Abstract. We present an analysis of a 10-day continuous *ASCA* observation of the narrow-line Seyfert 1 galaxy IRAS 13224-3809. The total band (0.7–10 keV) light curve binned with 500 s reveals trough-to-peak variation by a factor ≥ 37 . Rapid X-ray variability with a doubling timescale of 500 s has also been detected. The soft (0.7–1.3 keV) and hard (1.3–10 keV) X-ray band light curves binned to 5000 s reveal trough-to-peak variations by a factor ≥ 25 and ~ 20 , respectively. The light curves in the soft and hard bands are strongly correlated without any significant delay. However, this correlation is not entirely due to changes in the power-law flux alone but also due to changes in the soft X-ray hump emission above the power law. The variability amplitude changes across the observation but is not correlated with the X-ray flux. The presence of a soft X-ray hump below ~ 2 keV, previously detected in *ROSAT* and *ASCA* data, is confirmed. Time resolved spectroscopy using daily sampling reveals changes in the power-law slope, with Γ_X in the range 1.74–2.47, however, day-to-day variations in Γ_X are not significant. The Soft hump emission is found to dominate the observed variability on a timescale of $\sim a$ week, but on shorter timescales ($\sim 20\,000$ s) the power-law component appears to dominate the observed variability. Flux resolved spectroscopy reveals that at high flux levels the power law becomes steeper and the soft hump more pronounced. This result is further confirmed using an earlier *ASCA* observation in 1994. The steepening of the photon-index with the fluxes in the soft and hard bands can be understood in the framework of disk/corona models in which accretion disk is heated by viscous dissipation as well as by reprocessing of hard X-rays following an X-ray flare resulting from coronal dissipation through magnetic reconnection events. Time dependent accretion disk-corona models are required to understand the observed correlation between the soft hump emission and the power-law flux.

1. Introduction

Seyfert 1 galaxies are an important class of active galactic nuclei (AGN). They show a large range in the width of their optical emission lines e.g., full width at half maximum (*FWHM*) of the $H\beta$ line is found to be in the range ~ 1000 – $10\,000$ km s⁻¹. Seyfert 1 galaxies that are at the lower end of the line width distribution with $FWHM(H\beta) \lesssim 2000$ km s⁻¹ are called the narrow-line Seyfert 1 galaxies (NLS1; Osterbrock & Pogge 1985; Goodrich 1989) and are distinguished from the bulk of the Seyfert 1s (“broad-line Seyfert 1s” or BLS1s). The NLS1 galaxies are also found to have strong Fe II emission and $[O\ III]\lambda 5007/H\beta < 3$ (Osterbrock & Pogge 1985; Goodrich 1989). However, Rodriguez-Ardilla et al. (2000) have shown that the ratio $[O\ III]\lambda 5007/H\beta$ does not clearly distinguish between NLS1 and BLS1. Also Veron-Cetty et al. (2001) have shown that when only the narrow component of $H\beta$ is considered, the above ratio is similar between NLS1s and Seyfert 2 galaxies. X-ray properties of NLS1s are even more remarkable. These AGNs very frequently exhibit rapid and/or

large amplitude variability (Boller et al. 1996; Forster & Halpern 1996; Molthagen et al. 1998). The excess variance for NLS1s is typically an order of magnitude higher than that observed for samples of BLS1s with similar luminosity distribution (Leighly 1999a; Turner et al. 1999b). Giant-amplitude X-ray variability (up to a factor of 100) has also been observed in several NLS1s (Boller et al. 1997; Brandt et al. 1999). Some NLS1 galaxies show extremely rapid variability (on timescales of a few hundred seconds) by a factor of about 2–3 (Remillard et al. 1991; Boller et al. 1997; Brandt et al. 1999; Dewangan et al. 2001a). *ROSAT* (0.1–2.4 keV) observations have revealed that the soft X-ray continuum slopes of NLS1s are systematically steeper than those of BLS1s (Boller et al. 1996), the photon index Γ_X (photon flux $f_E \propto E^{-\Gamma_X}$) sometimes exceeding 3. *ASCA* observations have shown that the hard X-ray 2–10 keV continuum slope too is significantly steeper in NLS1s than that in the BLS1s (Brandt et al. 1997; Turner et al. 1998; Leighly 1999b; Vaughan et al. 1999b). The very strong anti-correlation between *FWHM* of the $H\beta$ line and both the X-ray slopes in Seyfert 1s (Boller et al. 1996) and in quasars (Laor et al. 1997), and “excess variance” (Turner et al. 1999b) suggests that the remarkable X-ray properties of NLS1s are

Send offprint requests to: G. C. Dewangan,
 e-mail: gulab@tifr.res.in

possibly due to an extreme value of a fundamental physical parameter related to the accretion process.

A popular explanation for the distinct properties of NLS1 galaxies is that they have lower black-hole masses than the BLS1 galaxies. Smaller black-hole masses result in shorter timescales, thus naturally explaining the rapid X-ray variability, since the primary emission would originate in a smaller region around the central black-hole. Smaller black-hole masses also naturally result in narrower optical emission lines provided the size of the broad emission line region (BLR) scales with the luminosity (Laor 1998).

A comparison of the soft X-ray properties of Seyferts and Galactic black-hole candidates (GBHCs) led Pounds et al. (1995) to make an analogy between the two types of objects. They suggested that NLS1s are the high state analog of BLS1 galaxies. The high state GBHCs show strong soft X-ray excess, with blackbody temperature ~ 2 keV, above a steep power law and are thought to emit a higher fraction of their Eddington luminosity. This led Pounds et al. (1995) to postulate that NLS1s must also be emitting a higher fraction of their Eddington luminosity, hence higher accretion rates relative to the Eddington accretion rate ($\dot{m} = \frac{\dot{M}}{\dot{M}_{\text{Edd}}}$) are required. Since NLS1s have comparable luminosity to that of BLS1s, a higher fractional rate also means a lower black-hole mass.

The higher the fraction of the Eddington luminosity emitted, i.e. the higher the fractional accretion rate, the greater the temperature attained by the accretion disk, i.e. the disk emission becomes energetically dominant in the soft X-rays (Ross et al. 1992). Thus NLS1s might be expected to show disk components which peak at higher energies than for BLS1s. The spectral energy distribution (SED) from far-infrared to X-rays of NLS1 galaxies appears to be similar to that of BLS1 galaxies, but the *UV* luminosity of NLS1s tends to be smaller than that of BLS1s (Rodríguez-Pascual et al. 1997). The lower *UV* luminosity of NLS1 galaxies compared to that of BLS1s could be due to the shift of the big blue bump (BBB) towards higher energies. The steep soft X-ray spectrum could be the high energy tail of the BBB (Mathur 2000). Pounds et al. (1995) noted that the excess soft X-ray emission of NLS1s may cause an increased Compton cooling of hot electrons in the corona resulting in a steeper hard X-ray power law. Higher accretion rates also result in an ionized surface for the accretion disk (Matt et al. 1993). Evidence for the ionized disk is found in the form of $K\alpha$ emission from the ionized states of Fe in NLS1s (Comastri et al. 1998; Turner et al. 1998; Vaughan et al. 1999a; Comastri et al. 2001; Turner et al. 1999a; Ballantyne et al. 2001). However, the ionized Fe $K\alpha$ line is not unique to NLS1 galaxies, and some BLS1 galaxies also show ionized Fe $K\alpha$. This may suggest that the luminosity of the central source plays as important a role as the accretion rate (e.g., Guainazzi et al. 1998).

Alternative explanations for the extreme properties of NLS1s are: (i) the size of the BLR of NLS1s is larger (i.e., the BLR gas is more distant from the nucleus) than that in the BLS1s (Guilbert et al. 1983; Mason et al. 1996; Wandel & Boller 1998) resulting in the narrowness of the width of the permitted lines due to a lower orbital velocity; (ii) we have a

nearly face-on view of a flattened BLR in NLS1s (Osterbrock & Pogge 1985). Assuming the motion of the BLR gas around the central super-massive black-hole to be virialized, the narrowness of the lines is due to the fact that the gas is moving preferentially on a plane that is almost perpendicular to the line of sight resulting in the smaller velocity dispersions, hence the line widths are reduced by a factor $\sin i$, where $i = 0$ is face-on. However, Boroson & Green (1992) and Kuraszekiewicz et al. (2000) do not favor the low inclination model, while Nandra et al. (1997) showed that the inner regions of BLS1s also appear to be observed nearly face-on. Reverberation results (Kaspi et al. 2000; Peterson et al. 2000) find that the BLRs of NLS1s and BLS1s have comparable sizes, while NLS1s have virial masses that are one order of magnitude smaller than BLS1s. This result shows that the size of the BLR does not scale with the mass of the central black-hole but with the luminosity (Laor 1997) which is connected to the accretion rate. Dewangan et al. (2001a, 2001b) suggested that both the steeper X-ray emission and narrower width of the $H\beta$ line, and also the anti-correlation between the slope of the X-ray spectrum and the width of the $H\beta$ line could be due to the variation in the fractional accretion rate. In this scenario, the higher fractional accretion rate producing an increased accretion disk emission in the soft X-rays and a steeper power law in the hard X-rays, results in a higher radiative pressure per unit gravitating mass. Thus, for a given density distribution of diffuse material, the BLR clouds will form further out in a higher-intensity radiation field, resulting in the narrower emission lines.

Variability studies using long ASCA (Advanced Satellite for Cosmology and Astrophysics) observations have been a valuable tool to explore the nature of the soft X-ray excess emission and other spectral components of NLS1s (Turner et al. 2001b; Romano et al. 2002). A 35-day long ASCA observation of a NLS1 galaxy, Akn 564, revealed that a slower varying soft excess component is superimposed on a fast varying continuum component (Turner et al. 2001b). Similar results are also inferred from a 12-day ASCA observation of another NLS1 galaxy Ton S180 (Romano et al. 2002).

IRAS 13224-3809 is an extremely variable NLS1 galaxy at a redshift of 0.06667 and with soft (0.1–2.4 keV) X-ray luminosity of 3×10^{44} erg s⁻¹ (Boller et al. 1993). The *FWHM* of the $H\beta$ line of this source is only ~ 700 km s⁻¹ (Boller et al. 1993; Leighly 1999b) which is comparable to the width of the forbidden line [O III] $\lambda 5007$. *ROSAT* observations (Boller et al. 1993) showed a complex soft X-ray emission that was very steep ($\Gamma_X \sim 4.4$) and rapidly variable (change in intensity by a factor of 2 in ~ 800 s). Subsequent ASCA observations in 1994 confirmed the complex soft X-ray emission and variability (Leighly et al. 1997; Leighly 1999a, 1999b). A 30-day *ROSAT* HRI monitoring of IRAS 13224-3809 has revealed the most extreme and multiple giant amplitude X-ray variability (Boller et al. 1997).

In this paper we present the results from a 10-day ASCA observation of the NLS1 galaxy IRAS 13224-3809. In Sect. 2 we describe our observations and data reduction. In Sect. 3 we discuss the time variability of the source. We analyze the mean spectrum in Sect. 4 and time resolved spectra in Sect. 5. In Sect. 6 we present flux resolved spectroscopy. In Sect. 7 we

compare our results for IRAS 13224-3809 with the properties of Akn 564 and Ton S180. Finally, we discuss the results in Sect. 8 and summarize our results in Sect. 9.

2. Observation and data reduction

ASCA consists of four focal plane detectors, two CCDs (the solid-state Imaging Spectrometers, SIS0 and SIS1, 0.4–10 keV, Bruke et al. 1991) and two GISs (the Gas Imaging Spectrometers, GIS2 and GIS3, 0.7–10 keV, Ohashi et al. 1996, and references therein). All the four detectors operate simultaneously. ASCA observed IRAS 13224-3809 (Principal Investigator: K. M. Leighly) for a total duration of ~ 834 ks starting from JD=2451731.562 (for the screened data) in the 1CCD mode. The data were reduced using standard techniques (Revision 2). Data screening yielded an effective exposure time of 228 ks for SIS0, 226 ks for SIS1, and 271 ks for both the GISs. The mean SIS0 count rate was $(5.063 \pm 0.061) \times 10^{-2}$ count s^{-1} , which is about 30% higher than the SIS0 count rate of $(3.051 \pm 0.095) \times 10^{-2}$ count s^{-1} found during a previous ASCA observation in 1994 (Leighly et al. 1997; Leighly 1999a, 1999b).

After the launch in 1993, ASCA SIS detectors degraded gradually in efficiency at lower energies, due to the increased dark current levels and charge transfer inefficiency (CTI). This degradation resulted in SIS spectra which diverge from each other and from the GIS data. The instruments can diverge by as much as 40% for energies below 0.6 keV for data taken in 2000 January¹. The degradation in efficiency is not well understood and it could not be corrected for by any of the software at the time of writing this paper. There has been a non-linear evolution of the SIS CTI during the last phase of ASCA observations (AO-8). The SIS team has revised the calibration of the non-uniform CTI effect and released a new calibration file (*sisph2pi_130201.fits*) on 2001 March 29. The IRAS 13224-3809 data were calibrated using the above revised calibration file.

The divergence of the SIS detectors at low energies can be compensated for in the spectral analysis by employing the technique of Yaqoob et al. (2000), who provide an empirical correction by parameterizing the efficiency loss as a time-dependent absorption term² (“excess N_H ”). The correction for SIS0 follows a linear relationship, $N_H(\text{SIS0}) = 3.635857508 \times 10^{-8} (T - 3.0174828 \times 10^7) 10^{20} \text{ cm}^{-2}$, where T is the average of start and stop times of the observation measured in seconds since launch. The SIS1 excess absorption term does not follow the simple linear relationship with time but it is found that a slightly larger absorption column can be applied to the SIS1 data so that both the SIS detectors agree well at lower energies. For the observations of IRAS 13224-3809, $N_H(\text{SIS0}) = 7.53 \times 10^{20} \text{ cm}^{-2}$, where $T = 2.37 \times 10^8 \text{ s}$ and we adopted $N_H(\text{SIS1}) = 1.05 \times 10^{21} \text{ cm}^{-2}$.

3. Time variability

Light curves were extracted using bin sizes of 500 s in the band (0.7–10 keV) from the SIS data and 5000 s in the soft (0.7–1.3 keV) and hard (1.3–10 keV) bands from both the SIS and GIS data. The soft and hard bands were chosen to have similar signal-to-noise and to separate approximately the two spectral components – soft excess and power law (see Sect. 4). The exposure requirements for the light curves were that the bins be at least 50% and 10% exposed in each instrument for the 500 s and 5000 s curves, respectively. Background light curves were extracted from the source free regions and subtracted from the source light curves after appropriate scaling to compensate for different sizes of extraction regions. We combined the 500 s light curves from the two SIS detectors only, and 5000 s curves in each band from all the four detectors. The observed counts correspond to a mean observed flux of $6.7 \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$, and luminosity of $5.9 \times 10^{42} \text{ erg s}^{-1}$ (assuming $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $q_0 = 0.5$) in the 2–10 keV band.

Figure 1 shows the background subtracted 0.7–10 keV band light curve with 500 s bins. Figure 2 shows the background subtracted SIS soft-band and SIS+GIS hard-band light curves in 5000 s bins. Also shown in Fig. 2 is the 0.7–10 keV band light curve, and hardness ratio (HR) defined as the ratio of count rates in the 1.3–10 keV and 0.7–1.3 keV bands.

The light curves binned to 5000 s (Fig. 2) show trough-to-peak variations in the count rate by a factor of ≥ 25 in the soft band, ~ 20 in the hard band. The light curve sampled on 500 s (Fig. 1) reveals even higher amplitude variations due to fast flickering, with a maximum amplitude of variability of a factor ≥ 37 . Close up examination of the light curve in Fig. 1 reveals several rapid variable events. The most rapid event, shown in Fig. 3, occurred at $2.755 \times 10^5 \text{ s}$ after the beginning of the observation. The count rate increased from 0.12 to 0.24 count s^{-1} just within 500 s. Several variable events with a change in the count rate by a factor of ~ 3 on a timescale of 3000–5000 s have been detected e.g., events seen at $3.265 \times 10^5 \text{ s}$, $3.69 \times 10^5 \text{ s}$, and $5.775 \times 10^5 \text{ s}$. The soft and hard X-ray light curves, shown in Fig. 2, show similar variability properties. We have calculated the cross correlation function (CCF) of the hard X-ray (1.3–10 keV) flux with respect to the soft X-ray (0.7–1.3 keV) flux. The CCF is plotted in Fig. 4, which shows strong correlation between the hard and soft X-ray fluxes without any significant time delay. Since the power-law component contributes $\sim 32\%$ of the total flux in the soft (0.7–1.3 keV) band as inferred from the mean spectrum (see Sect. 4), the observed correlation is partly due to variation in the power-law component alone. However, variability of the power-law flux alone is not sufficient to explain the soft X-ray variability. This can be seen from Fig. 5 which shows an expanded view of the flaring event seen at $1.9 \times 10^5 \text{ s}$ after the beginning of the observation. The 0.7–1.3 keV band flux changed by a factor of ~ 4 from $0.010 \pm 0.003 \text{ count s}^{-1}$ to $0.044 \pm 0.006 \text{ count s}^{-1}$, while the 1.3–10 keV band flux changed by a factor of 6 from $0.016 \pm 0.005 \text{ count s}^{-1}$ to $0.097 \pm 0.009 \text{ count s}^{-1}$. If the soft X-ray flux above the hard X-ray power law remains constant, so that the observed soft X-ray variability is entirely due

Fig. 1. SIS0+SIS1 light curve (in 500 s bins) of IRAS 13224-3809 obtained from the ASCA data taken during 2000 July 6–15. The light curves were extracted in the energy band of 0.7–10 keV. The horizontal axis shows the time in seconds from the beginning of the observation (MJD = 51731.188273 day).

Fig. 2. Light curves of IRAS 13224-3809 with 5000 s bins. The top panel is the SIS soft-band (0.7–1.3 keV) light curve; the second panel is the SIS+GIS hard-band (1.3–10 keV) light curve; the third panel is the total band (0.7–10 keV) light curve. The last panel shows the hardness ratio defined as the ratio of the count rates in the 1.3–10 keV and 0.7–1.3 keV bands. The light curves have been corrected for the background contribution. The horizontal axis shows the time in seconds from the beginning of the ASCA observation (MJD = 51731.188273).

to changes in the power-law flux alone, then a factor of ~ 12 change is required in the power-law flux in the 0.7–1.3 keV band. This required change is much higher than the factor of 6 observed in the 1.3–10 keV flux. Therefore, the soft-excess flux above the hard X-ray power law must also have changed by a factor of ~ 2.6 either simultaneously or with a short time delay with respect to the hard 0.3–10 keV flux.

From Figs. 2 and 5, it is clear that some events have a sharper rise in hard X-rays e.g., the flaring event seen at 1.9×10^5 s after the beginning of the observations, with

accompanying change in the hardness ratio, while during other flaring events between $3 - 6 \times 10^5$ s, there is no change in the hardness ratio. When the light curves are binned on a timescale of a day, another important type of behavior of the source is observed. Figure 6 shows the light curves and HR with time bins of a day. The HR appears to increase when the flux is rising or falling but settles down to a lower value when the maximum flux is reached. The hardness ratio tells only the relative changes in the soft and hard bands. Any possible change in the spectral shape will be investigated in Sect. 5.

Fig. 3. The most rapid variability event observed during the 10-day ASCA observation of IRAS 13224-3809. The light curve is an expanded view of the light curve shown in Fig. 1 during the variability event.

Fig. 4. Cross-correlation function of hard (1.3–10 keV) flux with respect to the soft (0.7–1.3 keV) flux observed during the year 2000.

3.1. Fractional variability amplitude

The fractional variability amplitude F_{var} and its error $\sigma_{F_{\text{var}}}$ are defined as

$$F_{\text{var}} = \sqrt{\frac{S^2 - \langle \sigma_{\text{err}}^2 \rangle}{\langle X \rangle^2}}, \quad \sigma_{F_{\text{var}}} = \frac{1}{F_{\text{var}}} \sqrt{\frac{1}{2N} \frac{S^2}{\langle X \rangle^2}}. \quad (1)$$

(Edelson et al. 2001) where S^2 is the total variance of the light curve, $\langle \sigma_{\text{err}}^2 \rangle$ is the mean squared error, and $\langle X \rangle$ is the mean count rate.

First we calculated the fractional variability amplitude of the total band (0.7–10 keV) light curve with 500 s bins to be $F_{\text{var}} = 73.5 \pm 2.6\%$. This quantity measures deviations relative to the mean, integrated over the entire duration of the observation. We also calculated F_{var} in the soft (0.7–1.3 keV) and the hard (1.3–10 keV) bands, from the light curves shown in Fig. 2 with 5000 s bins. F_{var} thus calculated is $75.3 \pm 4.6\%$ in the 0.7–1.3 keV band, and $66.1 \pm 3.8\%$ in the 1.3–10 keV band.

Fig. 5. An X-ray flare, in the soft and hard bands, from IRAS 13224-3809 observed 1.9×10^5 s after the beginning of the observation in the year 2000.

Fig. 6. Same as Fig. 2 except that the light curves are shown with time bins of 1 day.

We also measured F_{var} for each day after splitting the light curves with 5000 s bins into 10 evenly-sampled sections across the 10-day ASCA observation. Figure 7 shows F_{var} in the soft, and hard bands calculated for each day. The soft-band F_{var} changes across the 10-day observation, a constant fit resulting in a minimum χ^2 of 21.88 for 9 d.o.f. The hard-band F_{var} , however, does not appear to vary significantly, a constant fit to the hard-band F_{var} curve giving a minimum χ^2 of 9.13 for 9 d.o.f. However, there appears to be some similarity in the soft and hard-band F_{var} curves in Fig. 7. As already mentioned, the power-law component contributes significantly to the unabsorbed soft-band X-ray flux (see Sect. 4). Therefore, the gross similarity between the soft-band and hard-band F_{var} and a stronger variability of the soft-band F_{var} can be understood if the changes in the soft-band F_{var} are not only caused by variations in the power-law continuum flux but also by the intrinsic variations in the soft-excess component above the power law. It is quite possible that the variations in the above two

Fig. 7. Variability properties of IRAS 13224-3809. First two panels from the top show fractional variability amplitude in different energy bands as a function of time. The last panel shows the SIS0 count rate in the 0.7–10 keV band.

spectral components are correlated probably with a short time delay. The quantity F_{var} in the soft or hard band, is not correlated with the observed count rate as can be seen in Fig. 7 suggesting that the variability properties do not depend on the flux level.

4. The mean spectrum

For each detector, photon energy spectrum of IRAS 13224-3809 was accumulated from the entire observation. Pulse invariant channels were appropriately grouped for the spectral analysis while considering the degradation in the energy resolution of the SIS detectors. The data from the four instruments were fit simultaneously while keeping the relative normalizations free allowing for the small differences in the calibration of the absolute flux, and differences in the fraction of encircled counts contained in the SIS and GIS extraction cells. The spectral fits were performed with the XSPEC V11.0.1 package, using response matrices released in 1997 for the GISs, and response files generated using HEASoft v5.0.4 for the SISs.

The spectral shape was first determined by fitting a redshifted power-law model modified by Galactic absorption ($N_{\text{H}} = 4.79 \times 10^{20} \text{ cm}^{-2}$; Dickey & Lockman 1990; Model A) to the data above 2 keV. An additional absorption term was used for the SIS0 and SIS1 to compensate for the low energy degradation as described in Sect. 2. The models for Galactic absorption use the absorption cross-sections of Balucinska-Church & McCammon (1992). For this exercise we used the SIS data in the energy band of 2–7.32 keV and GIS data in the 2–10 keV band (both in the observer’s frame). The power-law fit yielded $\Gamma_{\text{X}} = 2.02 \pm 0.08$ and a minimum χ^2 of 243.52 for 183 dof. The errors quoted, here and below, were calculated for the 90% confidence level based on $\chi_{\text{min}}^2 + 2.71$.

The results of the fit described above are given in Table 1 for Model A. We list the best-fitting power-law photon index (Γ_{X}) in the 2–10 keV band, the unabsorbed power-law flux (f_{X}^{PL}) in the energy band of 2–10 keV, the minimum reduced

χ^2 (χ_{red}^2), and dof. The deviation of the best-fit model from the observed data is shown in Fig. 8 in terms of $\chi = \frac{N_i^{\text{obs}} - N_i^{\text{mod}}}{\sigma_i}$, where N_i^{obs} is the observed counts in energy channel i , σ_i is the standard error on N_i^{obs} , and N_i^{mod} is the best-fit model counts in channel i . The data below 2 keV is also shown in Fig. 8. This plot helps to indicate the significant features in the spectrum. A strong soft excess is evident, appearing as a hump of emission below 2 keV. This feature was also found in the ROSAT PSPC observations (Boller et al. 1993), and in the previous ASCA observation of 1994 (sequence number 2011000, Leighly 1999b). Hereafter, we refer to this component as the “soft hump”. Minor calibration problems are also visible mainly below 2 keV. We do not detect an Fe K α line from IRAS 13224-3809 in the energy range 6.4–7 keV where the deviations are below 3σ level (see Fig. 8). The 90% confidence upper limit for the equivalent width of Fe K α line is found to be ~ 400 eV.

4.1. The soft hump

We confirm the presence of the soft X-ray excess emission component previously observed by Boller et al. (1993) and Leighly (1999b). Similar features are well known in other NLS1 galaxies, e.g. in RE J1034+393 (Pounds et al. 1995), Akn 564 (Turner et al. 2001b), and Ton S180 (Romano et al. 2002). In these objects, Chandra LETG results (Ton S180, Turner et al. 2001a; NGC 4051, Collinge et al. 2001) show that the soft hump is a smooth continuum component, as opposed to a blend of unresolved spectral features. This allows us to choose a continuum component model to parameterize the soft hump emission. We use the blackbody model to characterize the soft hump component as it adequately models the shape and flux of the soft hump. We used the SIS data in the range 0.7–7.32 keV simultaneously with the GIS data in the range 1–10 keV, and fitted the redshifted blackbody and power-law model modified by the Galactic absorption (Model B). An additional absorption term as described above was also used for the SIS data. The best-fit blackbody and power-law model yielded a rest-frame temperature $kT = 130.7^{+3.4}_{-3.2}$ eV, absorption corrected blackbody flux, $f_{\text{X}} = 4.34 \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$ in the energy band of 0.7–1.3 keV, and $\Gamma_{\text{X}} = 2.11 \pm 0.05$ for minimum $\chi^2 = 421.98$ for 244 dof. The observed data and the best-fit model are shown in Fig. 9. Also shown in Fig. 9 are the deviations of the observed data from the best-fit model. The fit is poor mostly due to calibration problems at low energies and residuals near 1 keV. The absorption feature near 1 keV was detected in the earlier ASCA observation of 1994 and has been interpreted as the blueshifted absorption edges of oxygen (see Leighly et al. 1997). Here we note that the GIS and SIS detectors do not agree at the position of the absorption feature and we do not fit an absorption line or edge model. The uncertainty in the low energy calibration and the degradation in the energy resolution of the SIS detectors make it difficult to explore the absorption feature. We also note that the parameterization of the soft hump as a blackbody does not alter the power-law slope significantly. We find that the power-law continuum contributes 32.3% of the flux in the soft 0.7–1.3 keV band in

¹ Model A is the best-fit redshifted power-law model in the 2–10 keV band modified by the Galactic absorption. Model B is the combination of redshifted blackbody and power law modified by the Galactic absorption. The best-fit parameters for the model B were derived using the total energy band of 0.7–10 keV.

² Intrinsic flux in the energy band of 0.7–10 keV and in the units of 10^{-13} erg cm⁻² s⁻¹.

³ Intrinsic luminosity in the rest frame and in the energy band of 0.7–10 keV and in the units of 10^{42} erg s⁻¹.

⁴ Intrinsic flux of the soft hump (described by a blackbody) in the 0.7–2 keV band and in the units of 10^{-13} erg cm⁻² s⁻¹.

⁵ Intrinsic flux of the power-law component in the 2–10 keV band and in the units of 10^{-13} erg cm⁻² s⁻¹.

⁶ The Low, High, and Intermediate states correspond to the observed SIS0 count rates of ≤ 0.07 , $0.07 - 0.14$, and > 0.14 count s⁻¹, respectively.

the mean spectrum while the soft hump above the power-law contributes only 2.7% in the 1.3–10 keV band. Although the power law has a significant contribution to the soft X-ray flux, the blackbody contribution to the hard X-ray flux is negligible.

5. Time resolved spectroscopy

5.1. Method and selection details

To examine the spectral variations of IRAS 13224-3809, we extracted 10 time-selected spectra across the 9.6-day ASCA obser-

vation using Xselect 2.0. As the source is not bright enough, it was not possible to extract spectra following individual flares and dips with sufficient signal-to-noise ratio. Instead, we chose the sampling timescale of one day, except for the last day of observation for which the sampling time was 0.6 day. The vertical dotted lines in Fig. 1 show our 10 intervals within which spectra were extracted. The resulting “on-source” average exposure time was ~ 20 ks per detector. We set the ancillary response, and response matrix files to be those of the mean spectrum. Again, the energy channels were appropriately grouped to achieve a good signal-to-noise (a minimum of

Fig. 8. Deviation χ of the mean spectrum of 2000 July from the best-fit 2–10 keV power law modified by Galactic absorption where $\chi = \frac{N_i^{\text{obs}} - N_i^{\text{mod}}}{\sigma_i}$, N_i^{obs} is the observed counts in energy channel i , σ_i is the standard error on N_i^{obs} , and N_i^{mod} is the best-fit model counts in channel i .

Fig. 9. Mean spectra of IRAS 13224-3809 obtained in the year 2000 and the best-fit model – blackbody and power law modified by the Galactic absorption (Model B) fitted over the entire energy range (top panel) and deviation of the observed mean spectrum from the best-fit model (bottom panel).

20 counts per energy channel) while considering the spectral resolution of each detector. All fits were performed by fixing the relative instrument normalizations obtained from the best-fit values from the mean spectrum. The correction for the low energy SIS problem was performed in the same way as for the mean spectrum. All models included the Galactic absorption as

before. Figure 10 shows the results of our analysis in the form of a time series for the various parameters and are described in detail below. Time assignments of the spectra refer to the mid point of the observation, in days, from the beginning of the observation.

Fig. 10. Spectral variability of IRAS 13224-3809. From the top, the time series are the photon index, power-law flux in units of 10^{-13} erg cm^{-2} s^{-1} and in the 2–10 keV band, blackbody temperature in eV, blackbody flux in units of 10^{-13} erg cm^{-2} s^{-1} and in the 0.7–2 keV band, and the total flux in the 0.7–10 keV band. All the fluxes have been corrected for the Galactic absorption.

5.2. Variability of the continuum

We fitted each of the 10 time-selected spectra by a redshifted power-law model (Model A) using the 2–7.32 keV band for the SIS data and the 2–10 keV band for the GIS data (the same data exclusion as for the mean fit). The results of the fits are listed in Table 1. In order to explore the time evolution of the soft hump, we also fitted each spectrum by a combination of redshifted blackbody and power-law models (Model B). For these fits, SIS data in the band 0.7–7.32 keV and GIS data in the band 1–10 keV were used for each time-selected spectrum. The results of these fit are also listed in Table 1. As can be seen in Table 1, there are no significant changes in the best-fit photon indices obtained from fitting models A and B. Figure 10 shows the time series for the photon index, and model power-law flux in the 2–10 keV band, blackbody temperature, blackbody flux in the 0.7–2 keV band, and total flux in the 0.7–10 keV band. Note that the best-fit values for the power-law model plotted in Fig. 10 are those derived from model B. The best-fit values of Γ_X range from 1.74 to 2.47 across the 10-day observation, but the day-to-day variations are not significant. A significant variation in the Γ_X is observed between day 5 and day 9, the change in Γ_X being 0.57 ± 0.21 . We also note that the power-law component dominates the 2–10 keV band and the flux variations in this band on a timescale of \sim a day are due to the changes in the continuum level.

5.3. Variability of the soft X-ray hump

The blackbody flux (f_X^{BB}) in the 0.7–2 keV band roughly follows the power-law flux (f_X^{PL}) in the 2–10 keV band (see Fig. 10). The trough-to-peak variation in the soft hump flux is by a factor of ~ 4.7 , while that of the power-law flux is by a factor of ~ 3.5 suggesting that the soft hump is more variable than the power-law component on timescales of \sim a week. The

blackbody temperature varies from 98.4 eV to 137.6 eV across the 10-day observation, but these variations are not significant considering the error bars. The contribution of the power-law component to the total flux in the 0.7–1.3 keV band varies from 24% on day 10 to 48% on day 3 and is not correlated with any of the other spectral parameters.

To examine the time evolution of soft hump flux, we constructed a plot to highlight the variation of the *soft hump above the power law*. Figure 11 shows the *deviations* of the observed data from the best-fit 2–10 keV power-law model for all the 10 spectra. The data below 2 keV have also been plotted. We note that the soft hump is always evident above the power-law continuum. Strong variations in the soft hump are also evident.

5.4. Correlation between spectral parameters

In order to investigate possible correlation between spectral parameters, we have calculated linear correlation coefficients. Table 2 shows the matrix of linear correlation coefficients and the corresponding significance levels. Figure 12 shows plots of spectral parameters. The most significant correlations are those involving fluxes, both soft hump flux and power-law flux are strongly correlated with the total flux. The power-law photon index is better correlated with the soft hump flux (at 96.6% level) than with the power-law flux (at 91.8% level) suggesting that the shape of the power law is probably more sensitive to the seed photons than to the changes in the power-law flux. The soft hump flux is correlated with the blackbody temperature as is expected for blackbody emission.

6. Flux resolved spectra

The soft hump flux and the power-law flux appear to be correlated with the photon index at significance levels of 96.6% and 91.8% (Table 2; see also Fig. 12). In order to improve the statistical significance and to further explore the dependence of spectral parameters, we have carried out spectral analysis at different flux levels. We extracted three averaged spectra corresponding to the SIS0 count rates of ≤ 0.07 count s^{-1} (low), 0.07 – 0.14 count s^{-1} (intermediate), and ≥ 0.14 count s^{-1} (high). The spectra were analyzed in the same way as before and the results of the spectral fitting are given in Table 1. Figure 13 shows the deviation of the data from the best-fit 2–10 keV power law. In all the three states, the soft hump is present above the power law and is strongly variable. There is a significant change in the power-law slope between the low and the high states, $\Delta\Gamma_X = 0.44 \pm 0.12$. The soft hump flux in the 0.7–2 keV band also varied between the two states by a factor of ~ 5.6 , while the power-law flux in the 2–10 keV band varied by a factor of ~ 3.2 . Figure 13 also shows the contours of allowed values of Γ_X and blackbody normalization at 68%, 90%, and 99% confidence levels. It is clear from the contour plot that when the intensity of the source increases, the power law becomes steeper and the soft hump stronger.

In order to further confirm the above results, we have also analyzed the data obtained from an earlier observation in 1994 with ASCA. First we extracted light curves using bin sizes of

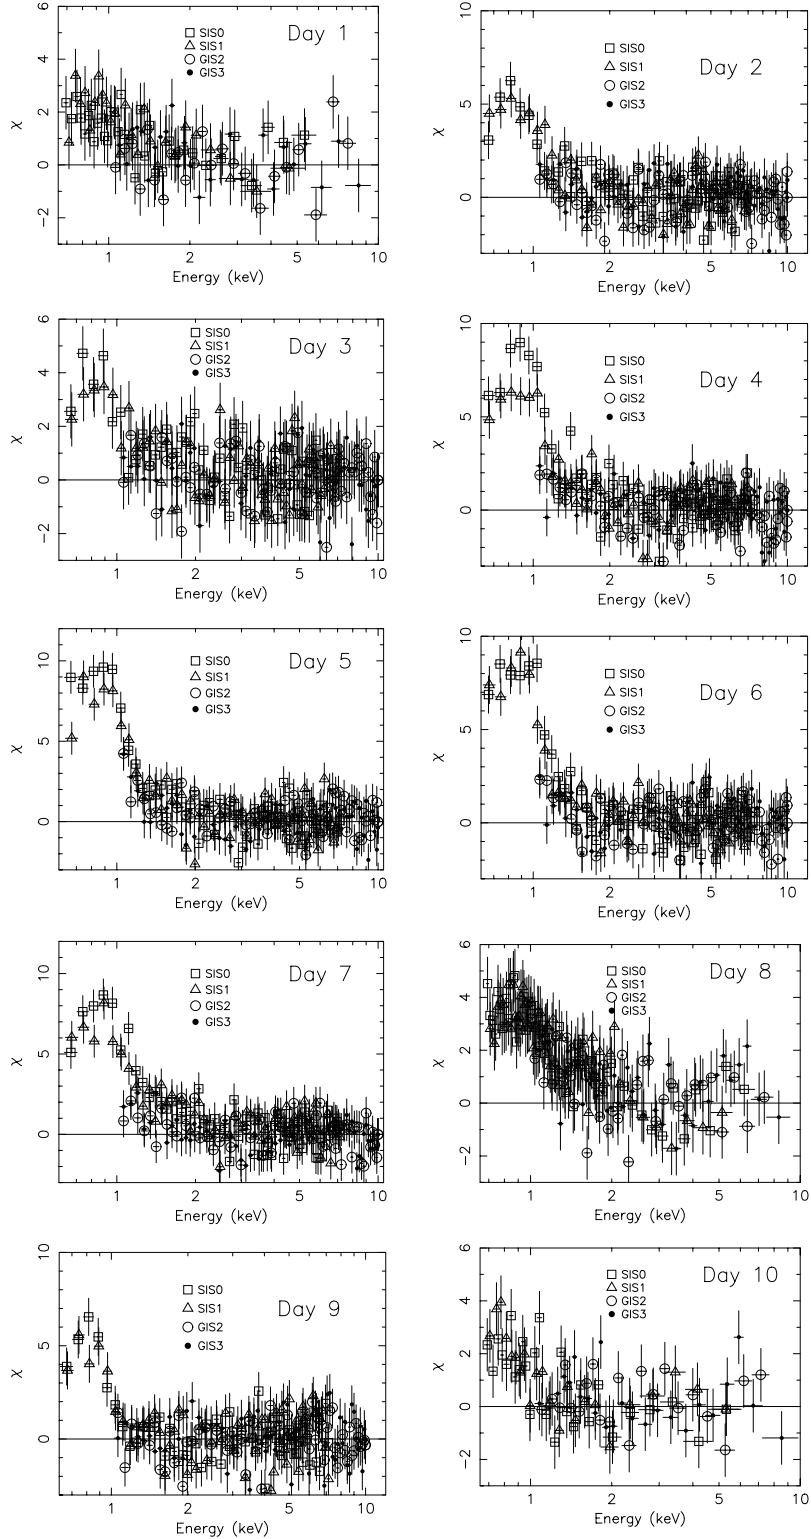

Fig. 11. Deviations χ of the time-selected spectra from the 2–10 keV best-fit power-law model modified by the Galactic absorption. A strong variation in the soft hump emission above the power law is evident.

500 s in the total band (0.7–10 keV) for the SISs. Background light curves were also extracted and the source light curves have been corrected for the background contribution. The exposure requirements were that the 500 s bins be at least 50% exposed. The final light curve was constructed after combin-

ing the light curves from the two SIS detectors and is shown in Fig. 14. The timing properties of the source using these data have been studied in detail by Leighly (1999a). Our aim here is to show our time selection for the low and the high intensity states of the source used for spectral analysis. We extracted

spectra from the two time intervals where the count rate is low (low state) and also from the time interval where the source count rate is high (high state). We also extracted spectra from the total time interval of the observation (mean spectrum). The spectra were analyzed in the same way as before except for the SIS gain correction which was not used. The mean, low and high state spectra were fitted by a redshifted power law modified by the Galactic absorption and in the energy band of 2–10 keV (Model A). The best-fit parameters are listed in Table 3. The deviations of the observed data from the best-fit power law are shown in Fig. 15. The soft excess, seen in Fig. 15, was again parameterized by a redshifted blackbody. The best-fit parameters obtained from the blackbody and power law modified by the Galactic observation (model B) are also listed in Table 3. It is evident from Table 3 that the photon index becomes steeper with corresponding increase in the blackbody flux in the high state compared to the low state. The same result is also seen in the χ^2 contour plots of Γ_X and blackbody normalization in Fig. 15. The above result is similar to the results shown in Fig. 13.

7. Comparison with Akn 564 and Ton S180

A comparison of our results for IRAS 13224-3809 with those obtained for Akn 564 (Turner et al. 2001b) and Ton S180

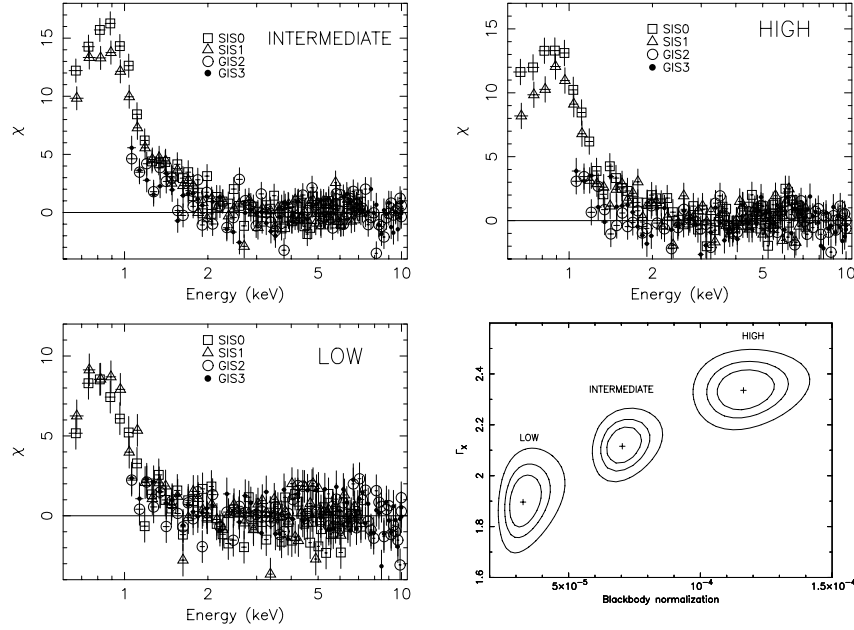

Fig. 13. Deviations χ of the flux-selected spectra from the best-fit 2–10 keV power law in the low, intermediate, and high state and the confidence contours at 68%, 90%, and 98% levels of the photon indices and blackbody normalizations derived from the best-fit Model B.

Fig. 14. Light curve of IRAS 13224-3809 sampled with 500 s and in the total energy bands derived from the observation of 1994. The vertical dotted lines show the time selection for the low and high flux states.

(Romano et al. 2002) reveals a broad similarity in the overall shape of the X-ray spectra (strong soft X-ray excess, steep power law) and variability properties. However, there are some important differences: (i) An Fe $K\alpha$ line is not detected from IRAS 13224-3809, while both Akn 564 and Ton S180 show the presence of an Fe $K\alpha$ line with a large equivalent width from highly ionized material. (ii) The contribution of the power law to the soft hump emission is only 32% in IRAS 13224-3809 while it is 75% for Akn 564 and 72% for Ton S180. (iii) The mean photon index ($\Gamma_X = 2.11^{+0.05}_{-0.06}$) of IRAS 13224-3809 is flatter than that of Akn 564 ($\Gamma_X = 2.538 \pm 0.005$) and Ton S180 ($\Gamma_X = 2.44 \pm 0.02$). (iv) The power-law slope appears to be correlated with the soft hump flux in Ton S180 and IRAS 13224-3809 while the correlation is absent in Akn 564. (v) The variability amplitude of the soft hump and power-law components are higher in IRAS 13224-3809 than that of Akn 564 and Ton S180.

8. Discussion

IRAS 13224-3809 shows the rapid and large amplitude variability seen earlier with *ROSAT* (Boller et al. 1993; Boller et al. 1997) and *ASCA* (Leighly 1999a). The 0.7–10 keV band light curve with 500 s bins shows trough-to-peak variation by a factor ≥ 37 during our 10-day *ASCA* observation. Rapid X-ray variability by a factor of 2–3 on a timescale of ~ 2000 s has also been observed. During the 10-day observation, the light curves sampled with 5000 s bins show trough-to-peak variations by a factor ≥ 25 in the soft band (0.7–1.3 keV), and about a factor of 20 in the hard band (1.3–10 keV). Variability events appear to be sharper in the hard X-ray band than in the soft X-ray band, and the intensities in the two bands are strongly correlated. Changes in the power-law component alone are not sufficient to produce the observed correlation but the soft hump above the power law changes its flux simultaneously or with a short time delay (see Fig. 5 and Sect. 3).

Fig. 15. Deviation χ of the spectra, observed in 1994, from the best-fit 2–10 keV power law. See text and Fig. 14 for definition of different spectra. Also shown are the confidence contours at 68%, 90%, and 98% levels of the photon index and blackbody normalization from the blackbody and power-law model fits to the different spectra.

The mean photon index of the X-ray power law, obtained from the spectral fit to the mean spectrum, is $\Gamma_X = 2.11^{+0.05}_{-0.06}$. The contribution of the hard X-ray power-law component to the flux in the soft band (0.7–1.3 keV) is only about 32% which is much smaller than that found for Akn 564 (75%, Turner et al. 2001b) and Ton S180 (72%, Romano et al. 2002), suggesting that the soft hump component is more pronounced in IRAS 13224–3809. Our time resolved spectroscopy reveals variations in Γ_X from $1.74^{+0.35}_{-0.34}$ to $2.47^{+0.12}_{-0.13}$, implying a $\Delta\Gamma_X = 0.73 \pm 0.37$. The mean power law appears to be flatter than that obtained for other NLS1 galaxies like Akn 564 ($\Gamma_X = 2.538 \pm 0.005$, $\Delta\Gamma_X = 0.27$, Turner et al. 2001b) and Ton S180 ($\Gamma_X = 2.44 \pm 0.02$, $\Delta\Gamma_X = 0.24$, Romano et al. 2002) and the variation in Γ_X is slightly higher in spite of the fact that the time span of the ASCA observations for the later two objects were longer. Thus IRAS 13224–3809 shows higher amplitude variability in the power-law slope as well as in the soft hump and the power-law intensity. This indicates that the physical parameters governing the X-ray emission vary by larger factors in IRAS 13224–3809 compared to that for Akn 564 and Ton S180.

8.1. The Γ_X -luminosity relation

Our time resolved spectroscopy has revealed that the 2–10 keV continuum steepens with increase in the flux. The photon index changes by ≈ 0.4 with the corresponding change in the power-law flux being a factor of ~ 3.2 between the low and high flux states observed in the year 2000. Similar behavior is seen during the 1994 observations. Figure 16 shows the plot of Γ_X against the 2–10 keV flux. The steepening of Γ_X with flux has also been observed in a number of Seyfert 1 galaxies

Fig. 16. The observed photon index in the 2–10 keV band, derived from the time resolved spectroscopy of 2000 (filled circles) and 1994 (open circles) observations, plotted against the observed count rate in the same energy band. The count rate is the average of the GIS2 and GIS3 count rates. Also shown is the best-fit function of the form $\Gamma_X = \Gamma_0 - KF^{-\delta}$. The best-fit parameters are $\Gamma_0 = 3.24 \pm 0.97$, $\delta = 0.39 \pm 0.32$.

(e.g., Singh et al. 1991; Done et al. 2000; Zdziarski & Grandi 2001; Vaughan & Edelson 2001, and Nandra 2001) and can be understood in the framework of thundercloud and accretion disk model of Merloni & Fabian (2001). The basic building blocks of this model are the active regions above an accretion disk, viewed as magnetic thunderclouds and triggered by magnetic reconnection. The sizes of the active regions are distributed as a power law. Rapid X-ray flares are produced in the active regions by inverse Compton scattering of soft photons from the disk and Γ_X -luminosity relation of the form $\Gamma_X = \Gamma_0 - KL^{-\delta}$ is expected (Merloni & Fabian 2001), where

the asymptotic value of Γ_X , Γ_0 , depends mainly on the optical depth τ_T of the active regions and disk or seed photon intensity. The exponent δ , which determines the amount of spectral variation, is mainly dependent on the spatial distribution of correlated flares. We have fitted the above $\Gamma_X - L$ relation to the IRAS 13224-3809 data (see Fig. 16) and obtained the best-fit values $\Gamma_0 = 3.24 \pm 0.97$, $\delta = 0.39 \pm 0.32$, where the quoted errors are at 1σ level. Thus for IRAS 13224-3809, the asymptotic photon index is similar within errors to that obtained for the Seyfert 1 galaxy MCG-6-30-15 ($\Gamma_0 = 2.30^{+0.63}_{-0.02}$; Merloni & Fabian 2001). Given the large error bars in Γ_0 for IRAS 13224-3809 as well as for MCG-6-30-15, the coronal optical depth for IRAS 13224-3809 does not appear to be significantly different from that inferred for MCG-6-30-15 ($\tau_T \geq 1.5$). However, better quality data such as that obtained from monitoring observations with *XMM-Newton* are required to make a firm conclusion. In the framework of thundercloud model a smaller covering fraction of the active regions is required for IRAS 13224-3809 than for MCG-6-30-15. The smaller the covering fraction, the larger the observed variability and the greater the chance of a large flare to occur (Merloni & Fabian 2001).

8.2. The soft hump emission

Our time resolved spectroscopy has revealed that the soft hump emission and the power-law flux are correlated (see Figs. 10, 13, 15). Pounds et al. (1995) first noted that the reprocessing of hard X-rays is insufficient to produce the observed soft hump emission of NLS1 galaxies and the soft hump emission could be the intrinsic disk emission resulting from near or super-Eddington accretion rates. In this scenario, sharper variability events are expected in the soft X-rays than in the hard X-rays which is contrary to that observed from IRAS 13224-3809 (see Fig. 5). On the other hand, in the framework of reprocessing models, sharper variability events are expected in the hard X-rays than in the soft X-rays. Although a correlation between the soft and hard X-ray flux is expected in both the above scenarios, it is difficult to understand the origin of soft X-ray emission either as the intrinsic disk emission or as the reprocessing of hard X-rays.

We propose yet another mechanism which may be partly responsible for the observed soft hump emission from NLS1 galaxies. If the accretion rate is super-Eddington, the accretion flow is likely to be dense and optically thick. The inner regions of such a disk are supported by the strong radiation pressure. Consequently, the disk puffs up and becomes geometrically thick (see e.g. Collin 2001). The electron density of the accretion disk emitting the big blue bump (BBB) can be written as

$$n_e \sim 3 \times 10^{16} T_5^{-1} M_8^{-1} \left(\frac{L_X}{L_{\text{Edd}}} \right) \left(\frac{R}{10R_S} \right)^{-2} \text{ cm}^{-3} \quad (2)$$

(Collin 2001), where T_5 is the temperature of the disk in units of 10^5 K, M_8 is the mass of the black-hole in units of $10^8 M_\odot$, R is the radial distance from the SMBH, R_S is the Schwarzschild radius, L_X and L_{Edd} are the X-ray and Eddington luminosity, respectively. For NLS1 galaxies, $T \sim 10^6$ K, $M \sim 10^6 M_\odot$,

thus $n_e \sim 3 \times 10^{12} \text{ cm}^{-3}$ for $R = 10 R_S$. If the disk thickness $H \gtrsim \frac{1}{n_e \sigma_T} \sim 10^{12} \text{ cm} \sim 3 R_S$, then the disk is optically thick for Thomson scattering. Thus for super Eddington rates, the disk can be optically thick and the high energy photons from the corona incident onto the disk will lose energy by direct Compton scattering and the disk electrons will gain energy. Due to the Coulomb interaction, electrons will quickly thermalize thus increasing the disk temperature and hence increasing the soft hump emission. The soft hump emission of NLS1 galaxies, therefore, may consist of intrinsic disk emission, reprocessing of hard X-ray emission by photoelectric absorption and by direct Compton scattering.

8.3. Correlation between the power-law flux and the soft hump emission

The soft-band flux and the power-law flux change either simultaneously or with short time delay (see Fig. 4). Our time resolved spectroscopy has revealed that the soft hump flux in the 0.7–2.0 keV band changes by the larger factor (~ 4.7) than the change (by a factor of ~ 3.4) in the power-law flux in the 2–10 keV band on a timescale of \sim a week. However, on a timescale of 20000 s the power-law flux changes by a larger factor (~ 6) than the change in the soft hump flux (by a factor of ~ 2.6) (See Fig. 5 and Sect. 3). The above trend suggests that it is the power-law component that is responsible for the most rapid ($\lesssim 1000$ s) variability while the soft hump dominates the longer timescale (\gtrsim a week) variability. Thus the 500 s variability reported here and 800 s variability of IRAS 13224-3809 reported in Boller et al. (1993) in the *ROSAT* band could be entirely due to changes in the power-law component. However, better signal-to-noise data over a broad energy band, for example with *XMM-Newton* is required to verify the above idea. Boller et al. (1993) rejected the standard thin accretion disk model, in spite of the good-fit to the *ROSAT* PSPC data, on the ground that the standard disk emission cannot produce the observed soft X-ray variability as the shortest timescales (e.g. thermal timescale, sonic timescale) possible for standard thin disks are longer than the observed variability timescale by a factor of 2–3. This apparent problem can be resolved if the observed rapid variability in the *ROSAT* band is due to the changes in the power-law component alone. If the heating of the corona is by magnetic reconnection (Merloni & Fabian 2001), the variability timescale could be as short as the coronal dissipation timescale which is given by $\tau(R) \simeq \frac{R}{R_S} \frac{M}{10^6 M_\odot} \frac{c}{v_{\text{dis}}}$ where R is the size of an active region (see Merloni & Fabian 2001) and v_{dis} is the dissipation velocity, $\frac{c}{v_{\text{dis}}} \gtrsim$ a few. Thus $\tau(R) \gtrsim$ a few $\times 100$ s and rapid variability of the power-law flux can be produced via inverse Compton scattering of disk photons in the active regions. An increased flux of the power-law component would further heat the disk due to increased irradiation. However, detailed time dependent accretion disk-corona models are required in order to understand the correlation between the soft hump emission and power-law flux and the variability amplitudes at different timescales.

9. Summary

1. On a 10-day baseline, the 0.7–10 keV band flux of IRAS 13224-3809 shows trough-to-peak variation by a factor ≥ 37 when sampled using 500 s bins. The hard-band (1.3–10 keV) and soft-band (0.7–1.3 keV) fluxes present trough-to-peak variations by factors ≥ 25 and ~ 20 , respectively when sampled using 5000 s bins.
2. The intensities in the soft and hard bands are strongly correlated and are due to changes in both the power-law flux and soft hump emission simultaneously or perhaps with short time ($\sim a \text{ few} \times 100 \text{ s}$) delay.
3. The fractional variability amplitude is variable in the soft and total bands but not in the hard band. None of the variability amplitude is correlated with the X-ray flux.
4. We confirm the presence of a “soft hump” above the power law at energies below $\leq 2 \text{ keV}$. The power-law component contributes only $\sim 32\%$ of the flux to the soft hump in the 0.7–1.3 keV band. The soft hump component shows flux variations down to timescales of 1 day, ranging by a factor of 4.7 in the 0.7–2 keV band. The soft hump flux appears to be correlated with the power-law flux.
5. The mean photon index is $2.11^{+0.05}_{-0.06}$. Time resolved spectroscopy reveals significant changes in Γ_X , $\Delta\Gamma_X = 0.57 \pm 0.21$ on a timescale of 5 days. However, day-to-day variations are not significant. Variations in the power-law flux on times of ~ 1 day are not due to changes in the power-law slope.
6. In our daily sampling, the photon index seems to be correlated with the flux of the soft hump, but due to poor signal-to-noise of the data, a firm conclusion cannot be made.
7. Flux-selected spectral fits reveal that at higher flux levels the power law becomes steeper and the soft hump and power-law flux higher. The photon index changes by $\Delta\Gamma_X \sim 0.4$ while the soft hump flux changes by a factor of 5.6 and the power-law flux by a factor of 3.2 between the low and high flux states.
8. The 1994 ASCA observation also reveals an increase in the Γ_X by ≥ 0.2 , the soft hump flux by a factor of ~ 6 and the power-law flux by a factor of ~ 2.8 from the low to high flux states.
9. An Fe $K\alpha$ line is not detected from IRAS 13224-3809. The 90% upper limit to the equivalent width of Fe $K\alpha$ is 400 eV.
