A PRELIMINARY REPORT ON OOCYTE DONATION EXTENDING REPRODUCTIVE POTENTIAL TO WOMEN OVER 40

MARK V. SAUER, M.D., RICHARD J. PAULSON, M.D., AND ROGERIO A. LOBO, M.D.

Abstract  Background. Fertility in women 40 years of age or older is decreased, and in those with ovarian failure it is thought to be irrevocably lost. The donation of oocytes to young (<35 years old) women with ovarian failure has allowed many considered infertile a chance to become pregnant. In these women gonadal hormone replacement results in an endometrium receptive to implantation. It is not known whether the endometrial response to such replacement is decreased in women over the age of 40.

Methods. To test the efficacy of oocyte donation to older women, we enrolled seven women 40 to 44 years old with ovarian failure in a trial of hormone replacement and embryo transfer, using oocytes obtained from women undergoing ovarian hyperstimulation solely for gamete donation.

Results. Seven stimulated cycles in the donors that were synchronized with nine cycles in the recipients resulted in eight embryo transfers. Five viable pregnancies were established, one with twins. A sixth pregnancy ended in miscarriage. Five normal infants were delivered by cesarean section, and one stillborn infant was delivered vaginally. The outcomes were compared with those in women under the age of 40 with ovarian failure who were also participating in our donor-oocyte program and in infertile ovulating women 40 or older who were undergoing standard in vitro fertilization. No significant differences in rates of implantation or ongoing pregnancy were noted in older women as compared with younger women receiving donated embryos. These rates, however, were higher than the rates in the infertile ovulating women of similar age who were undergoing standard in vitro fertilization.

Conclusions. These preliminary results suggest that the endometrium retains its ability to respond to gonadal steroids and provides a receptive environment for embryo implantation and gestation even in older women. (N Engl J Med 1990; 323:1157-60.)

FERTILITY in women over the age of 40 is generally acknowledged to be decreased. In analyzing a large series of women, Leridon suggested that fecundity in women actually begins to decline by 30 years of age. Fertility rates peak by the age of 25 and fall throughout the remainder of reproductive life. Although many in vitro fertilization programs accept women over 40, the pregnancy rates in such women have been reported to be decreased, and the rates of miscarriage may be increased. Fertility is similarly diminished in older women undergoing donor insemination. In them, the cumulative success rates for pregnancy fall after they reach 30 years of age and decline dramatically after age 35.

As many as 10 percent of women have ovarian failure by 40 years of age, and until recently these women were considered to be hopelessly infertile. With aging, diminished fertility is believed to occur principally as a result of oocyte senescence, but it could also be due to resistance to implantation of the embryo in the endometrium. After implantation, the loss of pregnancy is also increased in women over 40, presumably as a result of a combination of detrimental changes in aging oocytes and the endometrium.

We previously reported the establishment of a program involving the nonanonymous donation of oocytes. Initially, younger women provided oocytes to women under the age of 40 with ovarian failure. The donors were fertile women who underwent controlled ovarian hyperstimulation and transvaginal, ultrasound-directed aspiration of oocytes for the sole purpose of donation. Thirteen cycles were initiated, resulting in 11 embryo transfers and 6 ongoing pregnancies. Encouraged by our preliminary experience, we expanded the protocol to include women over the age of 40 with ovarian failure who were otherwise in good physical and psychological health. In this article we report the results of our initial trials of oocyte donation in these older patients. Since the oocytes were donated by a group of young, fertile women, we could determine whether age alone affects the receptivity of the uterus to embryo implantation.

Methods

Between February 1, 1989, and September 1, 1989, seven infertile couples consented to undergo at least one cycle of in vitro fertilization with donated oocytes. All the recipients were married women 40 to 44 years old who had previously been found to have primary ovarian failure. In all the women, the ovarian failure was considered to be idiopathic and had occurred at least two years before enrollment in our study. All the women had serum follicle-stimulating hormone values above 100 IU per liter and estradiol levels below 90 pmol per liter. There was no attempt to induce ovulation in these women because of the longstanding and severe nature of their ovarian failure, as demonstrated by their very high levels of follicle-stimulating hormone.

None of the women had any major medical problem. The couples and donors were also interviewed by a psychologist before study entry and deemed acceptable candidates for embryo donation. The couples were advised of the possible increased obstetrical risks in pregnant women over the age of 40. Individual consent forms were signed by the donors, the recipients, and the recipients’ husbands. The protocol for embryo donation had been reviewed and approved by the institutional review board of the California Medical Center, Los Angeles.

The women with ovarian failure were treated with oral micronized estradiol and intramuscular progesterone as previously described (Fig. 1). The medications were administered in divided doses and taken twice daily, except that estradiol was taken in three doses on the days when the dose was 6 mg. After this regimen of hormones, a histologically normal endometrial biopsy specimen was obtained from each recipient on day 26 of a simulated replacement cycle within two months of the embryo-transfer cycle.

All the women receiving embryos had a normal endometrial cav-
progesterone replacement began was arbitrarily designated as day 15 of the simulated cycle. The embryos were transferred on day 18 of the cycle. Pregnancies were confirmed by the measurement of serum levels of the beta subunit of human chorionic gonadotropin and by transvaginal ultrasonography. Individual implantations were verified by the presence of a distinct gestational sac on ultrasonography. Clinical pregnancies were confirmed by visible heartbeats within the gestational sacs at least eight weeks after the transfer of the embryo. All the women who became pregnant continued to receive 2 mg of estradiol orally and 100 mg of progesterone intramuscularly in daily divided doses for an additional 100 days.

The outcomes in the group of recipients were compared with those in two other groups in our in vitro fertilization program. The first group (n = 9) was composed of all the women under 40 with primary ovarian failure who had participated in the donor-oocyte program since its inception. The mean age in this group was 32 years (range, 27 to 39). The second group (n = 22) consisted of all ovulating but infertile women 40 or older (mean, 41) who participated in our standard program of in vitro fertilization from January 1987 through August 1989. Women undergoing ovarian hyperstimulation received either human menopausal gonadotropin (initial dose, 225 IU a day) followed by human chorionic gonadotropin (10,000 IU) when the follicles were mature, or leuprolide acetate and then human menopausal gonadotropin (225 IU a day) followed by human chorionic gonadotropin (10,000 IU) when the follicles were mature. We performed transvaginal aspiration, gamete and embryo culture, and transcervical transfer of the embryo, using the same gamete laboratory and personnel as previously described.

The numbers of oocytes obtained, fertilized, and transferred and the rates of implantation and pregnancy were compared in the three groups. The differences between groups were analyzed with either the nonparametric Mann-Whitney test or Fisher's exact test, as appropriate. A P value of less than 0.05 was considered to indicate significance.

**RESULTS**

Table 1 shows the outcomes of each of the cycles in the seven women 40 or older who received embryos. Five women underwent one cycle and two underwent two cycles. Six pregnancies resulted from eight transfers of embryos to these women. In one instance no transfer was performed because there was no fertilized oocyte. A total of 28 embryos were transferred during the eight transfers (mean ± SD, 3.5±1.1 embryos per transfer). Ten implantations resulted, for an implantation rate of 36 percent. Six of the seven women became pregnant. One pregnancy ended in a miscarriage after nine weeks of gestation. In one woman the pregnancy progressed normally, but the fetus died in the uterus after 40 weeks of gestation; no cause of stillbirth was apparent. The pregnancies in the other four women were normal, and they all delivered normal infants.
Table 1. Results of the Transfer of Fertilized Donor Ova in Women 40 or Older with Ovarian Failure.

| PATIENT No. | AGE (yr) | NO. FERTILIZED* | TOTAL NO. | NO. TRANSFERRED | NO. IMPLANTED† | OUTCOME
|-------------|----------|-----------------|-----------|-----------------|----------------|----------
| 1           | 41       | 4/6             | 4         | 2               |                | Singleton pregnancy; CS week 37 |
| 2           | 40       | 6/10            | 6         | 1               |                | Singleton pregnancy; CS week 38 |
| 3           | 44       | 1/21            | 1         | 1               |                | Singleton pregnancy; CS week 40 |
| 4           | 41       | 16/20           | 5         | 0               |                | Not pregnant |
| 5           | 40       | 0/10            | 0         | 0               |                | Not pregnant |
| 6           | 41       | 3/8             | 3         | 2               |                | Singleton pregnancy; NSVD, death of fetus week 40 |
| 7           | 43       | 3/6             | 2         | 2               |                | Twin pregnancy; CS week 38 |

*The number of donor ova fertilized by sperm from the recipient's spouse.
†The number of gestational sacs visualized by transvaginal ultrasonography four weeks after transfer.
ICS denotes cesarean section. SAB spontaneous clinical abortion, and NSVD normal spontaneous vaginal delivery.

Table 2 shows the results in the patients with ovarian failure who were 40 or older as compared with those in the younger patients with ovarian failure in our oocyte-donation program and those in the in vitro fertilizing women 40 or older who were undergoing ovarian hyperstimulation and oocyte aspiration in our in vitro fertilization program. There were no significant differences in outcome in the older as compared with the younger women with ovarian failure. Among the older women who underwent standard in vitro fertilization and embryo transfer, significantly fewer oocytes were retrieved, fewer embryos were transferred, and the rates of implantation and pregnancy were lower than in either the younger or older women who received donated embryos.

The overall rate of oocyte fertilization in the older women with ovarian failure was 41 percent (40 of the 97 oocytes retrieved). This was lower than the overall rate of fertilization (62 percent) among couples without male-factor infertility in our general in vitro fertilization program in 1988 (data not shown; P<0.05). The husbands of 2 of the 7 women in the study group, as well as those of 6 of the 22 infertile ovulating women who were 40 or older, were suspected of being infertile on the basis of abnormalities in their screening laboratory examinations (0 percent score on the hamster penetration assay).

The rate of fertilization was lower in both groups than in the group of women with ovarian failure who were under 40, none of whose husbands had such abnormalities. The poor rates of fertilization in two women (Patients 3 and 5) contributed greatly to the low overall rate. Despite poor fertilization rates in these two (0 of 10 and 2 of 10 oocytes in Patient 5, and 1 of 21 oocytes in Patient 3), when fertilization occurred the zygotes cleaved, implanted, and continued to develop in both cases, and the pregnancy was successful in Patient 3.

**DISCUSSION**

Ovarian failure occurs in most women in the United States between the ages of 48 and 51. Many women are either menopausal or perimenopausal by the time they reach their early forties. For women who delay childbearing until late in their reproductive lives, the likelihood of starting a family is decreased. For those with ovarian failure there are few options for pregnancy.

We have previously demonstrated that high rates of pregnancy can be achieved in women with premature ovarian failure if multiple embryos are transferred to them after hormonal stimulation of the endometrium. The rate of pregnancy in such women is approximately three times that reported by the national registry for infertile ovulating women who undergo standard in vitro fertilization and embryo transfer. We believe that the increased rate of embryo implantation results both from the receptive uterine environment artificially created in these recipients and from the transfer of multiple embryos from oocytes obtained from young, fertile donors.

The endometrium of women with ovarian failure can be made histologically normal with a combination of oral micronized estradiol and intramuscular progesterone. Endometrial-biopsy specimens from women receiving this hormone replacement regimen (both those under and those over 40) are histologically indistinguishable from normal endometrium. We therefore believed that in older women with ovarian failure a pregnancy rate similar to that of younger women with

the same problem was possible, provided that embryos of similar quality were transferred. Indeed, the rate of implantation (36 percent) in this older group was not different from that previously reported by us in women under the age of 35 (35 percent).  

The incidence of genetic anomalies in the offspring of women undergoing in vitro fertilization and embryo transfer is not different from that in the population at large.  

Whether the incidence of such anomalies in this older group of women with ovarian failure will resemble that of the younger donors who provide the gametes or that of their own age group is a matter of speculation. The increased incidence of anomalies in the offspring of older women in general may be due to either the older gametes or lack of rejection of abnormal conceptions by the endometrium of older women. Similarly, the rate of miscarriage in these older women is not yet known, but our results suggest that it is not different from that of younger women in the general population.

The obstetrical risk to the women in this study is unknown. However, infant mortality in women 40 or older is significantly increased [12 deaths per 1000 live births at age 40 vs. 9 per 1000 at age 30]. Maternal mortality rates are also higher (80 per 100,000 live births at age 40 vs. 20 per 100,000 at age 30). If high-risk obstetrical care is provided, the rate of obstetrical complications may not be appreciably higher than that in younger women. Careful screening of patients will further lessen complications if those with known high-risk factors, such as hypertension, diabetes mellitus, or thromboembolic disease, are excluded from participation. Since the risks are currently unknown, all women should be carefully screened and counseled regarding pregnancy before oocyte donation is attempted.

Oocyte donation provides older women with ovarian failure a reasonable chance at achieving pregnancy. To those with existing ovarian function, conventional in vitro fertilization and embryo transfer may still be offered, although the success of pregnancy is probably reduced and at best results in a live-born child in less than 10 percent of the initiated cycles. A recent report suggested that the creation of a functionally amenorrhea state by means of pituitary downregulation with a gonadotropin-releasing hormone agonist followed by ovarian hormone replacement allows the cycles of selected women with ovarian function to be synchronized with those of an oocyte donor. Such a protocol may be applicable to women whose ovarian failure is intermittent, as is often the case in perimenopausal women.

In this small series, the rates of pregnancy with donated oocytes in women with ovarian failure who were 40 or older approximated that in younger women in the same program, demonstrating that receptivity to embryo implantation can be maintained if not enhanced by hormone replacement therapy in such older women. The probability of randomly achieving pregnancy in women with ovarian failure in this age group with any other existing method is extremely low. Since women in this age group with functioning ovaries are considered appropriate candidates for infertility treatment, it seems appropriate that those without ovarian function should also be allowed a chance to experience pregnancy if they desire it.
