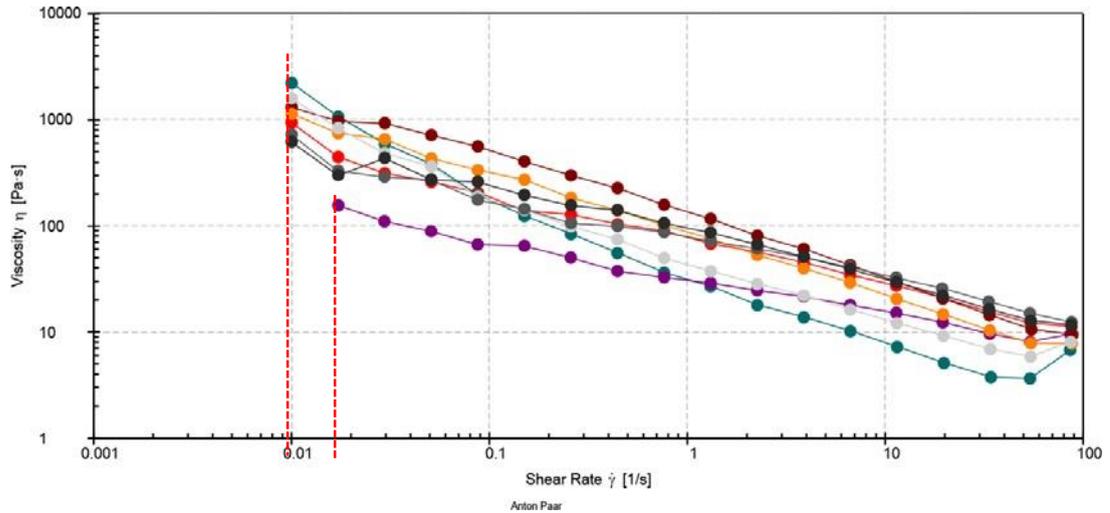

Figure 4.50: Viscosity (Pa·s) versus shear rate (1/s) of prepared unloaded hydrogels and a commercial vaginal cream, where \bullet =FG1, \bullet =FG2, \bullet =FG 3, \bullet =FG4, \bullet =FG5, \bullet =FG6, \bullet =FG7, \bullet =control, $---$ =yield stress at $37 \pm 2^\circ\text{C}$.

All formulations demonstrated shear thinning behaviour, where a decrease in viscosity was observed when the shear rate increased. In addition, all formulations only began flowing at shear rates $\geq 0.01 \text{ s}^{-1}$, which suggested that, at body temperature, the formulations displayed Bingham pseudoplastic flow characteristics. Bingham flow principles state that a critical level of stress (yield stress) is required to induce the flow of some liquids (Bjorn *et al.*, 2012). Therefore, below 0.01 s^{-1} , all formulations behaved as solids, absorbing the stress energy without flowing. After the critical stress point was reached, the formulations demonstrated non-Newtonian pseudoplastic flow.

It should be noted that the critical stress level for FG4 was slightly higher (>0.01) when compared to the other formulations. This suggests that more energy was required to induce its flow. Ideally, an operator should strive to compare dosage formulations of similar physiochemical properties. However, at the time of the study there were no MNZ-containing gels on the South African market, which necessitated the use of a cream for the control. The control demonstrated similar rheological properties to the rest of the formulations.

The low yield stress values for the preparation inferred easy pourability of the dosage form. This was deemed advantageous for facilitating easy extrusion from the packaging and spreading within the vaginal tract (Andrews *et al.*, 2009). Together with

its mucoadhesive properties, the hydrogel preparations maintained intimate contact at the site of application.

Additional assessment of the temperature-dependent characteristics of the formulations was investigated in this study in order to define the thermo-responsive nature of the formulations. Figure 4.52 illustrates a graph of temperature-dependent viscosity for the investigated formulations. A formulation was deemed thermoresponsive if it demonstrated an increase in viscosity over a temperature of interest (25 to 38 °C).

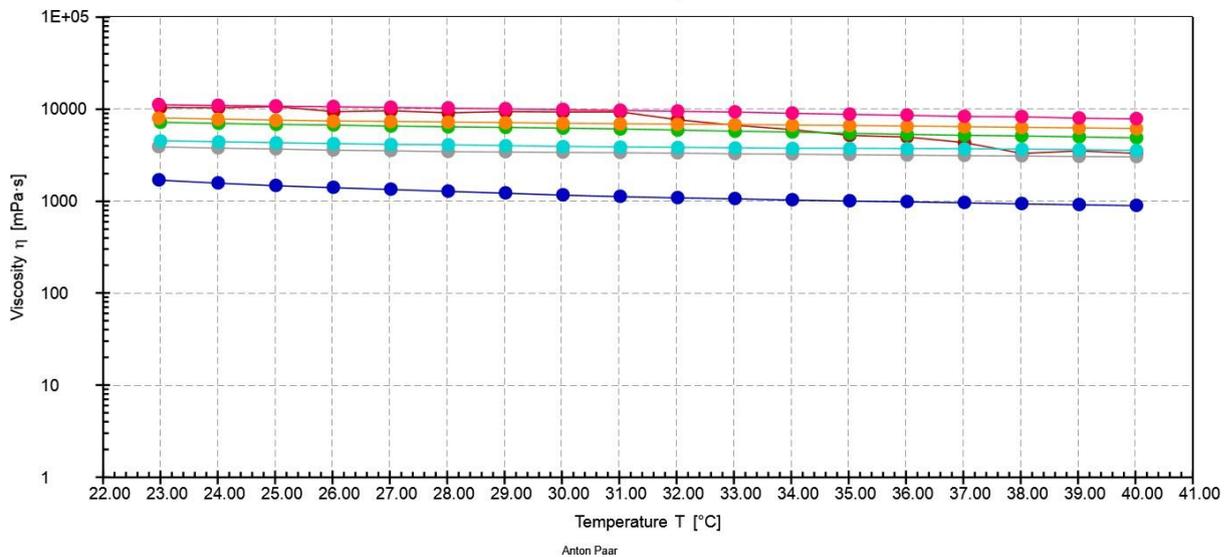

Figure 4.51: Graph of viscosity (mPa·s) as a function of temperature (°C) for prepared unloaded hydrogels and a commercial vaginal cream, where ●=FG1, ●=FG2, ●=FG 3, ●=FG4, ●=FG5, ●=FG6, ●=FG7, ●=control.

Nearly all formulations displayed similar temperature-dependent viscosity behaviour. At a constant shear rate, most formulations displayed uniform viscosity irrespective of a gradual increase in temperature. These findings impacted the study negatively by demonstrating that the prepared formulations were not thermo-responsive. No significant viscosity changes were observed for most formulations, with the exception of FG4. The temperature-dependent viscosity of the various formulations is presented in Figure 4.53.

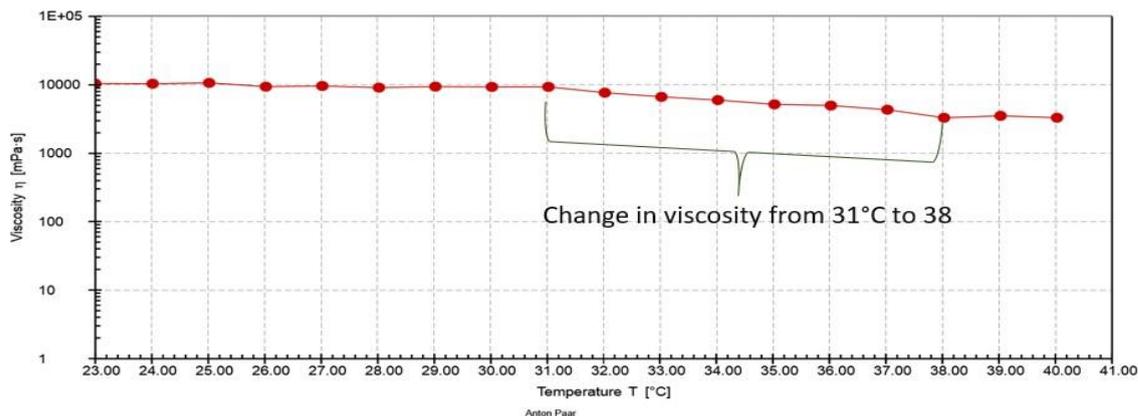

Figure 4.52: Graph of viscosity (mPa-s) as a function of temperature (°C) for FG7 containing poloxamer 188 18% m/v and hydroxypropyl methylcellulose (HPMC) 1.5% v/v.

It was noted that over the temperature range of 31 to 38 °C, the viscosity of FG7 decreased gradually. This minimal viscosity change was not anticipated because both poloxamer 188 and HPMC display positive thermoresponsive behaviour (i.e. an increase in temperature causes an increase in viscosity) around this temperature range (Baloglu *et al.*, 2011; Pal *et al.*, 2013). Formulation FG7 demonstrated great potential for thermoresponsiveness. It was subjected to further manipulation by varying polymer concentrations to yield ideal thermoresponsive characteristics for vaginal drug delivery. The results of this step are presented in Section 4.7.3.

4.7.2.4 Summary of optimal hydrogel formulation determination

Organoleptic assessments revealed that chitosan-containing formulations possessed unfavourable characteristics, such as bad odour. This was problematic, as formulations with bad odour are closely linked to poor patient compliance that can result in unfavourable therapeutic outcomes. It was resolved that chitosan would not be used for formulation purposes onwards. However, pH investigations of the various formulations revealed that all chitosan-containing formulations possessed ideal characteristics suitable for intravaginal drug delivery. As a result, and due to their undesirable sensory characteristics, the use of a PBS (pH 4.5) for the dissolution of the mucoadhesive polymer was proposed for future formulation purposes.

All rheological findings were unsatisfactory, thus declaring all such formulations unsuitable for MNZ-SLNs incorporation. However, the temperature-dependent

viscosity of FG7 prompted a brief investigation into the effect of polymer types and concentration on the overall thermal behaviour of future formulations. Hence, blank and loaded formulations were developed for further investigation and are discussed in the following section (see 4.7.3).

4.7.3 Incorporation of MNZ solid lipid nanoparticles (MNZ-SLNs) into optimal hydrogel formulation

In order to obtain an optimal hydrogel formulation for the incorporation of optimised 2% m/v MNZ-SLNs, four blank formulations were prepared and characterised for their pH, organoleptic and sol-gel transitioning abilities by means of a pH meter, sensory organs and test tube inversion methods. This investigation was prompted by the rheological findings of FG7. Table 4.35 provides an overview of the prepared hydrogel compositions and characteristics.

Table 4.35: Overview of hydrogel composition and characteristics for F-Gel 1 to 4, where P188 = poloxamer 188, HPMC = hydroxypropyl methylcellulose and MC450. = methylcellulose 450.

Sample code	Thermopolymer	Mucoadhesive polymer	pH	Organoleptic properties at $25 \pm 2^\circ\text{C}$	Sol-gel transition
F-Gel 1	P188 (18% m/v)	HPMC (1.5% m/v)	4.55 ± 0.01	Transparent, colourless, odourless	No
F-Gel 2	P188 (18% m/v)	MC450 (1.5% m/v)	4.53 ± 0.01	Transparent, colourless, odourless	Yes
F-Gel 3	P188 (6% m/v)	HPMC (1.5% m/v)	4.55 ± 0.01	Transparent, colourless, odourless	No
F-Gel 4	P188 (6% m/v)	MC450 (1.5% m/v)	4.55 ± 0.01	Transparent, colourless, odourless	No

The effect of the P188 concentration was investigated at two levels, *viz.* six and 18% m/v. Generally, T_{sol} decreases with an increase in polymer concentration (Gandra, 2013). Hence, it was envisioned that through the alteration of polymer concentrations

the desired sol-gel transition temperature (T_{sol}) could be achieved. Furthermore, the gelling ability of hydrogel formulation is altered by the presence of APIs and other excipients (Dumortier *et al.*, 2006). Therefore, to improve the gelling potential, HPMC was substituted with methylcellulose (MC) 450 to facilitate adequate sol-gel transition. The four formulations were prepared through the CM of gel production and their pH was adjusted by using PBS for the dissolution of the mucoadhesive polymers.

As seen in Table 4.35, pH and organoleptic properties for all formulations were satisfactory for intravaginal drug delivery. F-Gel 2 demonstrated sufficient sol-gel transition at 34 ± 2 °C and was, therefore, deemed ideal for MNZ-SLN incorporation.

The reduction of P188 concentration did not have a significant effect on T_{sol} because neither F-Gel 3 nor F-Gel 4 transitioned to form a gel. However, the substitution of HPMC with MC450 did have a significant effect on the formulation, because a sol-gel transition occurred at 34 ± 2 °C.

This phenomenon is possibly explained by the reduction of the hydroxypropyl molar substitution in HPMC. Under normal circumstances, HPMC displays a T_{sol} of 75 to 90 °C, which is not ideal for intravaginal drug delivery because the dosage form will remain in its sol state upon application and potentially result in leakage (Almomen *et al.*, 2015). The high occurrence of hydroxyl groups provides HPMC with extremely strong intermolecular interactions, resulting in its poor solubility in water and most organic solvents (Otoni *et al.*, 2018). By reducing the hydroxypropyl molar substitution, MC450 can interact with H₂O more freely and gelation is due to the intermolecular association of hydrophobic methoxy groups on the polymer chains that are a function of temperature. At ambient temperature and below, H₂O molecules form enclosed structures around the hydrophobic groups, causing MC450 to be more water soluble. Upon temperature increments, these structures fragment and reveal the hydrophobic groups, thus inducing the formation of hydrophobic aggregates where gelation occurs (Karoyo and Wilson, 2017). MC gels are completely thermoreversible and liquefy upon cooling. Furthermore, they undergo swelling and erosion *in vivo*; therefore, not warranting the removal of the dosage form after complete drug release (Bain *et al.*, 2010).

The respective physical characteristics of F-Gel 1 to 4 are depicted in Figure 4.54.

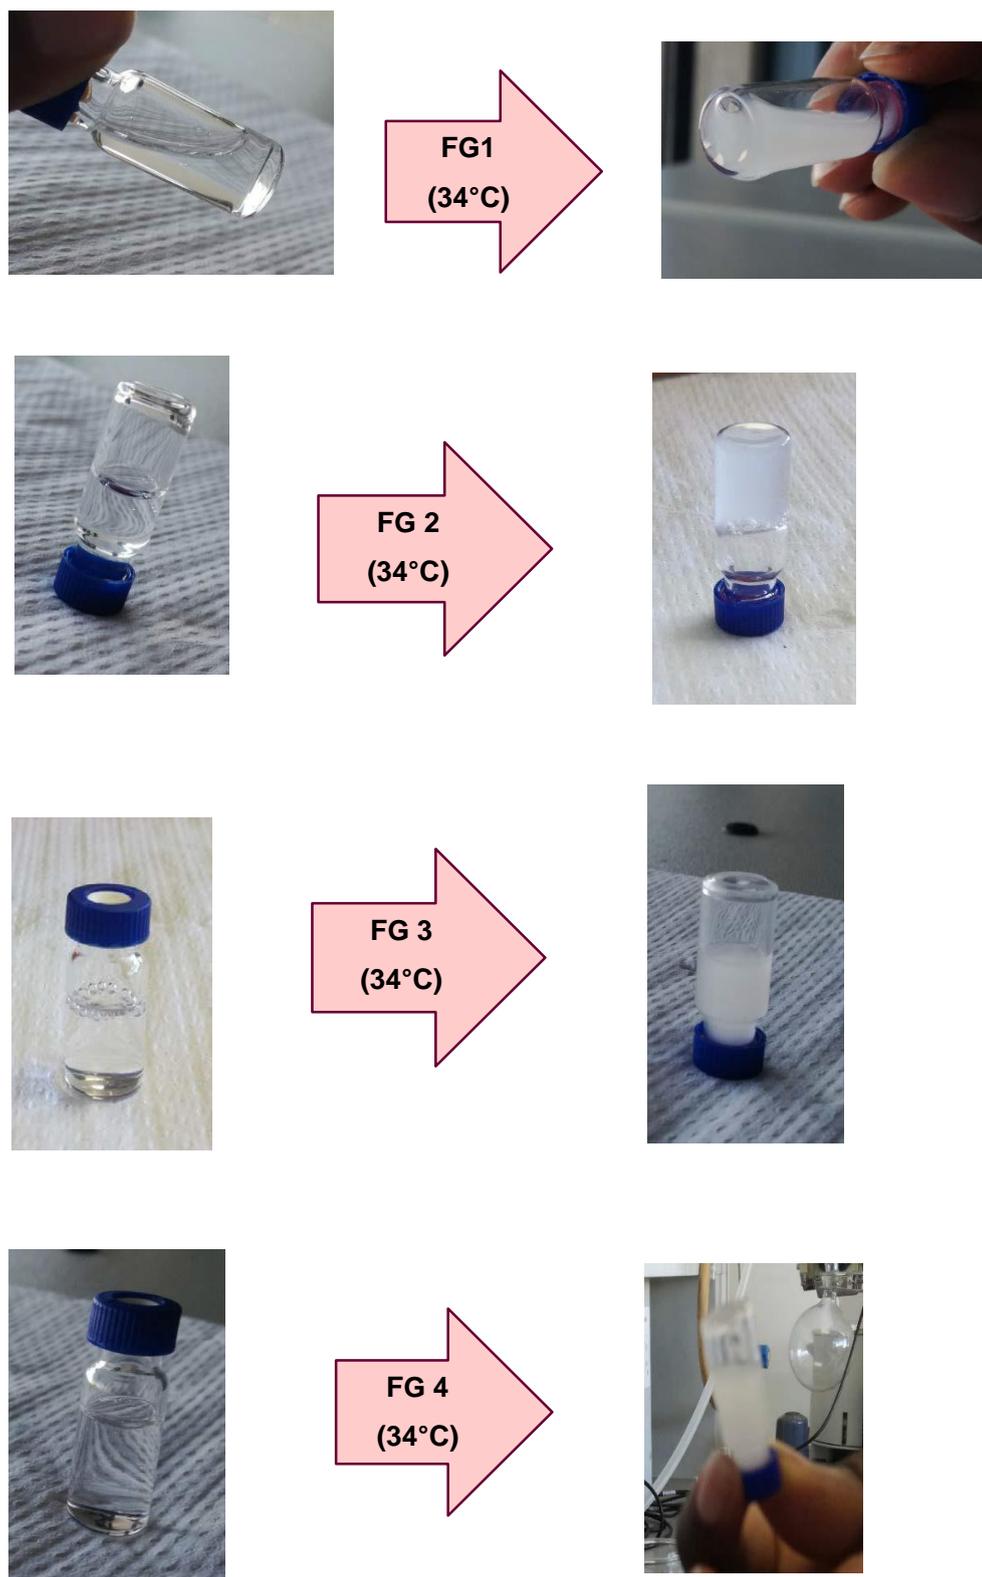

Figure 4.53: Physical characteristics of (a) F-Gel 1, (b) F-Gel 2, (c) F-Gel 3 and (d) F-Gel 4 at ambient and elevated (34 ± 2 °C) temperature.

At room temperature, all formulations were transparent and colourless, which demonstrated favourable organoleptic characteristics. Distinct changes in physical appearance were noted upon gradual temperature increments. At elevated temperatures, F-Gel 1 and 3 remained free-flowing, transparent and colourless liquids. F-Gel 2 solidified quickly at elevated temperatures to form an opaque, white non-flowing mass capable of supporting its own weight. However, F-Gel 4 did not solidify at elevated temperature but rather turned into a white opaque solution incapable of supporting its own weight. With continuous stirring and gradual temperature increments, F-Gel 4 solidified at 72 ± 2 °C; however, it was not deemed thermoresponsive for the purposes of this study because it did not transition at the body temperature of interest.

4.7.4 Characterisation of hydrogel incorporated with MNZ-solid lipid nanoparticles (MNZ-SLNs).

Three optimised 2% MNZ-SLN formulations were incorporated into three respective F-Gel 2 preparations by means of the CM of gel preparation. These formulations were referred to as MNZ-hydrogel(s), where they were characterised for their T_{sol} and drug content uniformity release, respectively.

4.7.4.1 Measurement of sol-gel transition temperature (T_{sol})

T_{sol} is the temperature at which a liquid or sol phase makes a transition to a gel phase (Tsao *et al.*, 2014). To facilitate satisfactory intravaginal drug delivery, the transition should occur in the range of 28 to 35 °C. $T_{sol} > 37$ °C results in a liquefied formulation upon insertion at physiological temperature. This, in turn, causes leakage, messiness and rapid clearance of the dosage form at the site of application (Mei *et al.*, 2017). Conversely, $T_{sol} < 25$ °C results in gel formation at ambient temperature, which can cause difficulty in dosage form extrusion from the packaging, with minimal spreading of the dosage form in the vaginal tract (Soliman *et al.*, 2016).

Due to limitations of available rheometers, a test tube inversion method was employed for the determination of MNZ-hydrogel T_{sol} in this study. The test tube inversion is a qualitative method that offers the operator a simple and rapid means of determining T_{sol} . All assessments were conducted in triplicates, allowing sufficient time for the

formulation to cool down to ambient temperature before re-testing. A summary of the test findings is given in Table 4.36.

Table 4.36: Summary of sol-gel transition determination of prepared MNZ-hydrogels using the test tube inversion method.

	MNZ-hydrogel 1	MNZ-hydrogel 2	MNZ-hydrogel 3	Mean ($n=3$)
T_{sol} (°C)	34	32	34	33.33 ± 2.82

The mean T_{sol} was calculated as 33.33 ± 2.82 °C. This is within the range for appropriate intravaginal drug delivery (Mei *et al.*, 2017). This dosage form exhibits great promise for convenient delivery of MNZ, whilst providing adequate spreading. Furthermore, the use of a mucoadhesive polymer aims to prolong dosage form retention at the site of application.

4.7.4.2 Drug content uniformity testing

In order to determine MNZ homogeneity in each formulation, drug content was established by means of RP-HPLC under optimised chromatographic conditions (see Section 4.2.4). Drug content was determined by assessing the area under the peak against the standard calibration curve of MNZ. Sampling of the three prepared MNZ-hydrogel formulations was done from the top, middle and bottom of the containers. A summary of the assay results is provided in Table 4.37.

Table 4.37: Summary of RP-HPLC assay results of prepared MNZ-hydrogels at 234 nm, MP (MeOH 85% v.v:H₂O 15% v/v), flow rate 1 ml/min.

	MNZ-hydrogel 1 (peak area)	MNZ-hydrogel 2 (peak area)	MNZ-hydrogel 3 (peak area)	Mean (n=3) (peak area)
Top sample	1 805 978	1 752 852	1 800 316	1 786 382 ± 23821.70
Middle sample	1 816 784	1 721 375	1 711 295	1 749 818 ± 47530.59
Bottom sample	1 802 713	1 712 359	1 705 623	1 740 232 ± 44266.47
Mean peak area	1 808 492	1 728 862	1 739 078	1 758 811 ± 35376.71
Concentration (mg/ml)	0.21 mg/ml	0.20 mg/ml	0.21 mg/ml	0.21 mg/ml
% recovery	105%	100%	105%	103.33 ± 2.36%

MNZ was well-distributed within each respective MNZ-hydrogel formulation. This was demonstrated by minimal deviations in peak response from the top, middle and bottom sample in each formulation. The mean % recovery was determined to be 103.33 ± 33%, which is a statistically significant deviation. Ideally, the % recovery should be found in the range of 98 to 102% (Ueda *et al.*, 2009). The deviation may be accounted for by human error during any of the preparatory steps when working with minute sample amounts.

4.8 IN VITRO DRUG RELEASE TESTING (IVDRT)

IVDRT plays a key role in pharmaceutical formulation development and quality control by monitoring the consistency and stability of dosage forms and facilitating the prediction of *in vivo* drug absorption (Stillhart *et al.*, 2017). FVDC was used to perform IVDRT on an optimised 2% MNZ-SLN preparation and a MNZ-hydrogel, respectively. Intravaginal conditions were replicated by means of a PBS (pH 4.5) at 37 °C. The drug release profiles of the respective formulations were determined using a plot of cumulative drug release as a function of time with the aid of Microsoft Excel® (2016)

(see Figure 4.55). The mean cumulative amount was calculated with the aid of Equation 3.18, from the mean ($n=3$) drug released at each sampling point.

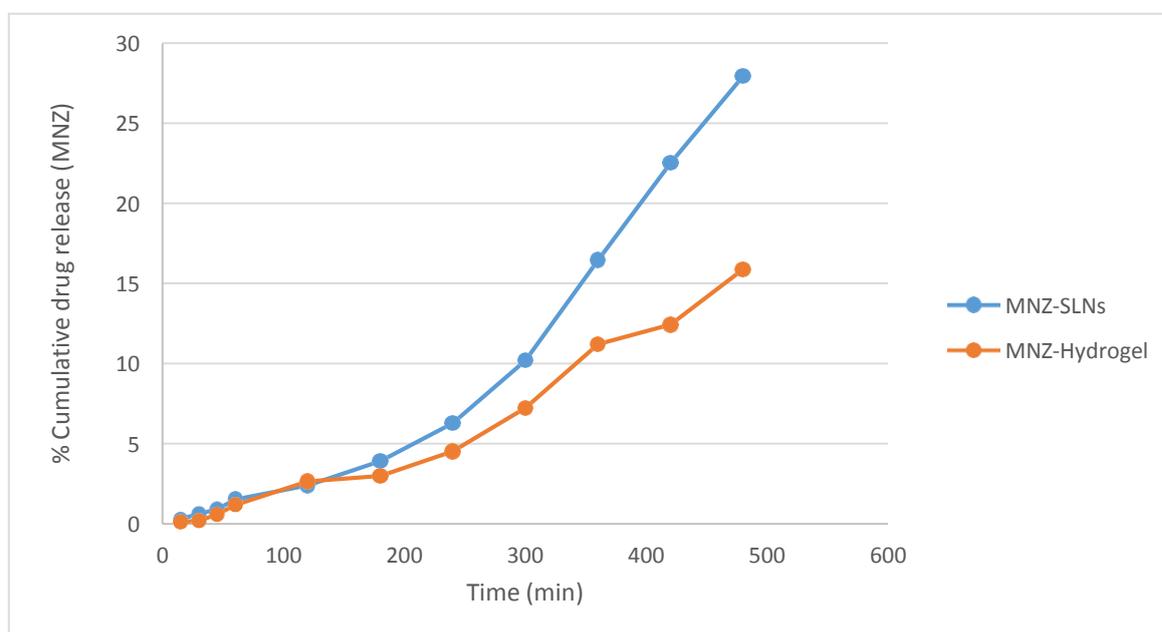

Figure 4.54: Plot of cumulative % drug release of miconazole nitrate (MNZ) as a function of time (min), where orange = MNZ-hydrogel and blue = MNZ-solid lipid nanoparticles (MNZ-SLNs).

IVDRT tests were conducted over a period of 480 minutes (i.e. eight hours). During this period, both formulations showed very similar release kinetics. The MNZ-hydrogel preparation exhibited a slower rate of drug release, with a total of 15.87% of MNZ released in an eight-hour period. This was in comparison to the 27.94% MNZ released from the optimised MNZ-SLN preparation in the same period.

The slow release kinetics of the MNZ-SLN preparation may be attributed to the solubilised drug in the lipid core which is released through dissolution or diffusion methods (Aljaed and Hosny, 2016). The drug rate was further extended by the incorporation of MNZ-SLNs into the hydrogel polymer network, possibly owing to the slower rate of drug diffusion through the hydrogel matrix or due to erosion. The IVDRT results gathered were used to generate non-linear mathematical models in order to assess MNZ drug release from the prepared dosage forms. Generally, the mechanism of drug release from hydrophilic polymeric matrices involves solvent penetration, hydration and swelling of the polymer, diffusion of the dissolved drug in the matrix and erosion of the gel layer (Chaterjee, 2011).

4.8.1 Non-Linear Mathematical modelling

Mathematical models play a significant role in establishing the mechanism of drug release and providing a guideline for NDDS (Nabatchian *et al.*, 2014). Data for this study were plotted and analysed with the aid of DDSolver™ (Microsoft Excel® add-ins, 2016). Various models including Zero-order, First-order, Korsmeyer-Peppas, Hixon and Crowell, Higuchi, Bakers and Lonsdale were investigated. To test the best-fitting model, the acquired r^2 value from each model was compared, and the one which demonstrated the highest numerical value was chosen as the best fit. This statistical analysis was conducted on the MNZ-SLNs and MNZ-hydrogel preparations, respectively (see Table 4.38).

Table 4.38: Correlation coefficients (r^2) for non-linear mathematical models for an optimised MNZ-solid lipid nanoparticles (MNZ-SLN) and MNZ-hydrogel.

Mathematical model	MNZ-SLNs (r^2)	MNZ-hydrogel (r^2)
Zero-order	0.8708	0.9351
First-order	0.8474	0.9250
Korsmeyer-Peppas	0.9941	0.9945
Hixson-Crowell	0.8552	0.9284
Higuchi	0.6175	0.7026
Higuchi with T_{lag}	0.9582	0.9338
Higuchi with F_0	0.7995	0.9457
Bakers and Lonsdale	0.6067	0.6960

The optimised MNZ-SLNs formulation that attained the highest r^2 of 0.9941 came from the Korsmeyer-Peppas model. The MNZ-hydrogel preparation that achieved the highest r^2 of 0.9945 also came through the Korsmeyer-Peppas mathematical model. Therefore, the Korsmeyer-Peppas model was deemed the best fit for both formulations.

4.8.2 Miconazole nitrate (MNZ) drug release models

Plots of % cumulative drug release profiles for the Korsmeyer-Peppas model are depicted in Figures 4.56 and Figure 4.57 for the optimised MNZ-SLNs formulation and MNZ-hydrogel, respectively.

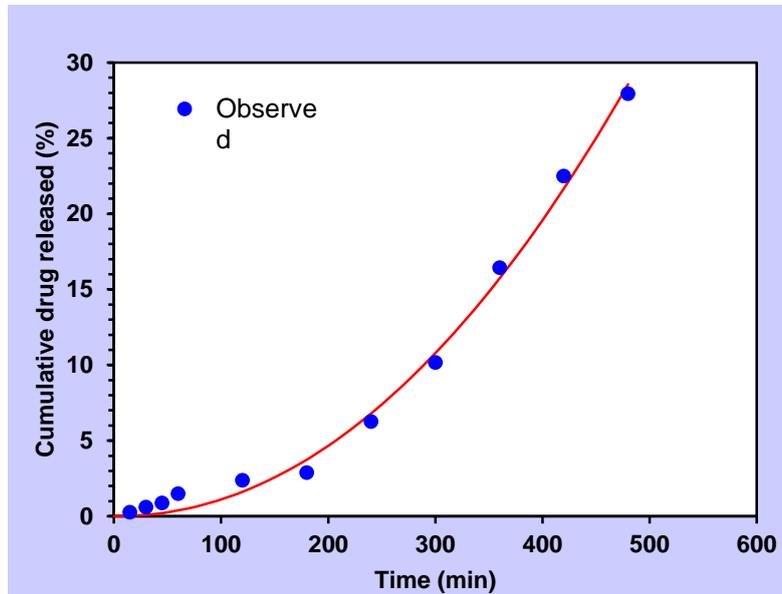

Figure 4.55: Plot of % cumulative drug release of an optimised MNZ loaded solid lipid nanoparticles (MNZ-SLNs) depicting the Korsmeyer-Peppas mathematical model fit.

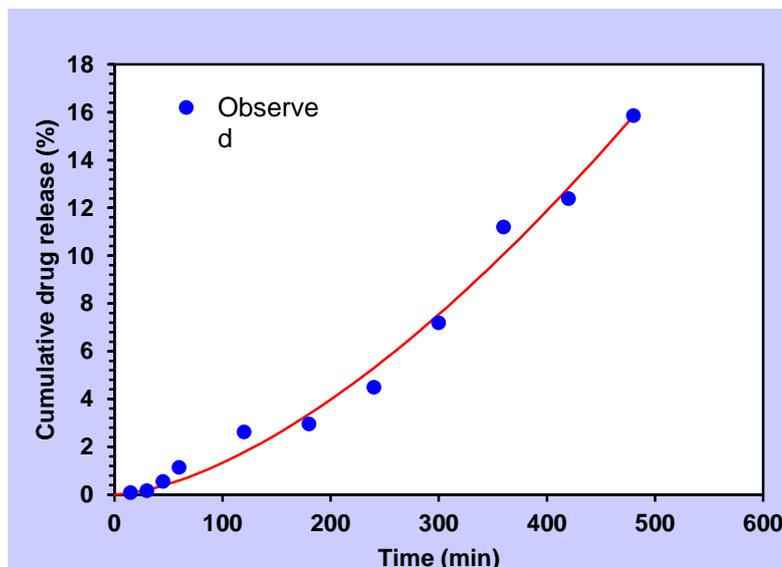

Figure 4.56: Plot of % cumulative drug release of a MNZ-hydrogel depicting the Korsmeyer-Peppas mathematical model fit.

The mechanism of drug release from matrices of swellable polymers is a complex phenomenon. Some systems display diffusion or erosion, whilst others exhibit a combination of both to facilitate controlled drug release (Grassi and Grassi, 2005). The Korsmeyer-Peppas model takes into account simultaneous processes, such as gel formation and the dissolution of polymers to model drug release, making it useful for describing drug release from several MR dosage forms (Shaikh *et al.*, 2015).

From the results presented earlier, it was observed that all formulations showed good correlation to the Kosmeyer-Peppas model. The release rate constant (kKP) and diffusional exponent (n) were key parameters which were governed by the release mechanism. n indicates the mechanism of drug release when more than one phenomenon is involved, where an n value of <0.43 indicates Fickian diffusion, $0.43 < n < 0.85$ indicates non-Fickian diffusion which combines erosion and diffusion mechanisms, $0.89 < n < 1$ suggests the case II transport and $n > 1$ suggests a super case II transport mechanism (Fu and Kao, 2011). The n value for MNZ-SLNs and MNZ-hydrogel in this study were determined as 2.071 and 1.580, respectively. This finding suggested a super case II drug release mechanism that involves the erosion of lipid or polymer matrix where applicable, as per Lee (1985) and Abbas and colleagues' (2013) earlier findings. kKP values for MNZ-SLNs and MNZ-hydrogel were determined as 0.000 and 0.001, respectively. The slightly higher kKP value of the hydrogel suggests faster discharge of the drug from the thermoresponsive gel upon insertion. This corresponds with Zhang *et al.*'s (2011) assertions.

4.8.3 Statistical significance

The statistical significance of drug release data from the two respective formulations were evaluated by means of a paired sample t-test (Microsoft Excel®, 2016). A t-test is conducted to ascertain if the means of two populations are equal so as to either accept or reject a null hypothesis (Kao and Green, 2008). The results of the test are depicted in Table 4.39.

Table 4.39: Results of t-test: Paired two sample for means where variable 1=% cumulative drug release from MNZ-solid lipid nanoparticles (MNZ-SLNs) and Variable 2=% cumulative drug release from MNZ-hydrogel.

	Variable 1	Variable 2
Mean	8.355455	5.339091
Variance	95.04205	30.69337
Observations	11	11
Pearson correlation	0.990048	
Hypothesised mean difference	0	
df	10	
t Stat	2.307963	
P(T<=t) one-tail	0.021829	
t Critical one-tail	1.812461	
P(T<=t) two-tail	0.043659	
t Critical two-tail	2.228139	

The test yielded a value of 0.021829 which means that the test was statistically significant when a p-value <0.05 is considered as statistically significant. Therefore, the test proved that there was a significant difference between MNZ release data for the MNZ-SLNs formulation and MNZ-hydrogel. Concluding that the difference did not occur simply because the data sets were atypical.

4.8.4 Summary of *in vitro* drug release testing (IVDRT)

IVDRT of the two prepared formulations indicated that they followed very similar release kinetics via the Korsmeyer-Peppas model. After a period of eight hours, only 27.94% of the API had been released from the MNZ-SLNs, which was significantly higher than the 15.87% of the hydrogel formulation. This finding suggests that the prepared hydrogel showed great potential as a vehicle in the delivery of MNZ, whilst facilitating controlled drug release.

4.9 ANTIMICROBIAL SUSCEPTIBILITY TESTING (AST)

The anti-fungal efficacies of MNZ-SLNs and the MNZ-hydrogel against *Candida albicans* species were investigated by means of a modified Kirby-Bauer disc diffusion assay. A commercially available cream and unloaded SLN and hydrogel preparations were used as controls. The respective mean ($n=3$) zones of inhibitions for each formulation is depicted in Figure 4.58.

A blank hydrogel and nanodispersion were used as positive test controls to determine whether or not the presence of excipients within the formulation contributed to the antifungal activity of the final dosage form. It was noted that the blank hydrogel had no activity against *Candida albicans spp.* since it did not inhibit its growth on the agar. This result was anticipated, as none of the excipients used in the formulation of the hydrogel possessed known antifungal activities. The blank nanodispersion, however, appeared to possess weak antifungal activity, as indicated by a mean zone of inhibition of 7.67 mm. It was recommended that further investigations be done to determine the influence of excipients in the SLN preparation, as time and resource constraints in this study hindered further investigation. .

Furthermore, a titanium metal PUS was used in the fabrication of the MNZ-SLNs formulation. Titanium is known to possess some antifungal properties (Betts *et al.*, 2013). One of the biggest concerns with SLNs formulated by means of PUS is possible dispersion contamination by eroding metal (Pooja *et al.*, 2015). Therefore, the resultant formulation was recommended for titanium or metal testing. A negative control by means of a blank segment of the agar was evaluated to determine whether or not any constituents within the MHA possessed any antifungal activity against *Candida albicans*. Complete growth was observed in that segment with a zone of inhibition of 0mm. This indicates that the storage conditions and agar were suitable for the germination of the fungi species.

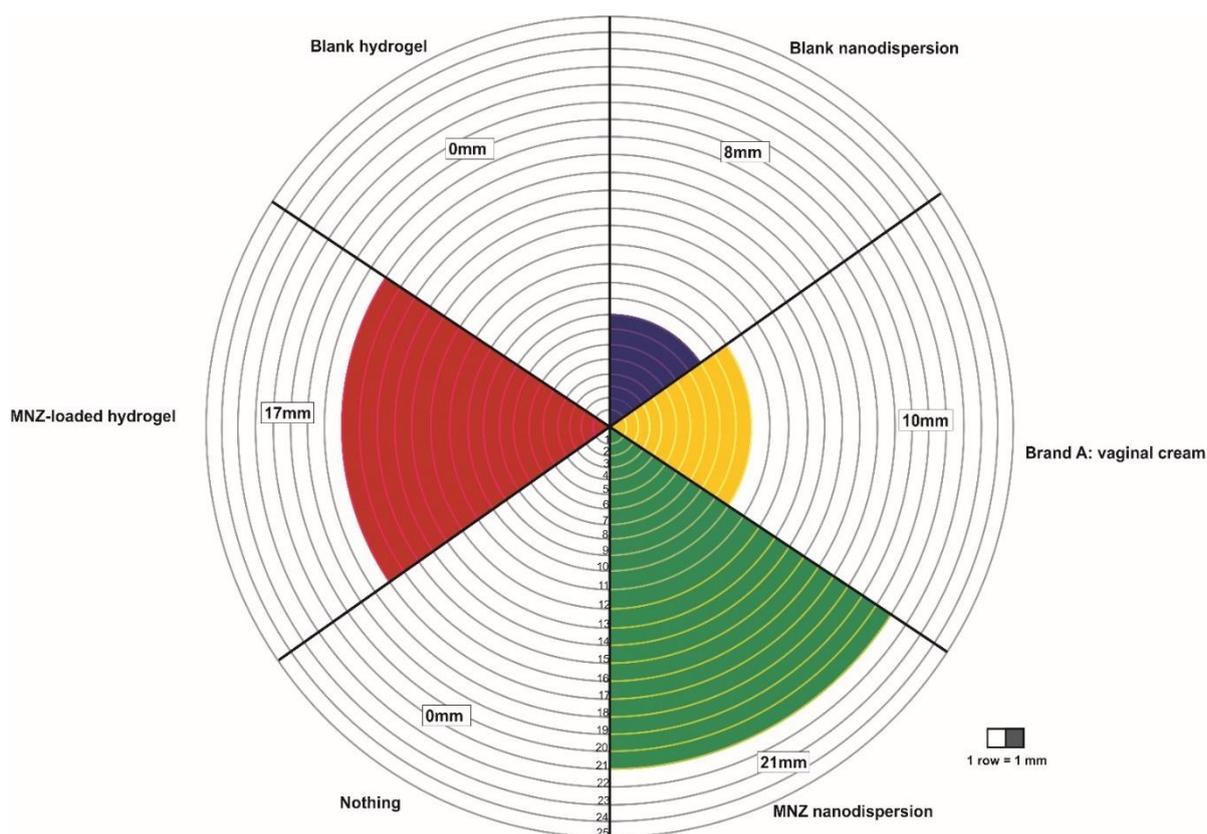

Figure 4.57: Mean zone of inhibition (mm) for various test formulations, where MNZ = miconazole nitrate.

The results indicate that the MNZ-SLNs, MNZ-hydrogel and a commercial antifungal cream demonstrated some activity against the *Candida albicans* spp. The antifungal activity of both the MNZ-SLNs and MNZ-hydrogel proved to be superior to the commercially available cream. This enhancement in antifungal activity could possibly be attributed to the reduction in particle size of the API by means of drug encapsulation within solid lipid nano-particles, thus enhancing the formulations' permeation through the agar. Additionally, the AST results correlated with the *in vivo* behaviour of the dosage form, which suggested that the prepared novel dosage forms show great potential in improving the therapeutic outcome of VVC as a result of *Candida albicans*.

4.10 CONCLUSION

This chapter comprised experimental results of the analytical method development and validation of MNZ, followed by its thermal analysis. These investigations allowed for the quantification of MNZ in bulk and complex formulations as well as the determination of drug-excipient compatibilities for the preparation of MNZ-SLNs.

MNZ-SLNs were prepared by means of a novel melt-emulsification sonication and low temperature solidification method. The resultant formulation was optimised statistically through the use of a CCRD, where a lipid concentration of 4% m/v and a sonication time of 260.94 seconds were deemed ideal. The optimised MNZ-SLNs were then characterised for particle characteristics, surface morphology, drug entrapment efficiency and stability. A thermo-responsive hydrogel formulation was developed and characterised for its organoleptic properties, pH, T_{sol} and drug content uniformity, where the organoleptic, pH and drug content uniformity were deemed favourable. The hydrogel T_{sol} was determined qualitatively by means of a test tube inversion method. This T_{sol} came to 33.33 ± 2.82 °C, which was deemed favourable for intravaginal drug delivery.

IVDRT were then undertaken to define the release kinetics of the optimised MNZ-SLNs and MNZ-hydrogel preparations. Both formulations suggested release mechanisms with the aid of the Korsmeyer-Peppas mathematical model. Finally, the superiority of the two formulations against a commercially available formulation against *Candida albicans* species was established through a modified Kirby-Bauer disc diffusion assay.

The final chapter of this study provides concluding remarks. An overview of the study's success, its limitations and prospective research suggestions will be discussed briefly.

CHAPTER 5

CONCLUSIONS AND RECOMMENDATIONS

This developmental study led to the formulation of a novel pharmaceutical dosage form. In chapter four, the experimental findings were presented. The focus of chapter five is to present a summary of the findings and draw subsequent conclusions.

5.1 CONCLUSIONS

Locally-acting imidazole creams were identified as first line agents in the treatment of uncomplicated VVC, but owing to poor patient adherence these dosage forms have been implicated in the high incidence of antifungal resistance and the subsequent reoccurrence of VVC infection. MNZ and imidazole antifungals were chosen as the model drugs for the purposes of this study, due to their lengthy treatment periods and frequent need for re-application. MNZ has also been associated with poor clinical outcomes. Therefore, it was necessary to conduct an investigation into ways of optimising this drug's delivery through the use of NDDS in the treatment of VVC. With the aid of reviewed literature, the physicochemical properties of MNZ *viz.* pKa and BCS were established. These characteristics suggested a highly lipophilic compound with poor aqueous solubility that made it an ideal candidate for solid lipid nanoparticle encapsulation. MNZ-SLNs were then developed and incorporated into a thermoresponsive mucoadhesive hydrogel for the intended treatment of VVC.

An analytical method was developed for the quantification of MNZ in bulk and complex pharmaceutical products by means of RP-HPLC by using an octyl stationary phase at 234 nm with an injection volume of 10 μ L, a flow rate of 1.0 ml/min and a MP composition of MeOH:H₂O (85:15). The developed method was determined as suitable for its intended use with a peak symmetry value of 0.94 and a linear equation of $y = 811214x + 67958$ within a working range of 0.125 to 1.00 mg/ml. LoD and LoQ were determined to be 0.015 and 0.052 mg/ml, respectively. All calculated % RSD values for accuracy and precision were within the acceptable limit of $\pm 2\%$. Forced degradation studies established that MNZ was labile under photolytic, oxidative, hydrolytic and thermal stress. As part of this study's pre-formulation studies, SDT investigations were undertaken to determine drug-excipient compatibility. MNZ demonstrated satisfactory

dissolution in cholesterol with the promise of facilitating high drug entrapment within the lipid vesicle.

A thirteen-run two-factor CCRD was employed as the RSM statistical tool in order to optimise the developed MNZ-SLNs for ZP, particle size (z-avg.), %EE, change in z-avg. and %EE upon storage. The predicted optimisation parameters were 4% m/v for lipid concentration and 260.94 seconds for sonication time. The mean %EE for the optimised MNZ-SLNs was 75.24%, with a mean z-avg. of 73.03 nm and a narrow PDI. The stability of the optimised MNZ-SLNs was monitored under accelerated conditions over a period of six months. A mean ZP value of 38.43 mV suggested a well-stabilised formulation. Minor z-avg. increments were observed over a period of six months, with a total drug loss of 12.63% from the lipid vesicles.

Unloaded hydrogels were formulated and characterised for their pH, organoleptic properties and rheology. The most promising formulation underwent further manipulation to a cosmetically pleasing thermoresponsive hydrogel with a T_{sol} of 33.33 ± 2.82 °C. An optimised MNZ-SLNs formulation was then incorporated into the hydrogel by means of simple mixing below the T_{sol} . The MNZ-SLNs hydrogel displayed uniform drug content within each assayed sample.

A FVDC was used to perform *in vitro* drug release studies from the MNZ-SLNs and MNZ-hydrogel. A plot of % cumulative drug release as a function of time showed slow release kinetics for MNZ over an eight-hour period. A % cumulative drug release value of 27.94% was obtained for MNZ-SLNs and a slightly lower 15.87% was obtained for the MNZ-hydrogel. These findings implied that the hydrogel retarded the release of MNZ to a greater extent than the SLN formulation. This data was fitted into various kinetic models with the aid of DDSolver™ (Microsoft Excel® add-ins, 2016). Both formulations attained the highest r^2 of 0.9941 and 0.9945, respectively, following the Korsmeyer-Peppas mathematical model. The Korsmeyer-Peppas model has been used to describe drug release from various MR dosage forms. A high diffusional exponent of >1 in both formulations suggest a super case II drug release mechanism facilitated through lipid or polymer matrix erosion.

A modified Kirby-Bauer disc diffusion assay was used to determine *Candida albicans* susceptibility to the developed formulations. Controls, in the form of unloaded

preparations and a commercially available cream, were used. MNZ-SLNs and a MNZ-hydrogel demonstrated superior antifungal activities when compared to the commercially available cream.

Based on these experimental findings, it can be concluded that the primary aim and objectives were achieved through the development, optimisation and characterisation of MNZ-SLNs which were incorporated into a mucoadhesive thermoresponsive system intended for localised intravaginal drug delivery.

52 RECOMMENDATIONS

The concept of nanomaterials and 'smart' drug delivery shows great promise in addressing the current global issue of microbial resistance by advising on new strategies that improve therapeutic outcomes. One manner of achieving this is through target-specific dosage forms that promote high patient acceptability.

This study achieved the set aims and objectives by successfully developing and characterising a novel formulation of MNZ-SLN-loaded *in situ* vaginal hydrogel. The study design utilised a quantitative approach, in which data was generated and analysed through experimental and computational techniques. Due to time and resource constraints further investigations were not feasible. Therefore based on the current study findings, recommendations for future works are proposed below:

- To conduct further studies into the possible release mechanisms of the prepared dosage forms. By extending the IVDRT time, a better release profile may be generated for mathematical modelling.
- To expand the range of input variables in the CCRD in order to gain a better understanding of the interactive effects between the input variables and measured responses.
- To further investigate the rate of MNZ decomposition under accelerated conditions in order to explain the interaction that results in such rapid degradation even at room temperature.
- To conduct long-term stability studies on MNZ-hydrogel so as to determine its ideal storage conditions.

- To perform histological analysis of mucosal tissue to determine the effects of lipid and surfactant concentration on *in vivo* toxicity.
- To investigate patient acceptability of applicator devices used to apply this dosage form.
- Propose additional strategies for antimicrobial stewardship in an effort to combat resistance of microbial species.

Abstract

Objective: To develop and optimize miconazole nitrate loaded solid lipid nanoparticles (MNZ-SLNs) for vaginal mucoadhesion, for the intended treatment of vulvovaginal candidiasis (VVC).

Methodology: MNZ-SLNs were developed by means of a novel low-temperature solidification and melt-emulsion ultrasonication method, a CCD was later employed for formulation optimisation. The resultant MNZ-SLN formulation was characterized for surface morphology, particle size, ZP and drug entrapment efficiency by means of TEM, PCS and high-performance liquid chromatography respectively. Finally, the optimal formulation was incorporated into a stimuli sensitive mucoadhesive hydrogel through the cold mechanical method of gel production. Which was characterized for anti-fungal activity, rheological and organoleptic properties.

Results: Response surface methodology statistical optimisation suggested that input variables of 4% m/v lipid concentration and 260.24 seconds sonication time would yield a stable formulation with high drug entrapment. Particle characteristics of the optimum formulation revealed a stable colloidal system with a mean particle size of 73.03 ± 0.78 nm and a high entrapment efficiency. The final formulation, which was comprised of

MNZ-SLN-loaded thermo-sensitive hydrogel displayed promising antifungal activity against *Candida albicans* species when compared to a commercially available cream. Further characterisation tests of the hydrogel displayed a sol/gel transition above 34°C with a modified drug release supported by the Korsmeyer-Peppas mathematical model.

Conclusion: A novel dosage form was developed with promising controlled release characteristics. Controlled release dosage forms assist in the promotion of patient compliance by decreasing the dosage requirements in the treatment of VVC.

Keywords: solid lipid nanoparticles, miconazole nitrate, mucoadhesive, thermo-sensitive hydrogels, controlled drug release.

**A.2. ABSTRACT SUBMITTED AND ACCEPTED FOR POSTER PRESENTATION
AT THE FIRST CONFERENCE OF BIOMEDICAL AND NATURAL
SCIENCES AND THERAPEUTICS (CoBNeST)**

Entry: Young scientist award: Basic Pharmacology

Venue: Spier Estate, Stellenbosch (7-10 October)

Development and validation of a RP-HPLC method for the quantification of miconazole nitrate in bulk or complex pharmaceutical products.

W.A Gwimo, G. Kilian, Y.E Kadernani

Department of Pharmacy, Faculty of Health Sciences, P.O. Box 77000, Nelson Mandela University, Port Elizabeth, 6031, RSA

Corresponding author: W.A Gwimo (s212243314@mandela.ac.za).

Abstract

Objective: To develop and validate a simple reverse phase high performance liquid chromatography (RP-HPLC) method for the quantification of miconazole nitrate (MNZ), a lipophilic antifungal drug, in pharmaceutical formulations.

Methodology: An isocratic RP-HPLC stability-indicating method was developed and optimised by means of an octyl (C₈) stationary phase with a mobile phase composition of methanol: water (85:15% v/v). Under the following chromatographic conditions, temperature of 40 °C, flow rate of 1ml/min and PDA detection of 234 nm.

Results: A linear calibration curve with a correlation co-efficient of 0.9998 was obtained within the working range of 0.125 to 1.00 mg/ml. The respective LoQ and LoD were 0.052 mg/ml and 0.015 mg/ml. Validation parameters were all deemed satisfactory for specificity, accuracy, precision and intermediate precision. Force degradation studies conducted under oxidative, hydrolytic, thermal and photolytic stress revealed MNZ was labile. Oxidative stress demonstrated the greatest degradation of 92.6% whilst thermal stress at 4°C facilitated the least degradation.

Conclusion: A simple, rapid and highly sensitive stability-indicating method was developed and validated for MNZ in bulk or complex pharmaceutical preparations.

Keywords: analytical method development, miconazole nitrate, high performance liquid chromatography, validation, force degradation studies.

TO WHOM IT MAY CONCERN

I, Debby Dewes, declare that I have proofread and edited the language (spelling, grammar, punctuation, consistency) of the dissertation by:

WIMANA ALEXIS GWIMO

entitled:

**DEVELOPMENT AND CHARACTERISATION OF MICONAZOLE NITRATE LOADED
SOLID LIPID NANOPARTICLES FOR INCORPORATION INTO A VAGINAL
MUCOADHESIVE SYSTEM**

Submitted in fulfilment of the requirements for the degree of Master of Science in the Faculty of Health Sciences at the Nelson Mandela University.

I cannot guarantee that the changes that I have suggested have been implemented nor do I take responsibility for any other changes or additions that may have been made subsequently.

Any other queries related to the language and technical editing of this treatise may be directed to me at 076 481 8341.

Dated at Port Elizabeth on 24 November 2018

D.K. Dewes
