Femtosecond dynamics of photogenerated quasiparticles in YBa$_2$Cu$_3$O$_{7-\delta}$ superconducting thin films shows at $T \leq T_c$ two main electronic processes: (i) quasiparticle avalanche production during hot-carrier thermalization, which takes about 300 fsec; (ii) recombination of quasiparticles to form Cooper pairs which is completed within 5 psec. In contrast, nonsuperconducting epitaxial films such as PrBa$_2$CuO$_4$ and YBa$_2$Cu$_3$O$_6$ show regular picosecond electronic response.

The discovery of high-$T_c$ superconductors in copper oxide compounds has attracted wide interest in the mechanisms leading to superconductivity and in possible applications. One area in particular, the transient optical response, has been the subject of recent studies dealing with the dynamics of pair breaking and applications to high-speed optical detectors with wide spectral range. Moreover, the optical interaction in these materials determines the nonequilibrium superconducting properties which may reflect pairing mechanisms. Several models have been proposed to explain the optical response of YBa$_2$Cu$_3$O$_{7-\delta}$ films to cw excitation and pulsed radiation of nanosecond time duration, but the full picture is still unclear. One of the main issues appears to be whether the optical response is predominantly bolometric (thermal) or due to nonequilibrium mechanisms associated with quasiparticle photogeneration.

In the present study, using femtosecond time-resolved spectroscopy we have clearly observed, for the first time, the transient optical response, has been the subject of recent studies dealing with the dynamics of pair breaking and applications to high-speed optical detectors with wide spectral range. Moreover, the optical interaction in these materials determines the nonequilibrium superconducting properties which may reflect pairing mechanisms. Several models have been proposed to explain the optical response of YBa$_2$Cu$_3$O$_{7-\delta}$ films to cw excitation and pulsed radiation of nanosecond time duration, but the full picture is still unclear. One of the main issues appears to be whether the optical response is predominantly bolometric (thermal) or due to nonequilibrium mechanisms associated with quasiparticle photogeneration.

In the present study, using femtosecond time-resolved spectroscopy we have clearly observed, for the first time, the transient optical response of YBa$_2$Cu$_3$O$_{7-\delta}$ films to cw excitation and pulsed radiation of nanosecond time duration, but the full picture is still unclear. One of the main issues appears to be whether the optical response is predominantly bolometric (thermal) or due to nonequilibrium mechanisms associated with quasiparticle photogeneration.

The pump beam monitors $\Delta R(t)$ due to the excited carriers as a function of the time delay $t$ between the two beams. Both beams were derived from a passively mode-locked ring dye laser which produces 60-fsec pulses at 625 nm (2 eV). The energy per pulse was 50 pJ and the repetition rate was 80 MHz. The pump and probe beams were focused onto a 30-µm-diam spot on the sample which was placed in a continuous-flow cryostat producing temperatures from 5 to 300 K. The intensity of the pump beam was modulated at 4 MHz using an acousto-optic modulator. The in-phase signal $\Delta R(t)$ associated with the probe beam was measured using a moderately fast Si photodiode, a preamplifier tuned to 4 MHz, and a fast lock-in amplifier; this provided an overall system resolution of $\Delta R/R \approx 10^{-6}$.

Measurements were made with perpendicular pump-probe polarizations in the $a$-$b$ plane of epitaxial thin films of high-$T_c$ materials, about 10 mm$^2$ in area. The films were deposited on (100) SrTiO$_3$ substrates by laser ablation using a UV laser. Their $c$ axis was perpendicular to the substrate and the best had sharp superconducting transitions (2 K wide) at $T_c = 90$ K and high critical currents. A PrBa$_2$CuO$_4$ and four YBa$_2$Cu$_3$O$_{7-\delta}$ films with thicknesses ranging from 1000 to 4000 Å were used. The pump beam was absorbed within the optical skin depth ($\sim 1000$ Å) and the initial density of photoexcited carriers was estimated to be $1 \times 10^{18}$ cm$^{-3}$.

Figure 1 shows a typical transient $\Delta R/R$ response of a superconducting YBa$_2$Cu$_3$O$_7$ film above and below $T_c$, the temperatures being respectively 300 and 40 K. For $T > T_c$, Fig. 1(a), there is a step-function response of $\Delta R > 0$ and it decays with a characteristic time of 3 nsec [Fig. 1(a), inset]; it is much slower at 100 K. This behavior is a typical bolometric response in a metal. Our measurements of the temperature dependence of the reflectivity $R$ show a positive $dR/dT$ of $5 \times 10^{-5}$ K$^{-1}$ and this allows us to estimate a sample temperature rise per pulse at 300 K of $\Delta T \approx 0.7$ K, consistent with calculations based on the absorbed energy and the sample.
Transient photoinduced reflectivity $\Delta R/R$ of superconducting 3000-Å YBa$_2$Cu$_3$O$_7$ film at (a) 300 K, bolometric response, and (b) at 40 K, quasiparticle to bolometric response. The heat capacity. The generated $\Delta R$ decays due to longitudinal heat diffusion into the film.

A completely different transient response for this film is observed for $T < T_c$, Fig. 1(b). At $t = 0$, $\Delta R$ builds up toward a negative peak with a characteristic time $\tau \approx 300$ psec, as shown in Fig. 1(b), inset, followed by a longer recovery of several psec duration with $\Delta R < 0$ and a crossing of the zero signal line into a plateau with $\Delta R > 0$. Since $R(T)$ increases with $T$ even when $T < T_c$, the initial rapid $\Delta R < 0$ response cannot be bolometric; it is due to an electronic response associated with photogenerated QP in the film. This is further substantiated by the results in Fig. 2(a) where the peak value of the reflectivity change, $(-\Delta R/R)_{\text{max}}$, is measured as a function of temperature at a constant excitation intensity of $3 \mu J/cm^2$.14 This peak value increases from zero at $T = T_c$ to a saturation value of $5 \times 10^{-4}$. A negative response of $\Delta R$ is not observed for $T > T_c$. The data in Fig. 2(a) are best fitted by a two-fluid model15 $[1 - (T/T_c)^4]$ of the relative density of Cooper pairs, with $T_c \approx 90$ K. A fit within BCS theory by a superconducting electron density obtained from the penetration-depth function in the weak-coupling limit16 is not as good. Thus the negative $\Delta R$ response is associated with QP generated by the breaking of Cooper pairs following photon excitation.

Such dramatic changes in the photocarrier response as a function of temperature are not observed for nonsuperconducting epitaxial thin films, as shown in Fig. 3 for PrBa$_2$Cu$_3$O$_7$ and YBa$_2$Cu$_3$O$_6$. We have observed in these films an instantaneous onset in electronic $\Delta R$ (no delay as in YBa$_2$Cu$_3$O$_7$) followed by an ultrafast relaxation of order 2–4 psec into a plateau. This is a typical response of nonsuperconducting films12,13 where the ultrafast dynamics has been identified12 as due to hot electrons and the plateau is bolometric in origin. To compare this behavior with that in YBa$_2$Cu$_3$O$_7$, we have measured the values of $\Delta R/R$ at the peak response as a function of temperature. As shown in Fig. 3, insets, these values are almost temperature independent for both films. This is again typical of nonsuperconducting films, and in contrast with all of our YBa$_2$Cu$_3$O$_7$ films [Fig. 2(a)].

The YBa$_2$Cu$_3$O$_7$ results in Fig. 1(b) show two main processes associated with the QP response: a fast build-
up and a relatively longer relaxation followed by a positive \( \Delta R \) plateau. We interpret the first process as an avalanche multiplication of QP due to hot-carrier thermalization which lasts for about 300 fsec and which occurs immediately after photon absorption. The second process is interpreted as a QP recombination into Cooper pairs followed by a thermal relaxation producing a bolometric signal with \( \Delta R > 0 \), similar to \( T > T_c \).

Following 2-eV photon absorption in YBa\(_2\)Cu\(_3\)O\(_7\), highly excited QP dissipate their excess energy to other electrons near the Fermi level, Cooper pairs across \( 2\Delta \), and phonons. The observed rise time \( \tau \) is a typical electron inelastic-scattering time which describes the thermalization process.\(^1\),\(^2\),\(^7\) This \( \tau \) of order 300 fsec is in agreement with the carrier scattering rate inferred from Drude \( \omega \) optical response\(^1\) and may be associated with electron-phonon scattering.\(^9\) The maximum number of QP that can be created as a result of a single-photon absorption is roughly \( g = 2\hbar \omega /2\Delta (0) \); here it is \( \sim 100 \) for \( 2\Delta (0) = 5kT_c \)\(^1\) and \( \omega = 2 \text{ eV} \). From \( g \) and the excitation intensity, the QP density \( \delta N_0 \) after the electronic thermalization process ends is estimated to be \( \delta N_0 \approx 10^{20} \text{ cm}^{-3} \). This amplification process is very important for observing QP response in superconductors; in many studies it has not been taken into account.

The optical QP response giving \( \Delta R < 0 \) may be explained within the superconducting extreme-clean-limit model,\(^1\),\(^5\),\(^6\) which is compatible with the two-fluid model used previously in Fig. 2(a). Various ir spectroscopic studies of YBa\(_2\)Cu\(_3\)O\(_7\) have shown\(^1\) that the Drude contribution to the optical conductivity \( \sigma(\omega) \), which is usually present in metals, shifts to zero frequency (clean limit) at \( T \ll T_c \). Therefore, generation of QP over the gap partially restores the Drude contribution \( \Delta \sigma \) to \( \sigma(\omega) \). Assuming that all other optical transitions do not change substantially upon irradiation, \( \Delta \sigma \) may be calculated by taking the difference due to the photogenerated QP \( \delta N_0 \) between a Drude contribution of 200 cm\(^{-1}\) width and one that is very narrow, representing the condensate in the two-fluid model.\(^1\) The changes \( \Delta \epsilon \) in the dielectric constant \( \epsilon_1 + i\epsilon_2 \) can then be calculated:

\[
\Delta \epsilon_2 = \delta N_0 \omega_p^2 / N \omega^3 \tau_s
\]

and \( \Delta \epsilon_1 = \Delta \epsilon_2 / \omega_\tau_s \). In Eq. (1), \( \omega_p \) is the plasma frequency (\( \approx 1 \text{ eV} \))\(^1\), \( \tau_s \) is the scattering time (\( \approx 200 \text{ cm}^{-1} \))\(^1\), and \( N \) is the total electron density (\( N = 6 \times 10^{21} \text{ cm}^{-3} \)).\(^1\) Using Eq. (1) with \( \delta N_0 = 10^{20} \text{ cm}^{-3} \), we calculate \( \Delta \epsilon \) of order \( 10^{-4} \); this is consistent with our measurements.

To obtain \( \Delta R/R \) from \( \Delta \epsilon \) for a thin metallic film, one has to do tedious calculations\(^1\) involving various integrals of the QP distribution function with distance over the film thickness, and to take into account the optical interference fringes which usually appear in thin films.\(^2\) It is therefore possible to obtain a sign change in \( \Delta R \) such that \( \Delta R < 0 \) even though \( \Delta \epsilon > 0 \), as is probably the case for the QP response of the 3000-Å YBa\(_2\)Cu\(_3\)O\(_7\) film shown in Fig. 1(b). The negative sign in \( \Delta R (QP) \) is consistent with the positive sign of \( \Delta R \) for the bolometric contribution. Measurements of \( \dot{\epsilon} \) as a function of temperature\(^2\) give \( \Delta \dot{\epsilon} < 0 \) for a temperature increase. However, since from Fig. 1(a) \( \Delta R > 0 \) for the bolometric response, then \( \Delta R \) has the opposite sign of \( \Delta \dot{\epsilon} \). The observed QP response in this case, with \( \Delta R < 0 \), is due to \( \Delta \dot{\epsilon} > 0 \), in agreement with the proposed model.

QP recombination may be described as quasielectron-quasihole recombination across \( 2\Delta \), in analogy with semiconductors. As is evident in Fig. 1(b) the recombination rate is very fast; the transient decays are not purely exponentials. We define a recombination time \( \tau_r \) as the time for the \( \Delta R (QP) \) signal to decay to half its maximum value and hence we measure it at various temperatures as shown in Fig. 2(b). For \( T < 40 \text{ K} \), \( \tau_r \) decreases with \( T \) and then starts to increase, reaching a value of 4.5 psec at 79 K.\(^4\) Since this increase in \( \tau_r \) occurs at temperatures where \( \delta N_0 \) decreases, we plot the product \( I_{\tau_r} = \Delta R(R)_{QP} \tau_r \) in Fig. 2(c); this is proportional to the integrated signal as a function of \( T \). A constant behavior of \( I_{\tau_r} \) at temperature where \( \delta N_0 \) and \( \tau_r \) change dramatically indicates that the QP generation and recombination processes are related.

QP recombination kinetics in superconductors was discussed by Rothwarf and Taylor\(^2\) in terms of two rate equations for the excess QP (\( \delta N \)) and the 2\( \Delta \) phonons (\( \delta n \)) released in the QP recombination process. For \( \delta N \gg N_T \), where \( N_T \) is the QP density in thermal equi-
librium, these equations are given by\(^{25}\)
\[
\frac{d}{dt}(\delta N) = -r(\delta N)^2 + 2\tau_B^{-1}(\delta n),
\]
\[
\frac{d}{dt}(\delta n) = -(\tau_B^{-1} + \tau_r^{-1})(\delta n) + \frac{1}{2} r(\delta N)^2,
\]
where \(r\) is the QP recombination rate, \(\tau_B\) is the Cooper-pair breaking time, and \(\tau_r\) is the phonon decay (escape) time.

The 2\(\Delta\) phonons released in the QP recombination are trapped within the excited volume and can further rebreak Cooper pairs; hence they act as a bottleneck for QP recombination.\(^{24,25}\) Under these conditions \(\tau_r = 2\tau_B,\)\(^{25}\) rather than \(\tau_r \sim (\delta N)^{-1}\) as is the usual nonlinear recombination kinetics in semiconductors. We checked the QP relaxation by changing the excitation intensity at 20 K; we verified that the QP dynamics did not change with \(\delta N(0)\).

We attribute the 2-ps QP decay to the 2\(\Delta\)-phonon relaxation time. Recent Raman-scattering measurements\(^{20}\) have shown that the optical phonons (\(A_g\) and \(B_{ig}\)) are in resonance with 2\(\Delta\) in YBa\(_2\)Cu\(_3\)O\(_{6.5}\). \(\tau_r\) is therefore determined by the decay of the 2\(\Delta\) optical phonons to acoustical phonons. From our data, \(\tau_r \approx 1\) ps; this corresponds to a phonon with a homogeneous Lorentzian line shape of 15-cm\(^{-1}\) width, in good agreement with the measured \(A_g\) phonon linewidth at \(T = T_c\) in YBa\(_2\)Cu\(_3\)O\(_7\).\(^{20}\)

There are two possible explanations for the increase in \(\tau_r\) at \(T \geq 40\) K. Acoustical phonons may be released during the QP recombination at the higher temperatures causing \(\tau_r\) to increase; it is determined by the escape time of these phonons from the illuminated volume.\(^{25}\) It is also possible that the QP recombination is accompanied by relaxation in \(A,^{25}\) causing a divergence in \(\tau_r\) as \(T_c\) is approached from the superconducting side; i.e., \(\tau_r \sim 0,\) as can be inferred from Fig. 2(c).

In conclusion, we have resolved the photogenerated QP dynamics in superconducting Y-Ba-Cu-O thin films using femtosecond spectroscopy. We identified two main ultrafast electronic processes: an avalanche production of QP during the thermalization of hot electrons following photon absorption, and QP recombination to form Cooper pairs with a rate dominated by the coupled optical-phonon decay.

We acknowledge fruitful discussions with D. Finnemore, D. Mattis, and M. Reiser. This work was supported in part by DOE Grant No. DE-FG 0289, ER 45409 and by a grant from BP America at Cleveland, Ohio.

Note added.—Chwalek et al.\(^{27}\) have measured femtosecond transient transmission in high-\(T_c\) superconducting Bi\(_2\)Sr\(_2\)Ca\(_2\)Cu\(_3\)O\(_{10+\delta}\) and YBa\(_2\)Cu\(_3\)O\(_{7-\delta}\) and found for both compounds nonequilibrium heating with a dramatic increase in relaxation time at temperatures below \(T_c\).
