## Abstract

and

We give a description of the varieties of n-dimensional representations and characters of fundamental groups of compact non-orientable surfaces.

## 1 Introduction

Let  $\Gamma = \langle g_1, \ldots, g_m \rangle$  be a finitely generated group and  $G \subset GL_n(K)$  a connected linear algebraic group defined over a field K which throughout the paper will be assumed to be algebraically closed and of characteristic zero. For any homomorphism  $\rho : \Gamma \to G(K)$  the set of elements

$$(\rho(g_1),\ldots,\rho(g_m)) \in G(K)^m = G(K) \times \cdots \times G(K)$$

satisfies evidently all the relations of  $\Gamma$  and thus the correspondence

$$\rho \to (\rho(g_1), \ldots, \rho(g_m))$$

gives a bijection between points of the set  $\operatorname{Hom}(\Gamma, G(K))$  and K-points of some affine K-variety  $R(\Gamma, G) \subset G^m$  whose geometric structure does not depend on the choice of generators  $g_1, \ldots, g_m$  of  $\Gamma$ .

The variety  $R(\Gamma, G)$  is usually called the *representation variety* of  $\Gamma$  into the algebraic group G. In the case  $G = \operatorname{GL}_n(K)$  we will denote it simply by  $R_n(\Gamma)$  and call it the variety of *n*-dimensional representations of  $\Gamma$ .

The group G acts on  $R(\Gamma, G)$  by simultaneous conjugation and its orbits are in oneto-one correspondence with the equivalence classes of representations of  $\Gamma$ . Under this action orbits of G are not necessarily closed and so the set of orbits (also called the geometric quotient) is not an algebraic variety. However if G is a reductive group, then one can consider a categorical quotient  $R(\Gamma, G)/G$  (see [11]), which is usually denoted by  $X(\Gamma, G)$  and is called the *variety of characters* (for more details see [10]). By construction, its points parametrize closed G-orbits. For  $G = \operatorname{GL}_n(K)$  an orbit of a representation  $\rho$  is closed iff  $\rho$  is fully reducible. It follows that the points of the variety  $X_n(\Gamma) =$  $X(\Gamma, \operatorname{GL}_n(K))$  are in one-to-one correspondence with the equivalence classes of fully reducible *n*-dimensional representations of  $\Gamma$  (see [10]).

If  $\Gamma$  is an arbitrary finitely generated group we know practically nothing about the structure of the varieties  $R_n(\Gamma)$ ,  $X_n(\Gamma)$ . It has been studied for classes of infinite nilpotent and solvable groups (see [10], [15]) and in detail for the class of finite groups only. Recall that if  $|\Gamma| < \infty$  then the description of  $R_n(\Gamma)$ ,  $X_n(\Gamma)$  is given by the classical representation theory of finite groups. Namely, every representation is fully reducible and up to equivalence there is only a finite number of irreducible representations and all of them are uniquely determined by their characters; in particular, dim $X(\Gamma, G) = 0$ , i.e.  $X(\Gamma, G)$  is a finite set for all finite groups  $\Gamma$ .

For topological applications it is important to know the description of the varieties of *n*-dimensional representations and characters for those groups  $\Gamma$  which arise as fundamental groups of some natural classes of manifolds. At present the answer is known for fundamental groups  $\Gamma_g$  of compact orientable surfaces of genus g only. First Goldman [4] found the number of connected components of  $R(\Gamma_q, \operatorname{SL}_2(\mathbb{C}))$  in real and complex topology
