Abstract. The sensitivity to two different emission inventories, injection altitude and temporal variations of anthropogenic emissions in aerosol modelling is studied, using the two way nested global transport chemistry model TM5 focussing on Europe in June and December 2000. The simulations of gas and aerosol concentrations and aerosol optical depth (AOD) with the EMEP and AEROCOM emission inventories are compared with EMEP gas and aerosol surface based measurements, AERONET sun photometers retrievals and MODIS satellite data.

For the aerosol precursor gases SO₂ and NO_x in both months the model results calculated with the EMEP inventory agree better (overestimated by a factor 1.3 for both SO₂ and NO_x) with the EMEP measurements than the simulation with the AEROCOM inventory (overestimated by a factor 2.4 and 1.9, respectively).

Besides the differences in total emissions between the two inventories, an important role is also played by the vertical distribution of SO₂ and NO_x emissions in understanding the differences between the EMEP and AEROCOM inventories.

In December NO_x and SO₂ from both simulations agree within 50% with observations.

In June SO₄⁻ evaluated with the EMEP emission inventory agrees slightly better with surface observations than the AEROCOM simulation, whereas in December the use of both inventories results in an underestimate of SO₄ with a factor 2. Nitrate aerosol measured in summer is not reliable, however in December nitrate aerosol calculations with the EMEP and AEROCOM emissions agree with 30%, and 60%, respectively with the filter measurements. Differences are caused by the total emissions and the temporal distribution of the aerosol precursor gases NO_x and NH₃. Despite these differences, we show that the column integrated AOD is less sensitive to the underlying emission inventories. Calculated AOD

values with both emission inventories underestimate the observed AERONET AOD values by 20–30%, whereas a case study using MODIS data shows a high spatial agreement.

Our evaluation of the role of temporal distribution of anthropogenic emissions on aerosol calculations shows that the daily and weekly temporal distributions of the emissions are only important for NO_x, NH₃ and aerosol nitrate. However, for all aerosol species SO₄⁻, NH₄⁺, POM, BC, as well as for AOD, the seasonal temporal variations used in the emission inventory are important. Our study shows the value of including at least seasonal information on anthropogenic emissions, although from a comparison with a range of measurements it is often difficult to firmly identify the superiority of specific emission inventories, since other modelling uncertainties, e.g. related to transport, aerosol removal, water uptake, and model resolution, play a dominant role.

1 Introduction

Greenhouse gases and aerosols play an important role in climate change (Charlson et al., 1991; Kiehl and Briegleb, 1993). Greenhouse gases reduce the emission of long wave radiation back to space, leading to a warming of the atmosphere. Aerosol can change the atmosphere's radiation budget by reflecting or absorbing incoming radiation (direct effect) and by modifying cloud properties (indirect effect). Quantification of the role of aerosols on the Earth's radiation balance is more complex than for greenhouse gases, because aerosol mass and particle number concentrations are highly variable in space and time, and the optical properties of aerosol are uncertain.

A good estimate of the emissions of aerosol precursor gases and primary aerosols in the emission inventories is therefore crucial for estimating aerosol impacts on air quality and climate change, and evaluating coherent reduction strategies.

Two major uncertainties of the current regional and global scale emission inventories comprise the accurate estimation of the quantity of the aerosols and precursor emissions, and the role of the temporal distribution of the emissions in the inventories.

Whereas some work on the impact of the temporal distribution of emissions on photochemistry in regional and urban areas has been performed (e.g. Pont and Fontan, 2001; Pryor and Steyn, 1995; Jenkin et al., 2002), to our knowledge no studies have been devoted to evaluate its impact on aerosol surface concentrations and mid-visible aerosol optical depths (AODs). The latter is an important parameter that is needed to calculate the Angstrom parameter, which provides information on the size of the particles in a given atmospheric column.

This study has two main objectives. The first objective is to evaluate uncertainties in gas, aerosol and aerosol optical depth calculations, resulting from two widely used emission inventories focussing on Europe. To this end we performed with the global transport chemistry TM5 model simulations using a zoom over Europe, for which we had two different emission inventories available, EMEP and AEROCOM. The European scale EMEP inventory has been used for many years in the evaluation of emission reduction strategies, and contains reported emissions by member countries, as well as expert estimates. The AEROCOM project provided a compilation of recommended global scale aerosol and precursor emission inventories for the year 2000 and was used in the recent AEROCOM global aerosol module intercomparison (Kinne et al., 2006; Textor et al., 2006; Dentener et al., 2006).

The second objective is to evaluate the role of the temporal and height distribution of the emissions on aerosol (precursor) concentrations and AOD calculations. For this we performed simulations using the EMEP inventory, with the standard recommendations on the temporal distribution of emissions (including seasonal variability) and compared it to a simulation ignoring daily emissions variations and another simulation that used annual averaged emissions.

The model performance was evaluated comparing aerosol precursor gases (NO_x , SO_2 , NH_3) and aerosols components (SO_4^- , NH_4^+ , NO_3^- , black carbon (BC) and particulate organic matter (POM)) to the EMEP network surface observations and to AERONET and MODIS AOD focussing on June and December 2000, over Europe.

Section 2 deals with the description of the simulations, model and emission inventories. In Sect. 3 a description of the remote sensing data and measurement data is given. In Sect. 4 the results are presented. We discuss the results in Sect. 5 and we finish with conclusions in Sect. 6.

2 Methodology

Using the two way nested global chemistry transport model TM5, we performed four simulations for the year 2000. Out-

put was analyzed for a summer (June) and winter (December) month to highlight the seasonal dependency of emissions and their interaction with the different meteorological conditions prevailing in summer and winter.

The first simulation (further denoted as S_{EMEP}) uses the EMEP inventory for the European domain, including their temporal (including, daily, weekly and seasonal variability) and height distribution. The second simulation S_{AERO} used the AEROCOM recommended emission inventory. The third simulation, S_{EMEP_c} , ignored the weekly and daily temporal distribution of emissions, but seasonal temporal distributions are still included. Finally we performed a simulation for which a seasonally constant temporal distribution was implemented, $S_{\text{EMEP}_c\text{-annual}}$.

2.1 The nested TM5 model

The TM5 model is an off-line global transport chemistry model (Bergamaschi et al., 2005; Krol et al., 2005; Peters et al., 2004) driven by meteorological ECMWF (European Centre for Medium-Range Weather Forecasts) data. The presently used configuration of TM5 has a spatial global resolution of $6^\circ \times 4^\circ$ and a two-way zooming algorithm that allows resolving regions, e.g. Europe, Asia, N. America and Africa, with a finer resolution of $1^\circ \times 1^\circ$. A domain of $3^\circ \times 2^\circ$ has been added, to smooth the transition between the global and finer region. The zooming algorithm gives the advantage of a high resolution at measurement locations. The vertical structure has 25 hybrid sigma-pressure layers. In this study the $1^\circ \times 1^\circ$ resolution was used for Europe/North African region spanning from 21° W to 39° E and from 12° S to 66° N.

Transport, chemistry, deposition and emissions are solved using the operator splitting. The slopes advection scheme (Russel and Lerner, 1981) has been implemented and deep and shallow cumulus convection is parameterised according to Tiedtke (1989).

The gas phase chemistry is calculated using the CBM-IV chemical mechanism (Gery et al., 1989a, b) solved by means of the EBI (Eulerian Backward Iterative) method (Hertel et al., 1993), like in the parent TM3 model, which has been widely used in many global atmospheric chemistry studies (Houweling et al., 1998; Peters et al., 2002; Dentener et al., 2003). In the current model version CO , NMVOC , NH_3 , SO_2 and NO_x gas phase, and BC (black or elemental carbon), POM (particulate organic matter), mineral dust, sea salt (externally mixed), SO_4^- , NO_3^- , NH_4^+ aerosol components were included. Mineral dust and sea salt (SS) were described using a log-normal distribution (3 for SS, 2 for dust) and their aerosol number and mass were separately transported using a fixed standard deviation of the size distribution (Vignati et al., 2005). The aerosol components SO_4^- , methane sulfonic acid (MSA) NO_3^- , NH_4^+ , POM, and BC, were included assuming that they were entirely present in the accumulation mode and externally mixed. In this first aerosol version of TM5, aerosol dynamics (coagulation, nucleation,

condensation and evaporation) are not included. However, gas-aerosol equilibrium of inorganic salts and water uptake is considered using the Equilibrium Simplified Aerosol Model (EQSAM version v03d, Metzger, 2000; Metzger et al., 2002a, b). This model allows non-iterative calculation of the equilibrium partitioning of major aerosol compounds of the ammonia (NH_4), nitric acid (NO_3), sulphuric acid (SO_4) and water system. EQSAM assumes internally mixed aerosols and that the water activity of an aqueous aerosol is equal to the ambient RH (relative humidity). Hence, aerosol water is a diagnostic rather than transported model parameter. Water uptake on SS, is calculated using the description of Gerber et al. (1985).

Formation of secondary organic aerosol was not explicitly described, but included as pseudo organic aerosol emissions for the AEROCOM simulation but not for the simulation using EMEP emissions (see Sect. 2.3.2).

Dry deposition is parameterized according to Ganzeveld (1998). In-cloud as well as below-cloud wet removal are parameterized differently for convective and stratiform precipitation, building on the work of Guelle et al. (1998), and Jeuken et al. (2001).

For BC and POM we assume 100% hydrophilic properties in our model, and hence we assume that BC/POM is removed by wet and dry depositional processes like soluble inorganic aerosol (SO_4^-). TM5 utilized information from the 6-h IPS forecast on 3-D cloud cover and cloud liquid water content, convective and stratiform rainfall rates at the surface, and surface heat fluxes to calculate convection.

Removal by convective clouds is taken into account by removing aerosols and gases in convective updrafts- with a correction for sub-grid effects on the larger model scale.

Removal by stratiform clouds considers precipitation formation and evaporation, and cloud cover, and takes into account a grid-dependency. Effectively rain-out on smaller grids works more effectively than on larger grids. Removal of gases further take their Henry solubility into account. For aerosol we used an in-cloud wet removal efficiency of 70% for the soluble aerosols and a below cloud removal efficiency of 100%. Sedimentation was only taken into account for dust and sea salt (large particles) and is considered to be negligible for the sub-micron accumulation mode.

2.2 Aerosol size distribution and AOD calculation

For optical calculations, the accumulation mode aerosol, comprising sulphate, nitrate, ammonium, aerosol water, POM and BC, is described by a fixed Whitby lognormal distribution, using a dry particle median radius of $0.034 \mu\text{m}$ and standard deviation (σ) 2.0. As mentioned before, dust and sea salt are described with multi-model lognormal distribution. Aerosol mass and number are transported separately, and as a consequence, the size distribution is allowed to change due to transport and deposition. Two modes are considered for anthropogenic dust (accumulation, $\sigma=1.59$ and

coarse, $\sigma=2.0$) and three modes for sea salt (Aitken, $\sigma=1.59$, accumulation, $\sigma=1.59$ and coarse, $\sigma=2.0$). As described before, water uptake by the aerosol is taken into account and modify the above mentioned diameters.

To calculate aerosol optical depth (AOD) at 550 nm, we use the Mie code provided by O. Boucher (2004, personal communication) to pre-calculate a look-up table for a number of refractive indices and lognormal distributions. The optical properties of these lognormal distributions are determined by numerical interpolation in discrete size intervals corresponding to the median diameter. In Table S1 of the electronic supplement (ES, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) the densities and optical properties that are used for the optical calculations are listed.

2.3 Emission data

In this study we used two independent emission inventories for aerosol and aerosol precursor gases for the year 2000. (i) The $50 \text{ km} \times 50 \text{ km}$ European scale EMEP inventory, which is widely used for air quality studies in Europe, and (ii) the $1^\circ \times 1^\circ$ global AEROCOM inventory, which is used for climate modelling studies. Below, a brief description of the two emission inventories is given, together with the major differences between the two inventories. In ES Table S2 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>), we present an overview of the species which are included in the two emission inventories.

2.3.1 EMEP emission inventory

The Co-operative Programme for Monitoring and Evaluation of the Long-range Transmission of Air Pollutants in Europe (EMEP) evaluates air quality in Europe by operating a measurement network, as well as performing model assessments.

The EMEP emission inventory (<http://aqm.jrc.it/eurodelta> and <http://webdab.emep.int/>) contains reported anthropogenic emission data for each European country, complemented by expert judgements when incomplete or erroneous data reports are detected. The $50 \text{ km} \times 50 \text{ km}$ emission inventory contains SO_2 , NO_x (as NO_2), NH_3 , NMVOC, CO, $\text{PM}_{2.5}$ and $\text{PM}_{\text{coarse}}$ for 11 CORINAIR source sectors. The emissions are temporally distributed per source sector using time factors. We consider hourly (a multiplication factor that changes each hour and modifies the daily emission), daily (a factor that changes the weekly emissions) and seasonally (a factor that changes each month, thus altering the seasonal distribution). For instance, it is important for traffic to include rush-hours and weekday-weekend driving patterns, and also the intensity of domestic heating differs from winter to summer. To match the $\text{PM}_{2.5}$ emissions with the components used in TM5 we assumed the following mass fractions: POM 35%, anthropogenic dust 15%, BC 25% and

sulphate 25%, based on Putaud et al. (2003). PM coarse is assumed to contain dust only. We added from the global AEROCOM emission inventory biomass burning, natural dust, sea salt and volcanic emissions for the year 2000 (see Sect. 2.3.2). Outside Europe we also use the AEROCOM inventory. ES Table S3 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) provides an overview of the 11 CORINAIR source sectors, together with the emissions per sector. Gas and PM emissions are distributed to different height levels based on the sector they belong to. Point sources and volcanoes are added to the appropriate height, see ES Table S4. Note that unlike for the AEROCOM inventory, we did not consider pseudo-SOA emissions.

2.3.2 AEROCOM emission inventory

AEROCOM (an AEROSol module inter-COMparison in global models, see <http://nansen.ipsl.jussieu.fr/AEROCOM>) evaluates aerosol concentrations, optical properties, and removal processes in 21 global models (Kinne et al., 2006; Textor et al., 2006). AEROCOM experiment B aims at constraining the models by providing a prescribed set of global natural and anthropogenic emissions for the year 2000. We briefly call this ad-hoc compilation of the best inventories that was available in the year 2003 the AEROCOM inventory, <ftp://ftp.ei.jrc.it/pub/Aerocom> (Dentener et al., 2006).

Monthly varying large scale biomass burning emissions of POM, BC and SO₂ are based on GFED 2000 (Global Fire Emissions Database) (Van der Werf et al., 2003). Global emissions amount to 34.7 Tg, 3.06 Tg and 4.11 Tg (SO₂), respectively. Fossil fuel/bio fuel related POM (12.3 Tg POM/yr) and BC (4.6 Tg C/year) emissions are based on Bond et al. (2004). Country and region based SO₂ emissions for the year 2000 are provided by IIASA (Dentener et al., 2006; Cofala et al., 2005) and geographically distributed with the EDGAR3.2 1995 data base. Global emissions amount to 138.3 Tg SO₂/year and 3.5 Tg SO₄/year. Natural emissions of SO₂ (e.g. volcanoes) are an update of the GEIA recommended datasets.

Daily averaged DMS emissions were taken from the LMDZ model (O. Boucher, 2003, personal communication) using the DMS surface water concentrations of Kettle and Andreae (2000) and the horizontal wind speed (Nightingale et al., 2000). Yearly DMS amount to 20.8 TgS. Daily sea salt emissions were taken from Gong (2002, 2003a, b), interpolated to a three modal distribution with a cut-off at $r=10 \mu\text{m}$, resulting in 8356 Tg/year. Similarly, daily dust emissions for 2000 are based on Ginoux (2004), were interpolated to 2 log-normal modes, corresponding to a global total of 1681 Tg/yr.

Secondary organic aerosol is an important component of the aerosol system (Kanakidou et al., 2005). Since most AEROCOM models did not include a description of the formation of SOA (Secondary Organic Aerosol), and there are major difficulties to describe the formation pro-

cesses of SOA, AEROCOM therefore made the simplifying assumption that 15% of natural terpene emissions form SOA, altogether amounting to 19.11 Tg POM/year. In the TM5 model most other anthropogenic emissions such as NO_x are taken from the EDGAR3.2 (1995) database, <http://www.mnp.nl/edgar>. NH₃ emissions were based on Bouwman et al. (1997, 2002), and distributed using the hours of daylight per month after Dentener and Crutzen (1994). For the other components the yearly emissions are equally distributed over the year with no seasonal variations. ES Table S5 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) includes the height of the emissions which are applied in the AEROCOM emission inventory.

2.3.3 EMEP emission inventory versus AEROCOM emission inventory

There are substantial differences between the two emission inventories in describing BC, dust, POM, and sulphate emissions. The EMEP inventory contains detailed country based knowledge on a 50×50 km resolution, while the AEROCOM inventory offers the advantage of global consistency. EMEP reports PM_{2.5} emissions, which were disaggregated by us into individual aerosol components. For example, we assume that 25% and 35% of the PM_{2.5} emissions consists of BC and POM, while the AEROCOM BC and POM emissions are based on a technology based global inventory of black carbon emissions from fossil fuel and bio-fuel combustion (Bond et al., 2004). 15% of the EMEP PM_{2.5} is assumed to be anthropogenic dust (e.g. vehicular movements causing re-suspension of particles), while AEROCOM contains only natural dust emissions (Ginoux et al., 2004). Particularly relevant for this study are the emissions from the Sahara. Finally, we assume that the remaining 25% of the EMEP PM_{2.5} emissions is primary sulphate. In the AEROCOM simulation we assume that 2.5% of all SO_x of the AEROCOM emissions is emitted as primary sulphate. These different procedures result for the European domain in different primary sulphate emissions of 0.22 and 0.23 Tg/year, respectively.

Focussing on the European domain, we give in ES Table S6 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) an overview of the resulting total emissions of NO_x, CO, SO₂, NH₃, SO₄, sea salt, BC, POM and dust included in the two inventories for Europe in June, December and the annual amount.

The annual emissions of the two inventories are generally within 20%, however the annual AEROCOM POM emissions are higher by 45%, NH₃ by 37% and mineral dust by 34%. The difference between the European scale NH₃ AEROCOM (6.0 Tg) and EMEP (4.4 Tg) emissions stems likely from the recent NH₃ emission abatement measures to combat eutrophication problems in Northern Europe. These are included in the EMEP, but not in the Bouwman et al. (2002) in-

ventory. The much larger POM emissions in the AEROCOM inventory are due to the presence of SOA pseudo-emissions, which were not included in the EMEP emission inventory.

The differences in dust emissions are only due to the anthropogenic dust sources from agriculture and transport included in the EMEP inventory. These emissions are added to the natural mineral dust from AEROCOM which was included in both inventories.

Larger differences appear in June, where we see that AEROCOM emissions of NO_x , SO_2 , SO_4 , NH_3 , and POM are higher by 39%, 18%, 31%, 67% and 248%, respectively. Except for POM, these differences are mainly due to the seasonal time factors which are applied to the EMEP inventory only.

For December (ES Table S6, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) the above mentioned discrepancies are smaller than in June, due to compensating effect of the seasonal distribution and the yearly discrepancies of the two inventories.

3 Description measurement data sets

For evaluation of the computed gas and aerosol concentrations we compare with EMEP measurements of SO_2 , NO_x , and aerosol components. Model calculated AOD is compared with sun photometer data from the AERONET stations located in Europe, and MODIS (Moderate Resolution Imaging Spectro radiometer) satellite data.

The EMEP air quality monitoring network measures since the late 1970s ozone, heavy metals, Persistent Organic Pollutants (POPs), Volatile Organic Compounds (VOC) and particulate matter ($\text{PM}_{2.5}$, PM_{10} , SO_4^- , NO_3^- and NH_4^+) at ca. 150 sites in Europe. The aerosols are measured with a daily time resolution; SO_2 and NO_x are reported hourly. Not every station measures all components, therefore the number of EMEP stations available for comparison with model results differs per component.

One of the artefacts occurring with the main filter type (quartz) used by most EMEP stations is the evaporation of ammonium nitrate at higher temperatures. Temperatures exceeding 20°C cause complete NH_4NO_3 evaporation from the quartz filter, a loss of 100%; and a loss of about 25% for NH_4^+ , based on $5\text{--}10\ \mu\text{g}/\text{m}^3\ \text{NO}_3^-$ and $10\text{--}20\ \mu\text{g}/\text{m}^3\ \text{SO}_4^-$ at Ispra during a summer month (ratio 2:1 for $(\text{NH}_4)_2\text{SO}_4/\text{NH}_4\text{NO}_3$).

Temperatures between 20 and 25°C cloud lead to a loss of 50% of the nitrate aerosol (Schaap et al., 2003a, b). Therefore almost all reported summer NH_4NO_3 and NH_4^+ concentrations present only a lower limit, rather than a realistic concentration.

The AERONET (AErosol RObotic NETwork) Cimel sun photometers (Holben et al., 1998) used in this study are given in ES Table S7 (<http://www.atmos-chem-phys.net/6/4287/>

2006/acp-6-4287-2006-supplement.pdf). Due to cloudiness not all days of June and December could be used for aerosol retrieval. The sun photometer measures (every 15 min) in a 1.2° field of view, at eight solar spectral bands (340, 380, 440, 500, 670, 870, 940 and 1020 nm). These solar extinction measurements are used to calculate for each wavelength the aerosol optical depth, with an accuracy of $\pm 0.01\text{--}0.02$ (Eck et al., 1999). Sun photometer acquires aerosol data only during daylight and in cloud free conditions. In this work the cloud screened and quality-assured level 2 data are used.

We used AOD at 550 nm, calculated from the AOD values reported at 870 and 440 nm, using the information on the Angström coefficient (S. Kinne, personal communication, 2004).

The MODIS (Moderate Resolution Imaging Spectro radiometer) on board of NASA's Terra Earth Observing System (EOS) mission retrieves aerosol over land (Kaufman et al., 1997) and ocean (Tanré et al., 1997) at high resolution. MODIS has one NADIR looking camera which retrieves data in 36 spectral bands, from $0.4\ \mu\text{m}$ — $14.5\ \mu\text{m}$ with spatial resolutions of 250 m (bands 1–2), 500 m (bands 3–7) and 1000 m (bands 8–36). Daily level 2 (MOD04) aerosol optical thickness data are produced at the spatial resolution of $10\times 10\ \text{km}$ over land, aggregated from the original $1\ \text{km}\times 1\ \text{km}$ pixel size. As the swath width is about 2330 km, the instrument has almost a daily global coverage. Uncertainties in the MODIS products over land are relatively large. High albedo areas like the Sahara Desert and snow/ice covered regions and complex terrain are difficult for the MODIS instrument, leading to a large bias with models and ground based observations (Chin et al., 2004). Reported MODIS aerosol errors are $\Delta\tau_a = \pm 0.05 \pm 0.15\tau_a$ (Remer et al., 2005). Level 2 cloud screened, version 003 files are used for this work. We present in Sect. 4 a case study for the 11 June 2000.

4 Results

In this section we present first an evaluation of the impact of using the EMEP and AEROCOM inventories (S_{EMEP} and S_{AERO}) and compare them with EMEP measurements (Sect. 4.1). In Sect. 4.2 we subsequently demonstrate the spatial variability of AOD associated with using these two emissions inventories, and compare it to MODIS retrievals. In Sect. 4.3 we assess the temporal variability of AOD by comparing to AERONET sun photometer data. Finally in Sect. 4.4, we perform two sensitivity studies to analyse the impact of daily, weekly and seasonal temporal distribution of emissions on gas, aerosol and AOD calculations. For the interested reader, detailed station information and statistics per component are presented in the accompanied electronic supplement to this paper.

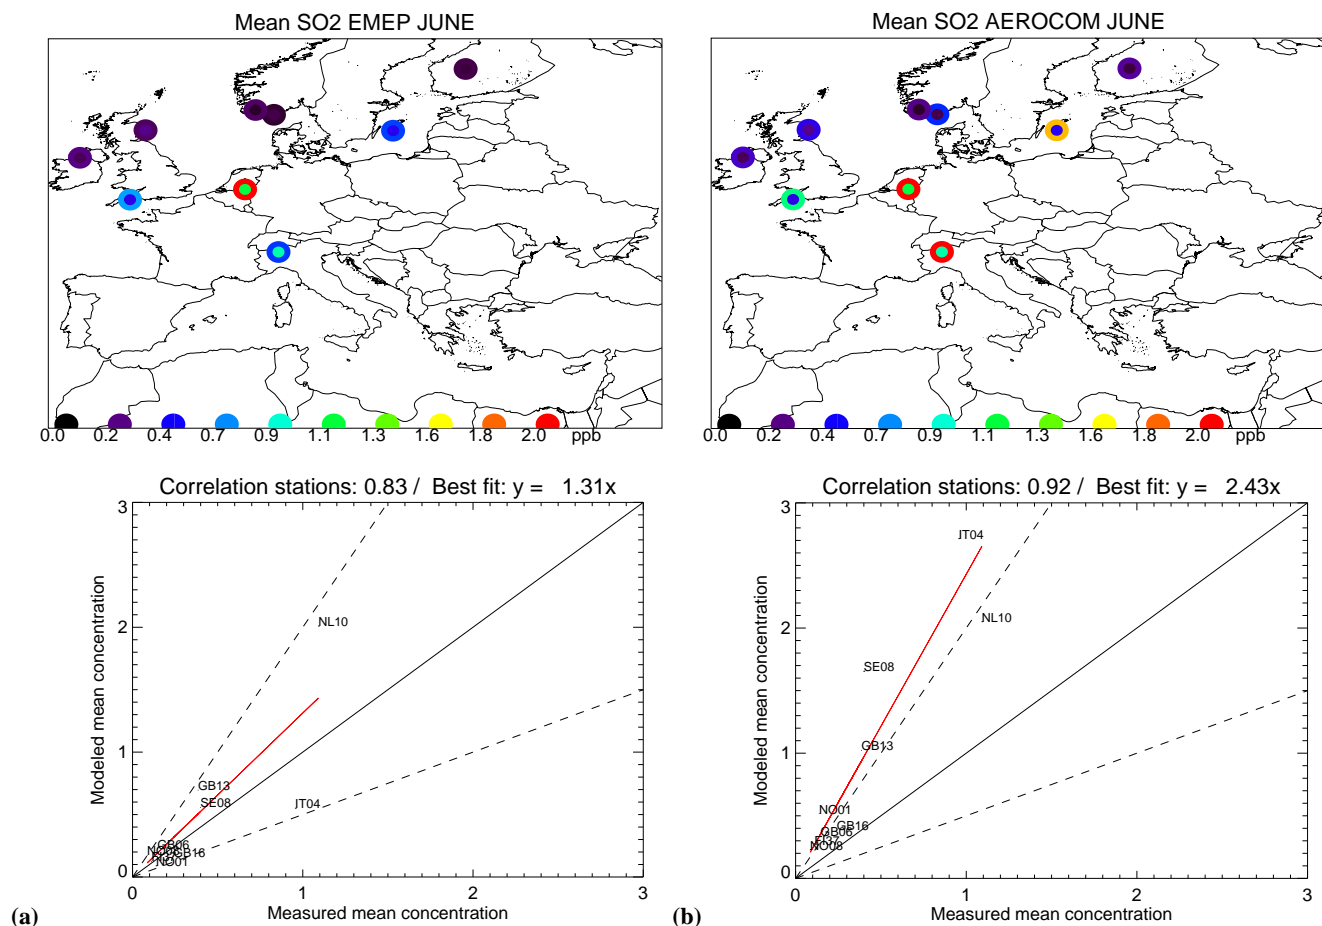

Fig. 1. (a), (b), (c) and (d) are presenting the monthly average measured mixing ratio (inner circle) of SO₂ and calculated (outer circle) SO₂ by S_{EMEP} and S_{AERO} for June and December 2000. For reference, the 2:1 and 1:2 lines are shown as the dashed lines, the 1:1 line as solid and the line of best fit is red solid.

4.1 Evaluation of S_{EMEP} and S_{AERO} with surface observations

In order to compare EMEP station data with model results on a $1^\circ \times 1^\circ$ grid, we selected those measurement stations able to represent the model spatial scale and which had sufficiently data completeness for the month under consideration. First we compare daily average concentrations modelled at the EMEP stations to the measurement data. If the temporal correlation between the time series (with a data completeness of at least 10 days/month) is less than 0.5 (either in S_{EMEP} and S_{AERO}), due to measurement errors and sparse data availability, we excluded the stations from the analysis. An other possible reason for bad correlation between model and measurements, is that apparently the sub-grid scale local meteorology can not be accurately described by the resolution ($1^\circ \times 1^\circ$) of the model.

This procedure allows a fair comparison between measured and modelled concentrations. Subsequently we de-

termined the spatial correlation using the monthly averaged concentration, and calculate the model bias.

We evaluate the sulphate and nitrate aerosol precursor gases SO₂, and NO_x, and the aerosol components SO₄⁻, NO₃⁻, NH₄⁺ and BC. The overall evaluation is presented in Figs. 1, 2 and 3, which shows the monthly mean concentration distribution over Europe.

4.1.1 SO₂

In Figs. 1a–d we present an evaluation of S_{EMEP} and S_{AERO} computed SO₂ concentrations. In June, both simulations show high spatial correlation coefficients, of 0.83 and 0.92, respectively (based on 9 stations, 68 station rejected). The June mean SO₂ concentrations for S_{EMEP} are in better agreement (an overestimate of 31%) with the measured values than S_{AERO} (an overestimate by a factor 2.4). This discrepancy can not be explained by differences in the emissions alone, since the AEROCOM emissions of SO₂ are only 18% higher over Europe than the EMEP inven-

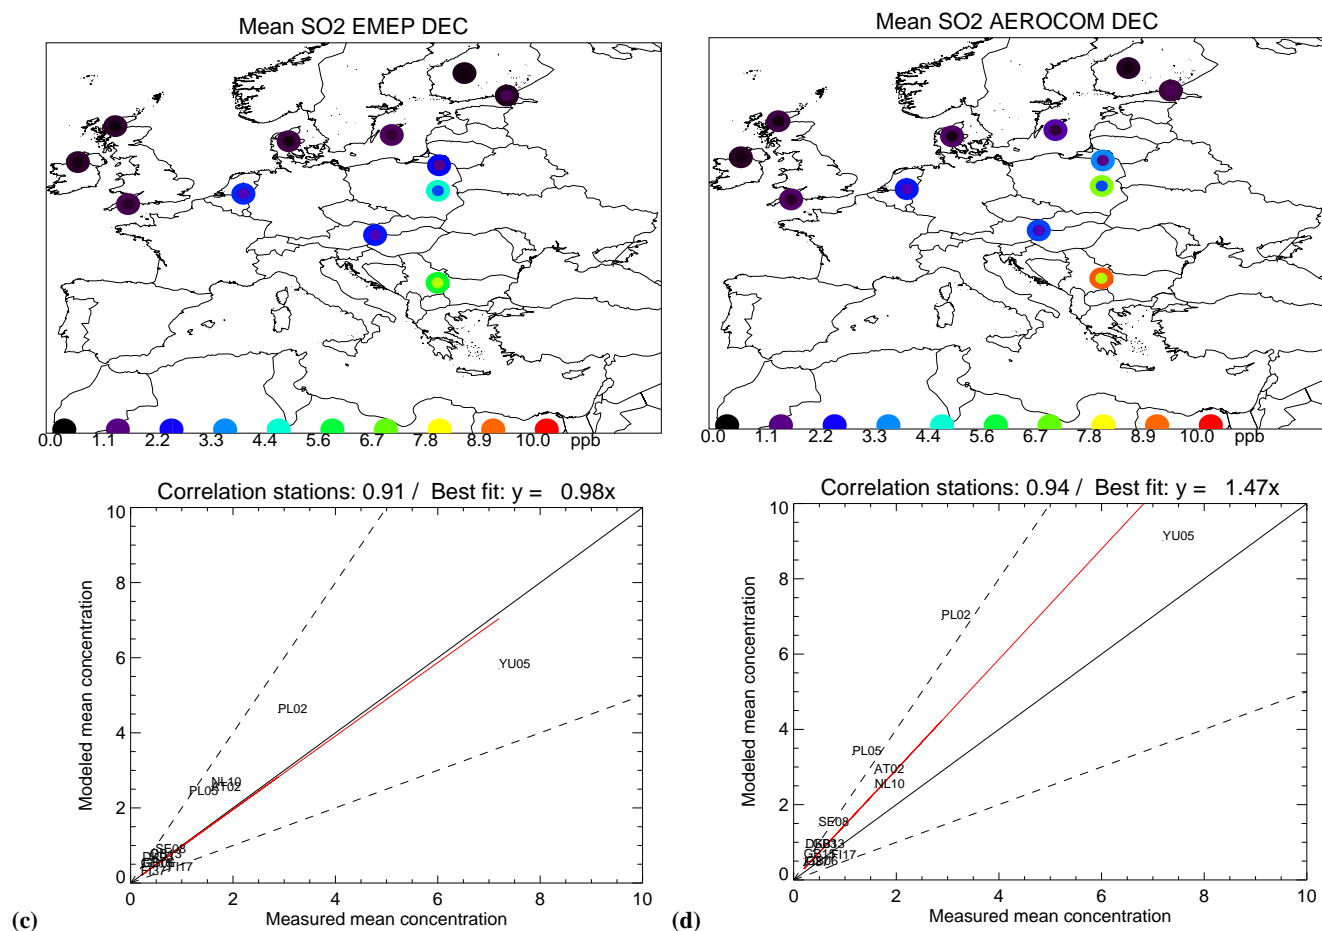

Fig. 1. Continued.

tory (ES Table S6, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>). A likely explanation lies in the vertical distribution of the emissions applied in the inventories (ES Tables S4 and S5). For that reason we present in Figs. 2a and b the June mean SO₂ surface concentrations. Especially in the eastern part of Europe the SO₂ concentrations by SAERO at ground level are up to a factor of 2 higher due to the higher fraction of emissions in the lowest model layer. When we compare the SO₂ distributions at 950 hPa (± 500 m, Fig. 2c and d) we observe especially in Eastern Europe an opposite situation; smaller SO₂ emissions from domestic heating (contributing by 6.8% to all emissions). In SAERO SO₂ is emitted at ground level only, which could be held responsible for the higher SO₂ concentrations at ground level, where in EMEP 50% of SO₂ is emitted at a higher level.

For December the difference between the SO₂ calculations by SEMEP and SAERO is much smaller, see Figs. 1c and d (based on 12 stations used and 66 rejected). On a monthly averaged basis SEMEP concentrations are 2% lower than the measurements, with a spatial correlation coefficient of 0.91.

SAERO overestimates the measurements with 47% and has a high spatial correlation of 0.94. Note that the high correlation coefficients are statistically not robust (Figs. 1c and d), since they are determined by a few stations with a high spread in the monthly mean concentrations. The better agreement for the two simulations in December is in line with the smaller differences (2%) between the two emission inventories (see ES Table S6, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>). Tables S9a and S9b of the electronic supplement contain for each station the calculated monthly mean and correlation coefficients for SEMEP and SAERO together with the measured monthly mean and the number of measurements for June and December.

4.1.2 NO_x

In June, SEMEP slightly overestimates (by 28%) the monthly mean NO_x values, while the SAERO simulation overestimates NO_x by a factor of 1.95 (not shown). Spatial correlation coefficients are 0.79 and 0.53, respectively (based on 11 stations, 49 rejected). The difference

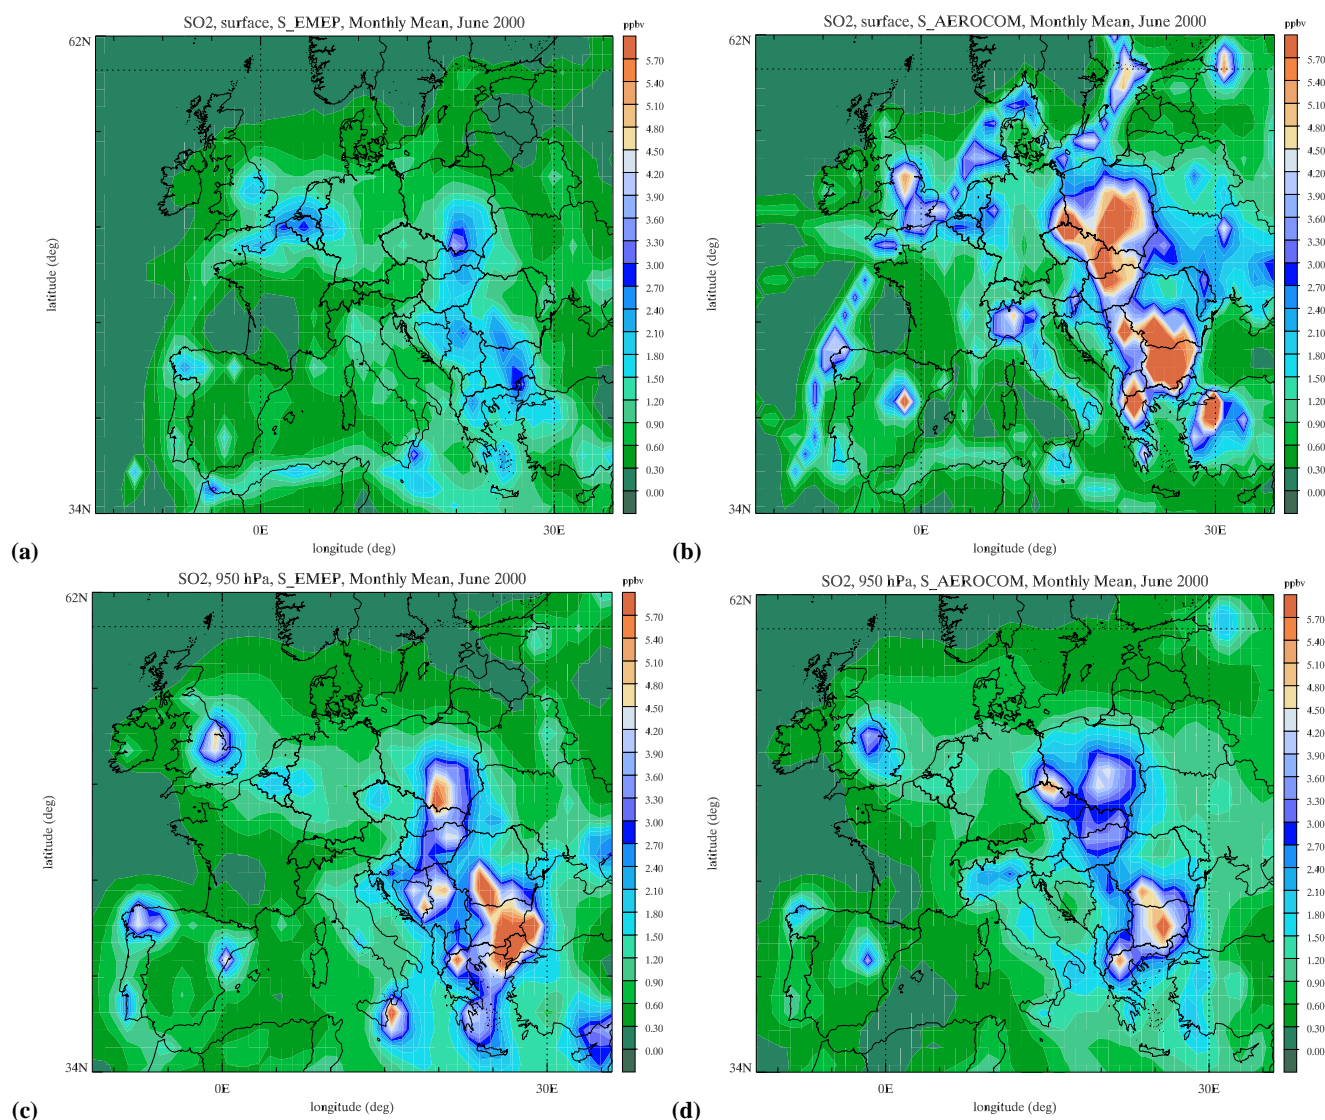

Fig. 2. Monthly SO_2 distribution by S_{EMEP} and the S_{AERO} at surface level (a and b, respectively) and 950 hPa (c and d, respectively) for June 2000.

can be partly explained by the overall higher (39%, ES Table S6, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) monthly emissions in the AEROCOM inventory compared to EMEP. However, the stations available for comparison with measurements seem heavily biased to Northern Europe, where indeed the spatial difference between the EMEP and AEROCOM inventory seems higher. The vertical distribution plays also here an important role. The monthly mean NO_x surface concentrations by S_{AERO} are up to a factor of 2 higher in the Northern part of Europe, due to higher emissions in the lowest model layer (not shown). The differences in monthly mean NO_x concentrations at ± 500 m between S_{AERO} and S_{EMEP} are smaller.

In December, S_{EMEP} and S_{AERO} NO_x mean concentrations are closer to the measurements, and are respectively 7% and 11% higher (see ES Table S10b, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>). Spatial correlations are 0.76 and 0.79 for S_{EMEP} and S_{AERO} , respectively (based on 17 stations, 43 rejected).

4.1.3 SO_4^-

Figures 3a–d present the EMEP measured and modelled (S_{EMEP} and S_{AERO}) SO_4^- concentrations for June and December 2000. Spatial correlation coefficients are comparable for S_{EMEP} (0.66) and S_{AERO} (0.65) (based on 38 stations

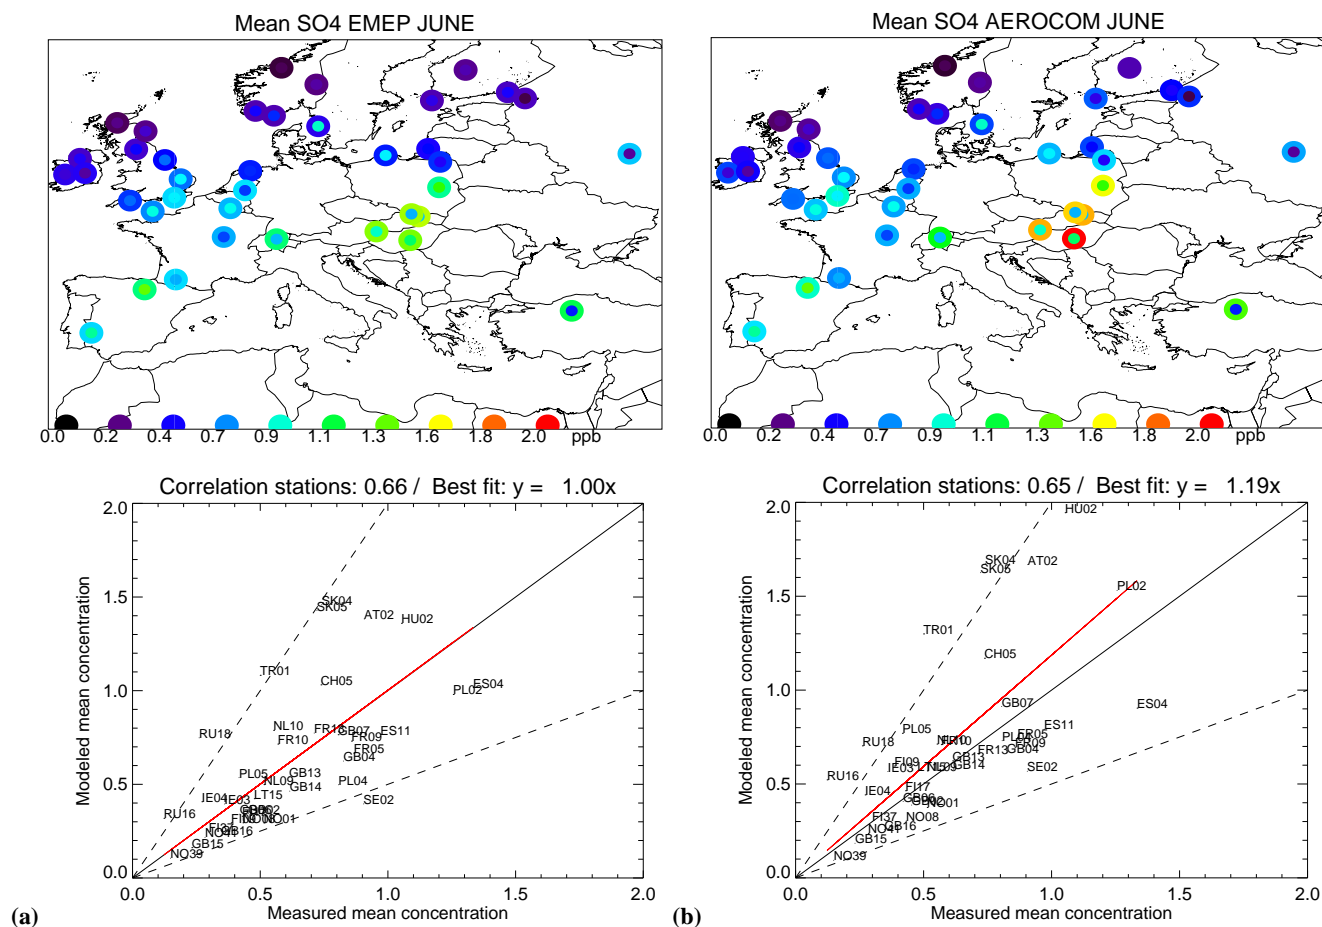

Fig. 3. (a), (b), (c) and (d) are presenting the monthly average measured mixing ratio (inner circle) of SO_4^- and calculated (outer circle) SO_4^- by SEMEP and SAERO for June and December 2000. For reference, the 2:1 and 1:2 lines are shown as the dashed lines, the 1:1 line as solid and the line of best fit is red solid.

used and 33 rejected). The modelled SO_4^- concentrations by SEMEP match the measurements while SAERO on average slightly overestimates SO_4^- aerosol concentrations by 19%. Especially over central Europe (Austria, Hungary, Czech Republic and Poland) significantly higher SO_4^- concentrations are calculated by SAERO than for SEMEP, which can be attributed to the higher over-all emissions. For December the differences between the two simulations are rather small and both SEMEP and SAERO underestimate on average the modelled SO_4^- aerosol concentrations compared with measurement data by as much as a factor 2 (based on 23 stations, 45 rejected). The wintertime underestimation of sulphate concentrations has been observed earlier and is possibly due to a lack of oxidation chemistry in the model (Jeuken, 2000; Kasibhatla et al., 1997). More detailed information in Tables S11a and S11b of the electronic supplement (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>).

4.1.4 NO_3^-

Since in summer EMEP measurements have serious measurement artefacts (see Sect. 3) we can only analyse differences between nitrate aerosol computed by SEMEP and SAERO for December. Substantial differences are found for NO_3^- aerosol: SAERO calculates a maximum concentration of $22.1 \mu\text{g}/\text{m}^3$ over Germany, while the SEMEP calculated maximum amounts to $9.6 \mu\text{g}/\text{m}^3$. Over Poland SAERO calculates NO_3^- aerosol values of $5 \mu\text{g}/\text{m}^3$, while SEMEP calculates NO_3^- aerosol $< 2 \mu\text{g}/\text{m}^3$. The higher NO_3^- found with the AEROCOM inventory, can be understood from higher NO_x (+39%) and NH_3 (+67%) emissions in the AEROCOM (taken from EDGAR3.2 database) than in the EMEP inventory.

Reactions (1–4) show how NO_3^- aerosol formation is related to both NO_x and NH_3 emissions:

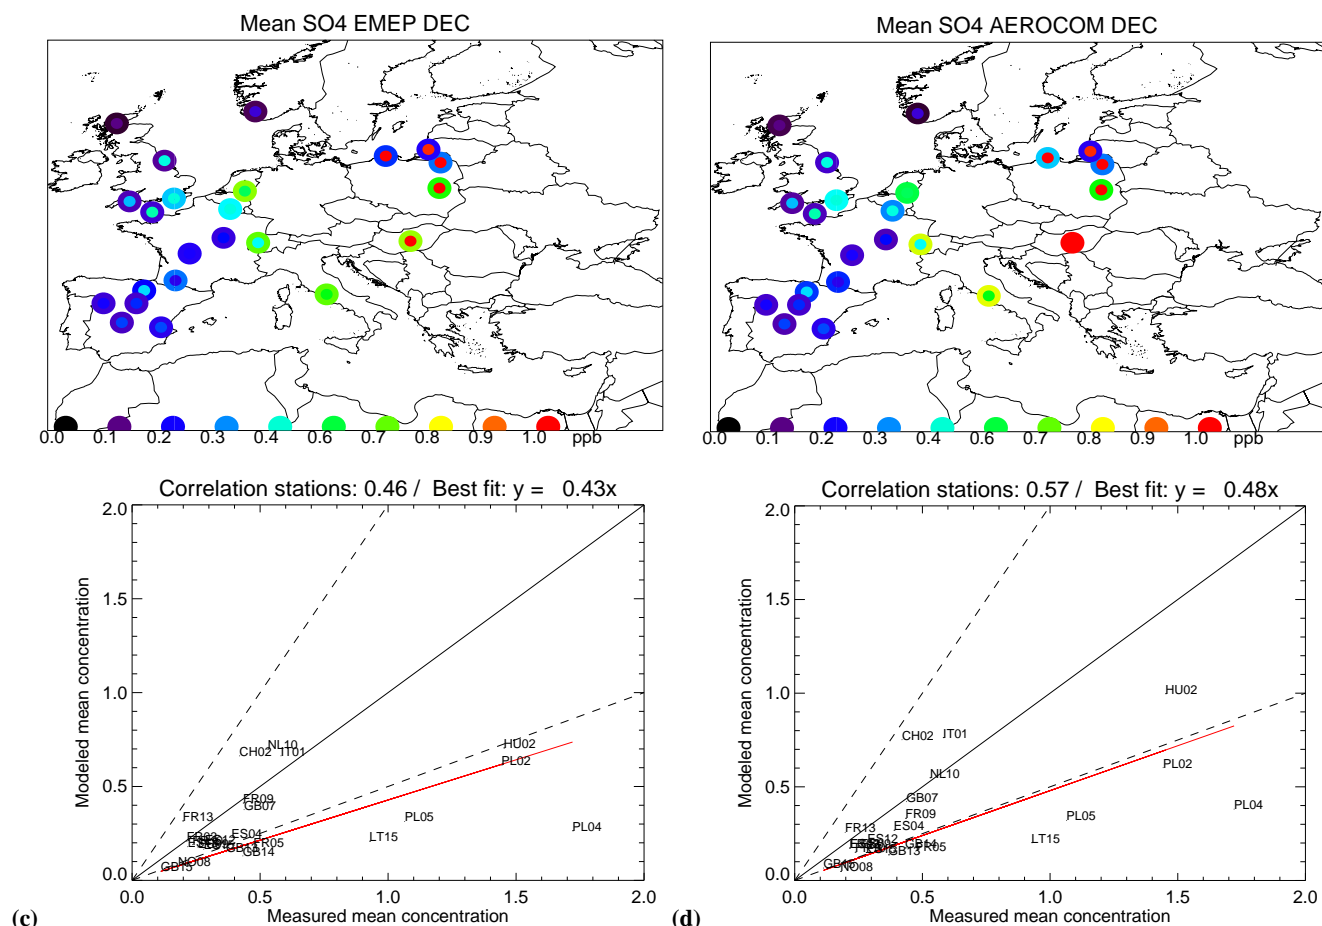

Fig. 3. Continued.

and,

The hydrolysis of N₂O₅ on wet aerosol surfaces is an important pathway to convert NO_x into HNO₃ (Dentener and Crutzen, 1993; Riemer et al., 2003; Schaap et al., 2003a, b):

For December S_{EMEP} overestimates measured aerosol nitrate by a factor of 1.37, and S_{AERO} by a factor of 1.62. Table S12 in the ES (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) shows that S_{AERO} aerosol nitrate concentrations are at all stations higher than those of S_{EMEP} (except for PL02). A possible explanation for these differences could be related to higher NH₃ emissions (21% higher in winter) in the AEROCOM than in the EMEP inventory. High spatial correlation coefficients of 0.84 (EMEP) and 0.91 (AEROCOM) are found (based on 6 stations, 15 rejected), indicating that the spatial gradients of the

monthly mean concentrations are relatively well reproduced by the model.

4.1.5 NH₄⁺

EMEP reports in many cases the sum of NH₃ and NH₄⁺, also called total ammonium (NH_x). For these cases we compared measurements to the modelled sum of the two components.

S_{EMEP} NH_x concentrations agree well with measurements for June, and are on average only 4% higher. In contrast, S_{AERO} overestimates NH_x on average by a factor of 2.0. Analyzing the monthly mean concentrations (ES Table S13a, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>), we see that for all stations the values are higher for S_{AERO} than for S_{EMEP} (based on 20 stations, 17 rejected). The overestimation of S_{AERO} can be explained by the 67% higher summer NH₃ emissions compared to the EMEP emission inventory. The spatial correlation coefficients are high with 0.81 and 0.80, respectively.

For December S_{AERO} agrees better with the measurements, and on average S_{AERO} and S_{EMEP} underestimate the

Table 1. Monthly mean BC and POM concentrations ($\mu\text{g}/\text{m}^3$) for all the stations calculated by S_{EMEP} and S_{AERO} , together with EMEP measurement data for December 2002 and June 2003.

measured values with 7%, and 26%, respectively (based on 12 stations, 26 rejected). More detailed information per station in ES Table S13b .

4.1.6 BC

Unfortunately we have only one station (Ispra, Italy) to our disposal for comparison with black carbon (BC) simulations for the year 2000 (<http://ccu.jrc.it/>). Modelled mean BC concentration of $1.37 \mu\text{g}/\text{m}^3$ computed by S_{AERO} is about 45% higher than the measured mean of $0.93 \mu\text{g}/\text{m}^3$ for June. In the same month, S_{EMEP} underestimate BC by 33% ($0.62 \mu\text{g}/\text{m}^3$). In December, the concentrations are $2.17 \mu\text{g}/\text{m}^3$, $1.42 \mu\text{g}/\text{m}^3$, and $1.90 \mu\text{g}/\text{m}^3$ for S_{AERO} , S_{EMEP} and measurements, respectively. More BC measurements are available for 2002 and 2003. However, a quantitative comparison with the 2000 simulations is difficult since the year-to-year variations can be large. For instance, EMEP measured in Ispra for June 2002 a monthly mean of $1.38 \mu\text{g}/\text{m}^3$, compared to $0.93 \mu\text{g}/\text{m}^3$ in June 2000. Nevertheless, to give an qualitative impression we present in Table 1 the average of the calculated BC concentrations of the 9 stations by S_{EMEP} and S_{AERO} and the EMEP measurement data for December 2002 and June 2003. BC concentrations for each station are given in ES Table S14a. For some stations the model corresponds very well with the measurements; in December with AT02, in June 2003 with AT02, DE02, FI17 and SE12. However, at the majority of the stations the model underestimates BC concentrations, sometimes up to a factor of 7 (PT01). While the latter value may be influenced by wood burning for residential heating purposes. A possible explanation for these underestimations may be related to the uncertainties in the emission factors for BC in emission inventories, and unaccounted sources of BC which contribute to underestimation of BC in the emission inventories, as discussed by Schaap et al. (2004).

4.1.7 POM

Also for POM we have only one station (Ispra, Italy) to our disposal for model comparison for the year 2000. In June, the

monthly mean POM concentration by S_{AERO} ($2.35 \mu\text{g}/\text{m}^3$) is a factor of three higher than by S_{EMEP} ($0.70 \mu\text{g}/\text{m}^3$), because SOA emissions are included in the AEROCOM emission inventory, while for EMEP not. However POM by S_{AERO} is still underestimated when compared to the measured monthly mean ($3.00 \mu\text{g}/\text{m}^3$). In December the modelled monthly mean POM concentrations for S_{AERO} and S_{EMEP} are the same ($1.43 \mu\text{g}/\text{m}^3$), but heavily underestimated when compared to the measured monthly mean ($9.59 \mu\text{g}/\text{m}^3$). More POM measurements are available for 2002 and 2003. As described above, a quantitative comparison with 2000 calculations can be difficult due to year-to-year variations. Also given in Table 1 is the average of the calculated POM concentrations of the 9 stations by S_{EMEP} and S_{AERO} and the EMEP measurement data for December 2002 and June 2003. POM concentrations for each station are given in ES Table S15 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>).

In June 2000, POM concentrations by S_{AERO} are for any station higher than by S_{EMEP} , and agree better with measurement 2003 data, but still underestimated up to a factor of 5. In December the differences between S_{EMEP} and S_{AERO} are smaller and are for all the stations underestimated when compared to measurements.

4.2 Case study of AOD over Europe on 11 June 2000

In this section we demonstrate the ability of our model to represent the spatial distribution of aerosol as seen from the MODIS satellite, by MODIS AOD retrieval for 11 June 2000. This specific event also allows evaluation of the factors determining spatial differences resulting from the use of the two inventories. This specific day was chosen, since it represents a relatively cloud-free day throughout especially in central and eastern Europe, with heterogeneous contributions of desert dust intrusions in southern Europe and mixed pollution and dust in central and northern Europe.

The MODIS retrieved AOD is displayed in Fig. 4a. Three regions of high AOD (0.6–0.9) are observed: Southern Italy/Balkans, the Czech Republic/Romania, and North East

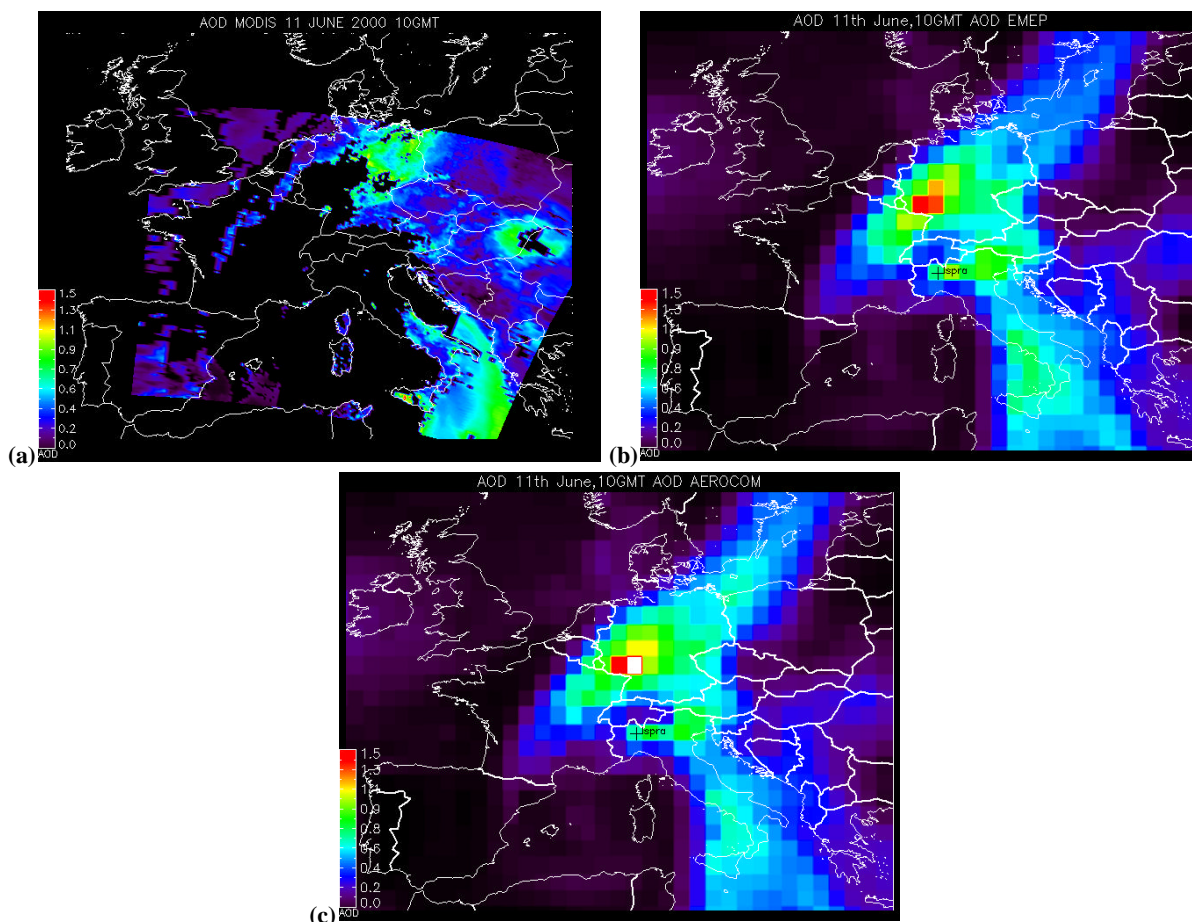

Fig. 4. AOD over Europe for 11 June 10:00 GMT, 2000 by MODIS (a), AOD by SEMEP (b) and SAERO (c). White colours represent AOD values larger than 1.5. Note that for aerosol equilibrium calculations an upper limit for RH 95% was used. No cloud masking was applied to model results.

MODIS MOD04.L2.A2000163.1035.004.2002365174903.hdf, variable optical_Depth_Land_And_Ocean is used.

Germany. Elsewhere the retrieved AOD was of the order of 0.1–0.2. It should be noted that in other parts of Europe no aerosol was reported, due to detection of clouds by the MODIS cloud screening algorithm. Over the southern part of Italy, MODIS registers small and large Angstrom coefficients, indicating that both coarse (dust) and fine particles are found in this region. Over the eastern part of Europe MODIS registers large Angstrom coefficients, which is typical for small particles, e.g. inorganic sulphate- and nitrate aerosols.

With our CTM we can compare these observations with model calculated AOD, but additionally, with the model we are able to evaluate the contributions to AOD of single aerosol components. Figures 4b and c depicts the computed AOD distribution over Europe for 11 June 2000, 10:00 GMT for SEMEP and SAERO, respectively. We note here that the AOD calculations are based on the relative humidity in the cloud free part of the $1^\circ \times 1^\circ$ model grid-box (diagnosed from the grid-box average RH) and that the RH should not exceed

95%. However, clouds are not “masked” in our model calculations. To avoid calculations of highly uncertain RH in regions with almost complete cloud cover we discard the regions with ECMWF cloud cover larger than 90%. The distribution of AOD over Europe as calculated with the two inventories is very similar: maximum AOD values of 1.4 (SEMEP) and 1.6 (SAERO) are found over the western part of Germany, and bands of high AOD (0.6–0.9) are calculated over almost entire Germany, Austria, and Italy. Clean air travelling behind a frontal system in the western part of Europe, England, Denmark, the Netherlands, Belgium, France, and Spain is associated with AOD smaller than 0.2. The high model AOD given by the two model simulations agrees very well with MODIS over Germany and Italy, but the high AOD retrieved over the Czech Republic/Romania is underestimated by the two model simulations. The model calculated AOD over Western Europe seems somewhat lower than the retrieved values.

Table 2. Averaged AOD values together with the corresponding correlation coefficients for June and December 2000 for all the AERONET stations used in this work. The values are based on monthly mean AOD calculated by TM5 with the EMEP emission inventory and the AEROCOM emission inventory for each station.

	Monthly mean + sdev AOD S_{EMEP}	r.	Monthly mean + sdev AOD S_{AERO}	r.	Monthly mean + sdev AOD AERONET
June average	0.15±0.16	0.22	0.16±0.14	0.22	0.19±0.11
December average	0.08±0.06	0.05	0.07±0.05	0.02	0.12±0.06

How do individual components contribute to the AOD?

A desegregation of individual components indicates that especially in the vicinity of Southern Italy, dust contributes with 0.15 (or 25%) to the AOD, which is in agreement with the MODIS observed Angstrom coefficients. In Northern Europe dust contributes with 0.05 to the computed AOD of 0.9. There the high computed AOD is caused by elevated concentrations of inorganic aerosols (SO_4^- , NO_3^- and NH_4^+) and associated aerosol water (aerosol water makes up to 70% of the total aerosol mass over this area). The presence of small particulate inorganic aerosols in this area is found back in the Angstrom coefficients retrieved by MODIS which range from 2.5 to 4. According to the ECWMF meteorological data underlying our model, high RH (>90%) and cloud cover around 70% prevail in the western part of Germany and high AOD is calculated due to the uptake of large amount of water by the inorganic aerosols. MODIS does not register AOD at all for this area, due to the reported presence of warm clouds. While this is consistent with the ECMWF meteorology, MODIS does probably often discard aerosol in the vicinity of regions with partial cloud cover and high RH .

As outlined in the previous section, the use of the AEROCOM emissions inventory leads to higher surface concentrations of SO_4^- and NO_3^- , because summertime emissions are higher. These differences are partially reflected in the calculated AOD. As mentioned above, the AOD geographical patterns of S_{AERO} and S_{EMEP} are similar, but over the Baltic Sea AOD difference up to 0.4 are calculated, due to higher SO_4^- concentrations over this area. In ES Table S11a (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) we see that higher SO_4^- concentrations are calculated by S_{AERO} than by S_{EMEP} (up to a factor of 2) for the Finish, Swedish and Lithuanian stations. Over the southern part of Italy, higher AOD values are calculated by S_{EMEP} , up to 0.2 difference. For this area S_{EMEP} calculates higher SO_4^- concentrations than S_{AERO} , up to $9 \mu\text{g}/\text{m}^3 \text{SO}_4^-$ difference.

In the next section we will compare the calculated AOD values to AERONET measurements.

4.3 Comparison of modelled AOD with AERONET

In this section we compare modelled AOD with the retrieved AOD at a selected number of AERONET stations. While the geographic coverage of AERONET is rather limited as compared to the satellite data described in the previous section, we use the much higher time resolution to evaluate the temporal evolution of AOD in our model. To ensure monthly representativity we select for this comparison AERONET stations for which more than 50 observations per month are reported; i.e. for June 9 stations and for December only 6. An observation may represent a time span ranging from a few minutes to 15 min. The model output was sampled at station location at an hourly frequency. Table 2 present the average of the observed and computed (S_{EMEP} and S_{AERO}) monthly mean AOD for all stations, together with the temporal correlation for June and December. In ES Tables S16 and S17 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) the observed and computed (S_{EMEP} and S_{AERO}) monthly mean AOD and their temporal correlation for each station is given for June and December 2000, respectively. Correlations between model and measurement are rather low and range for individual stations between -0.04 and 0.52 . On average the June AOD of S_{EMEP} is 5% lower than the S_{AERO} AOD and both simulations underestimate AERONET AOD by on average 30%. Also for December both simulations underestimate the AERONET AOD by 35%. To demonstrate the factors contributing to temporal variability we now focus in more detail on 5 stations in June (Figs. 5a–e) with a relatively large measurement records, and a widely varying geographic location: (i) El Arenosillo is a coastal site in Southern Spain (ii) Moldova is located in Eastern Europe, (iii) IMC Oristano is located on Sardinia in the Mediterranean Sea, (iv) Ispra is located at the foothills of the Alps in Northern Italy and (v) Avignon is located in the South/East part of France. Apart from the calculated AOD, we also show the contribution of the dominant aerosol component to AOD.

Modelled dust had a substantial contribution to the total AOD in El Arenosillo (Fig. 5a) around the 4, 9, 17–19, 25–27 June. Indeed on these days high AOD were observed by AERONET (up to 0.55 on 26 June) and AERONET Angstrom coefficients ranged from 0.4–1.5, indicating the

presence of large dust particles. The monthly mean AOD values calculated for both the emission inventories (0.09 ± 0.11) are in line with the monthly mean AOD observed by AERONET 0.12 ± 0.07 (ES Table S16). Temporal correlation coefficients of simulation and measurements are about 0.5. The high correlation is clearly caused by a correct timing of the dust events by the model and similar in both simulations.

For IMC Oristano (Fig. 5b) we see again the large influence of dust on AOD. AERONET AOD values goes up (>0.2) on days where the model calculates high dust loads. This is confirmed by the small Angstrom coefficients retrieved for the days with high dust events (not shown). However, the high observed and modelled AOD in the period 5–9 June seems unrelated to dust and caused by a large contribution of inorganic aerosol. Calculated monthly mean AOD values are about 0.15 and in agreement with AERONET retrieved AOD of 0.15. The rather low time correlation appears to be the result of large diurnal variations in measured AOD which are not reproduced by the model.

At Ispra, two pollution events are visible in the measured AOD: 3–6 and 9–13 June.

The first pollution period could be an error in the cloud screening algorithm (G. Zibordi, personal communication, 2005) and is therefore neglected. However, consistent with observations, from the 9 to 13 June the model calculates a large contribution of inorganic aerosol to the total AOD (Fig. 5c). Note that AERONET reports cloud cover during parts of this event. We have seen in Sect. 4.2 that the model calculates high SO_4^- aerosol concentrations for this area (up to $20 \mu\text{g}/\text{m}^3$). During this episode, high relative humidity (*RH*) values of 76% were measured at the EMEP measurement station. ECMWF meteorological data used by TMS showed average *RH* values of 82% for the same 5 day period. These high *RH* values in combination with high inorganic aerosol loads increase the uptake of water by aerosol, and hence AOD.

At Moldova (Fig. 5d), inorganic aerosol impacts the total AOD in a similar way. High concentrations of inorganic aerosol together with high relative humidity cause high AOD values by AERONET and the model. One exception is encountered on 21 June when the model calculates high AOD values (0.5) due to the presence of inorganic aerosol and high *RH* values (90%), where AERONET observes low AOD (0.08) values. The model calculates a monthly mean AOD of about 0.18, which is close to the monthly mean observed by AERONET.

The high AOD values calculated at Avignon (Fig. 5e) are caused by the high relative humidities together with high concentrations of inorganic aerosol, leading to AOD values up to 0.8. The model calculates a monthly mean AOD of about 0.10, which is about 30% lower than the monthly mean observed by AERONET (0.15).

Noticeable in all comparisons is the relatively small difference between the S_{EMEP} and S_{AERO} AOD results, compared to the AERONET observed AOD. Apparently, the differences observed close to the surface, quickly become smaller (or are even compensated) at some height, as was also observed in Figs. 2c and d for SO_2 and NO_x . The height distribution of the emissions is obviously a less important factor for AOD values than for surface concentrations.

4.4 Temporal distribution of emissions

In the previous sections we evaluated the overall impact of the EMEP and AEROCOM emission inventories on aerosol (precursor) and AOD calculations. In this section we evaluate uncertainties arising from the neglect of the temporal variations of the emissions. Apart from seasonal variations in emissions, this includes also variations on shorter time-scales, like diurnal, and day of week variations. Outside Europe and the USA this information is often not available, which is one of the reasons that these variations are normally not included in global emission inventories of anthropogenic emissions. To study the role of temporal variation of emissions over Europe, we performed two additional simulations. We compared S_{EMEP} (including temporal variation factors) with S_{EMEP_c} , which uses constant hourly and daily emissions. In S_{EMEP_c} however, we retained the seasonal information on emissions. The importance of these seasonal variations was already shown in ES Table S6 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) where AEROCOM emissions in June appeared to be higher due to a lack in seasonal variation. In Sect. 4.4.2 we assess this issue again by comparing a simulation without seasonal variations ($S_{\text{EMEP}_c_{\text{annual}}}$) with S_{EMEP_c} .

4.4.1 The impact of daily and weekly emission variations

For short-lived species, like NO_x and NH_3 , the short-term emission fluctuations are quite important. To illustrate this we show in Figs. 6a and b the temporal evolution of NO_2 and NH_3 emissions, and the corresponding S_{EMEP} and S_{EMEP_c} concentrations for Ispra (8.6°E , 45.8°N) for the period 1–8 June. At Ispra, the NO_2 emission variations are dominated by a daily cycle, and the influence of weekend/working day emission variation is small, about 10%. There appears a strong co-variance of night-time stability and accumulation of NO_2 emission in S_{EMEP_c} in the beginning of the week, dominated by fair weather conditions. During the second half of the week the differences are smaller because unstable meteorological conditions caused more vigorous mixing and advective transport. Similarly, NH_3 accumulation appeared in S_{EMEP_c} during the first part of the week, but not in the second (Fig. 6b). In December (not shown) these day-night differences in concentrations are much less, since the day-night contrast in atmospheric stability is smaller. NH_3 and

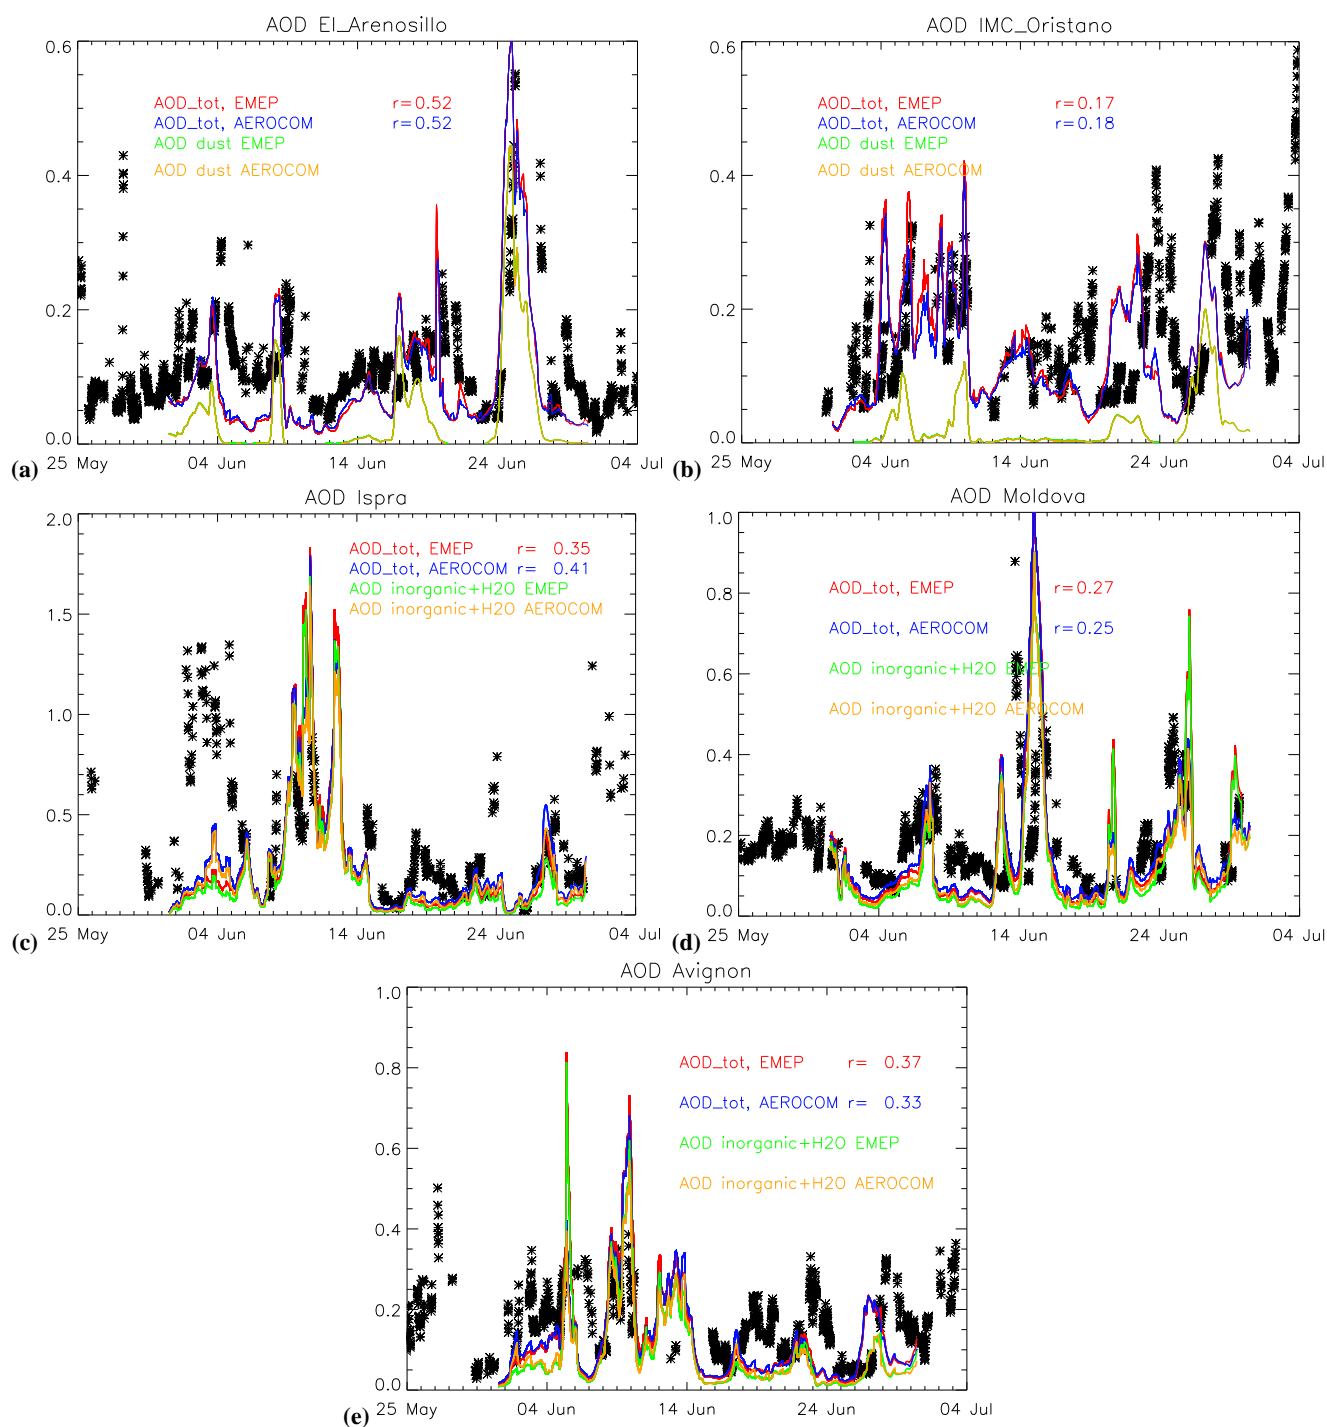

Fig. 5. Total AOD of TM5 with EMEP emission inventory (red line) and AEROCOM emission inventory (blue line) and AERONET AOD (black stars), together with the AOD of the component which has the largest contribution to the total AOD, for El Arenosillo (a), IMC_Oristano (b), Ispra (c), Moldova (d) and Avignon (e). Brown presents AOD by dust for AEROCOM (a, b) or inorganic aerosol and the associated water for (c–e). Green AOD by dust (a, b) or by inorganic aerosol and the associated aerosol water for (c–e).

NO_x concentrations by S_{EMEP} are in general lower than by $S_{\text{EMEP-c}}$.

We analyse in ES Table S18 the significance of this comparing the modelled concentrations for the simulations with and without the temporal distribution, and when possible also

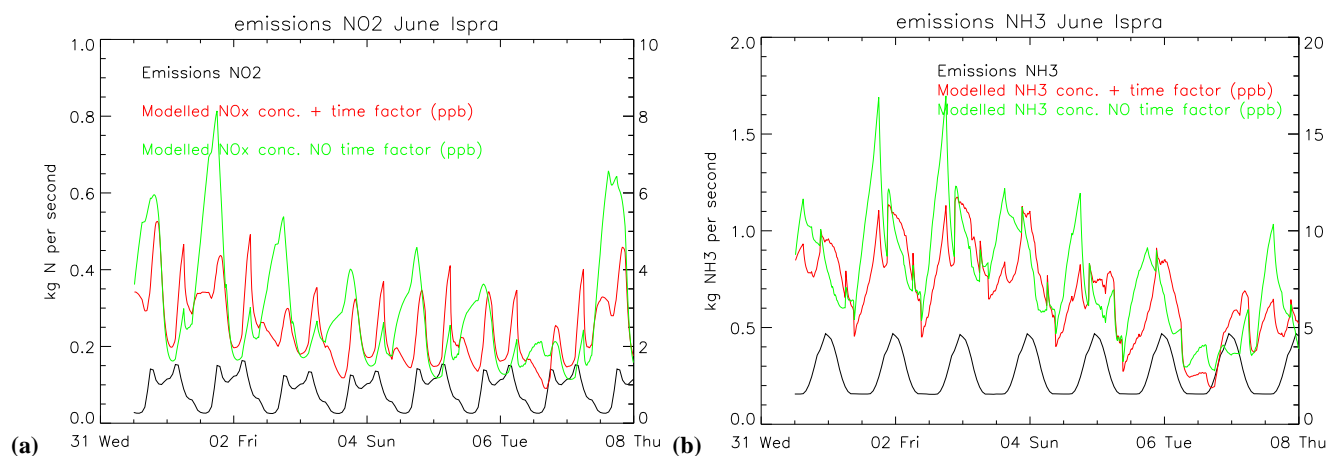

Fig. 6. The temporal distribution of NO₂ (a) and NH₃ (b) emissions together with the modelled concentrations with and without temporal variation, for Ispra, June 2000.

Table 3. Averaged concentrations and the corresponding standard deviation of all stations of the aerosol precursor gases NH₃ and NO_x for which the correlation coefficient for calculated NO_x between SEMEP and SEMEP_c in June is <0.8.

	NH ₃ ppb			NO _x ppb			EMEP data
	SEMEP	SEMEP _c	r	SEMEP	SEMEP _c	r	
June average	3.84±2.07	3.99±2.26	0.78	4.85±1.68	5.11±1.72	0.56	4.71±1.70
December average	2.60±1.85	2.54±1.70	0.85	9.37±6.40	9.36±6.22	0.94	8.53±4.09

with available observations. We analyzed the 14 EMEP measurement locations (44 rejected), for which the deviation between the two simulations was found to be important (i.e. nearby regions of high emissions). The correlation coefficient for calculated NO_x between SEMEP and SEMEP_c for these 14 stations in June is <0.8, indicating the importance of the daily and weekly distribution of the NO_x emissions. The average concentrations of NH₃ and NO_x for all the stations by SEMEP and SEMEP_c for June and December is given in Table 3.

For June the monthly averaged NH₃ and NO_x concentrations are on average and in almost all cases somewhat lower when daily and weekly emission variations are taken into account, up to 13% for NO_x and 25% for NH₃. Correlation coefficients of hourly modelled concentrations at the selected locations are between 0.29–0.74 for NO_x, and between 0.65–0.89 for NH₃ (ES Table S18a, <http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>). The results of the modelled NO_x concentrations of both simulations agree on average very well with both observations.

We have very few representative NH₃ measurement data available; e.g. for NH₃ in the Netherlands (NL10) calculated by SEMEP is lower (5.90 ppb) than by SEMEP_c (6.42 ppb), but is for both cases far below the measured value of 23 ppb. At

HU02 NH₃ SEMEP is 3.01 ppb and NH₃ SEMEP_c is 3.20 ppb, which agrees better to the measured mean concentration of 3.52 ppb. It seems that the spatial variability of measured NH₃ is too large to prove that the modelled NH₃ improves when including high time resolution.

In December, SEMEP and SEMEP_c, correlate on average better than in June, and the concentrations deviate less strongly, indicating that also in other regions, in winter boundary layer mixing plays a less important role. Clearly including the hourly and daily emission-variability can not explain all model-measurement differences.

Differences in precursor concentrations (NH₃, NO_x) lead to differences in the calculated nitrate aerosol, which are smaller in all cases for SEMEP in June (up to 30%). In December, when model results of SEMEP and SEMEP_c can be compared to artefact-free NO₃⁻ aerosol measurements (ES Table S19, 16 stations, including stations with temporal correlation coefficient smaller than 0.5) differences are rather small and do not lead to a clear improvement. For most longer-lived species the impact of daily and weekly emissions factors is smaller than 1–2%. The explanation for this observation is that for species that have a lifetime of more than a day, advective fluxes are dominating and mask the short-term emission variations.

Table 4. Averaged computed (S_{EMEP} and S_{EMEP_c}) and observed NO_3^- aerosol concentrations, together with the corresponding temporal correlation coefficient of all the stations, for December 2000.

	Monthly mean ppb S_{EMEP}	December NO_3^- aerosol		EMEP ppb measurements	
		r	Monthly mean ppb S_{EMEP_c}		r
December average	1.40 ± 0.93	0.45	1.41 ± 0.92	0.44	0.93 ± 0.62

Table 5. Averaged computed (S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$) and observed SO_4^- aerosol, BC and POM concentrations and the corresponding temporal correlation coefficient of all the stations, for June 2000.

	SO_4^- ppb S_{EMEP_c}	SO_4^- ppb $S_{\text{EMEP}_{c_annual}}$	EMEP ppb data
Average	0.64 ± 0.50	0.72 ± 0.56	0.60 ± 0.39

	0.63 ± 0.47	0.76 ± 0.54	4.85

4.4.2 The impact of monthly emission variations

In this section we show that the seasonal distribution of emissions has a stronger impact on simulated SO_4^- , BC and POM concentrations than the hourly and daily variations. In our discussion we focus on June, similar effects but opposite in sign can be found for December. In ES Table S20 (<http://www.atmos-chem-phys.net/6/4287/2006/acp-6-4287-2006-supplement.pdf>) we present the monthly mean concentrations for sulphate aerosol, BC and POM for June 2000. For BC and POM we compare measurement data of June 2003 (no measurement data available for 2000).

In June, the use of annual average emissions ($S_{\text{EMEP}_{c_annual}}$) leads in general to higher emissions of e.g. SO_2 and NO_x , since the intensity of residential and commercial heating, is less during summer than in winter. As a consequence, aerosol and aerosol precursor concentrations are generally higher in simulation $S_{\text{EMEP}_{c_annual}}$. For instance, at Jarczew (PL02) the monthly mean SO_2 concentration increases from 1.57 ppb (S_{EMEP_c}) to 2.26 ppb ($S_{\text{EMEP}_{c_annual}}$); compared to a measured monthly mean of 1.57 ppb. For NH_3 again large differences up to 30% at the stations between S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$ are found. NH_3 concentrations computed by S_{EMEP_c} are higher, which demonstrates the application of higher emission factors for NH_3 emissions during the summer months (agricultural activities are higher during summer months than in winter); but again it is difficult to discern better model performance on the basis of a few stations.

Differences in NO_x concentrations between S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$ are small (up to 8% higher by $S_{\text{EMEP}_{c_annual}}$). For the majority of the stations the NO_x concentrations by

$S_{\text{EMEP}_{c_annual}}$ agree a little better with measurement data. However, on average, the modelled NO_x concentrations of S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$ are the same (5.71 ppb) and in reasonable agreement with the measured values (4.48 ppb; 27% higher).

The larger SO_2 emissions also increase the calculated SO_4^- concentrations comparing $S_{\text{EMEP}_{c_annual}}$ with S_{EMEP_c} . For sulphate aerosol we have a substantial amount of measurements available allowing for robust evaluation of the improvement resulting from using seasonally resolved emissions. Like in Sect. 4.1, in our analysis we excluded 30 stations for which the temporal correlation coefficient of model results with measurement data is less than 0.5. In June, in all 41 cases SO_4^- by S_{EMEP_c} is lower than by $S_{\text{EMEP}_{c_annual}}$, and agree better with measurement data. The mean concentrations averaged for all stations (Table 5) are 0.64 ± 0.50 for S_{EMEP_c} , 0.72 ± 0.56 (ppb) for $S_{\text{EMEP}_{c_annual}}$ and for the measurements 0.60 ± 0.39 (ppb).

Monthly mean BC concentrations (Table 5) by $S_{\text{EMEP}_{c_annual}}$ are higher than S_{EMEP_c} (up to 50%); however on average both simulations seem to substantially underestimate BC in June. Note again that we have compared to data obtained in June 2003, since no observations are available for 2000. We find differences up to 40% in POM monthly mean concentrations between the S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$. As noted before the difference with measured OC is very large, associated with the neglect of SOA formation. We used a constant factor of 1.4 in the conversion from POM to OC. While this factor is fairly uncertain, the value for this factor was chosen for consistency with the assumptions made in the AEROCOM database.

Table 6. Averaged computed (S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$) and observed AOD values of all the stations, together with the corresponding temporal correlation coefficient for June 2000.

	Monthly mean + sdev AOD S_{EMEP_c}	r.	Monthly mean + sdev AOD $S_{\text{EMEP}_{c_annual}}$	r.	Monthly mean + sdev AOD AERONET
Average	0.15±0.15	0.22	0.16±0.16	0.23	0.19±0.11

What is the impact of the emission variability on calculated AOD?

The substantial differences found between the monthly concentrations of S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$ translate in relatively small (<10%) differences in AOD calculations, consistent with the deviation of the main contributing inorganic sulphate concentrations. Comparison of S_{EMEP_c} and $S_{\text{EMEP}_{c_annual}}$ modelled AOD with the AERONET stations (Table 6) shows that on average AOD for $S_{\text{EMEP}_{c_annual}}$ (0.16) is getting slightly better agreement with AERONET (0.19) than S_{EMEP_c} (0.15). AOD values for the stations can be found in ES, Table 21.

5 Discussion

We showed that despite the over-all annual and European scale agreement, large differences in the geographical distributions of EMEP and AEROCOM emission inventories were found. In addition we showed the strong influence of the recommended vertical distribution of the emissions on the distribution of aerosol precursor gases. The differences were translated in relatively large divergences of NO_x and SO_2 concentrations where especially the AEROCOM recommended emissions tend to overestimate measured NO_x (from EDGAR3.2 database), SO_2 and to a lesser extend SO_4^{2-} concentrations for June 2000 when compared with EMEP measurement data.

Some studies (e.g. Pont and Fontan, 2001; Pryor and Steyn, 1995; Jenkin et al., 2002) have previously evaluated the impact of temporal distribution of emissions on O_3 concentrations. These studies demonstrated that the temporal variation of precursor emissions NO_x and VOC are resulting in a day-of-week dependence of O_3 concentrations. Schaap et al. (2003) showed the role of seasonal variation of NH_3 emissions on the NH_3 and NO_3 aerosol calculations. Our study confirmed latter study that the daily and weekly distribution of emissions is important for NH_3 , NO_x and NO_3 calculations. In addition we demonstrated that the additional information from daily and weekly time resolution is not very important for SO_2 , and SO_4^{2-} , BC and POM calculations; however monthly variations of the emissions can strongly impact the calculated concentrations. Therefore, a major improvement of the current global inventories of aerosol and aerosol precursor would be a systematic evaluation of the

seasonal cycle of anthropogenic emissions. The strong influence of the emission height on our calculations was somewhat surprising. Processing of emission in models seems to be more important than emissions themselves, indicating that each model has “a mind of its own”, and therefore largely independent of emissions input. Similar results were obtained when harmonizing aerosol emissions in AeroCom Exp. B, Textor et al. (2006). Little information is available on emission heights of anthropogenic emissions. The recommended emissions height used for AEROCOM inventory was based on expert judgement and not on data; whereas the EMEP height recommendation is based on only very few bottom-up studies on emission heights; and the recommendations may be strongly biased. Surprisingly within Europe there is no compilation available about the stack-heights of large point source; nor about the plume rise associated with them. Effective plume rise of other sources are not known.

We showed that a further uncertainty is introduced by the desegregation of $\text{PM}_{2.5}$ emissions in the EMEP inventory into aerosol components; where especially BC concentrations are for both the months underestimated compared to the measurement data. A bottom-up approach retaining as much as possible information on aerosol size and composition would be desirable for future European inventories. We further showed the sensitivity of model results to the assumed seasonal distribution of NH_3 emissions; for which relatively little is available.

The AEROCOM inventory also contained pseudo-emissions for secondary organic aerosol. Indeed it was shown that the secondary organic aerosol may several times exceed the primary organic aerosols. At present, some global and regional models include parameterisations of organic aerosol formation. However, as discussed by Kanakidou et al. (2005) uncertainties in the SOA formation are at least a factor of two, which results in difficult to quantify uncertainties in the European aerosol budget.

Despite substantial differences in calculated aerosol concentrations at the Earth's surface the associated AOD was less different. In both simulations the highest AOD was related to regions with high relative humidity, in the vicinity of clouds. In these areas of high RH (>90%), large quantities of water on inorganic aerosol are calculated (>50 $\mu\text{g}/\text{m}^3$). MODIS does not report successful AOD retrieval for these areas. Whether or not this aerosol should be classified as cloud or rather as aerosol with a large water fraction is an

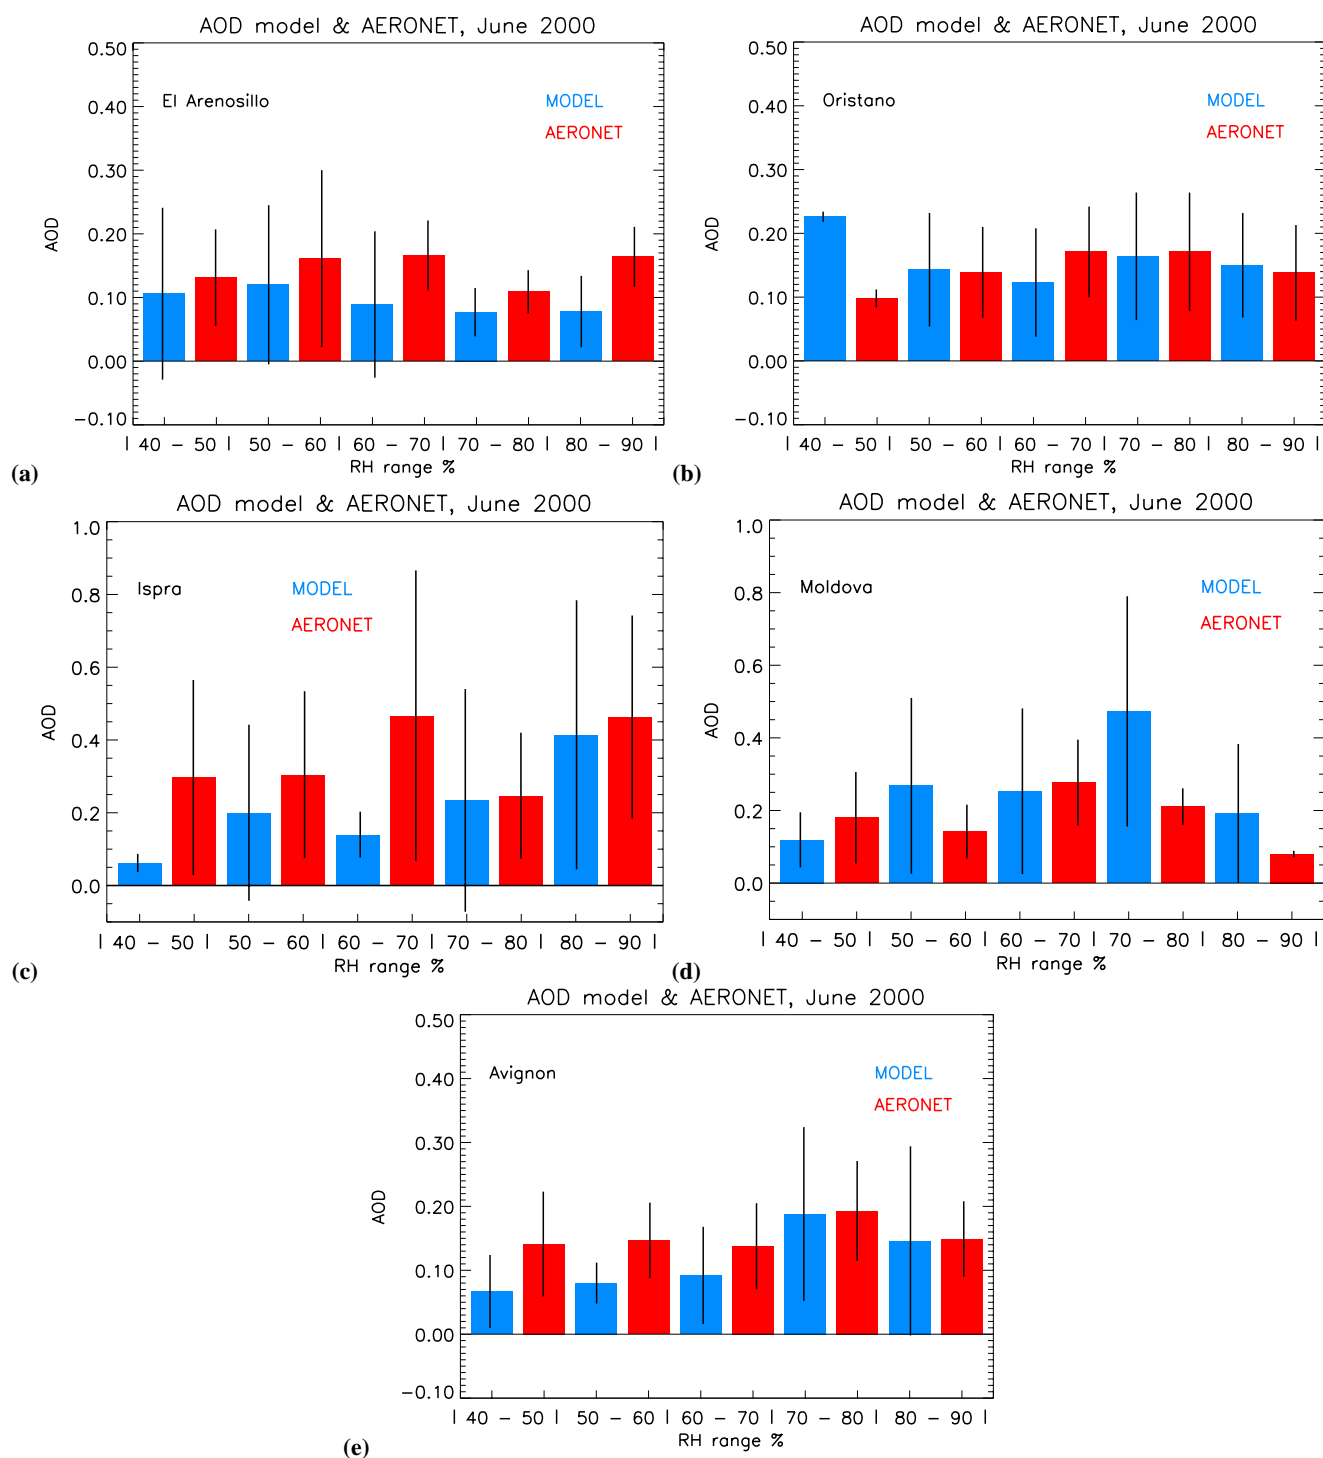

Fig. 7. AOD calculated by the model (blue) and observed by AERONET (red) at different relative humidity ranges (40–50%, 50–60%, 60–70%, 70–80%, 80–90%), for El Arenosillo (a), IMC Oristano (b), Ispra (c), Moldova (d) and Avignon (e) for June 2000. The black line presents the standard deviation.

open question. However, we do think that these aerosols are frequently present and are often not “seen” by satellite retrievals.

From the model point of view the aerosol equilibrium model used in our study (EQSAMv_03d), or any other equilibrium model, is not tested for high relative humidity, rendering the calculations of aerosol water rather uncertain.

Whether the AOD calculation by the model strongly depends on the *RH* (influence of *RH* on aerosol water) or does the model underestimate/overestimate aerosol concentrations, we present in Fig. 7 the *RH* dependency of AOD calculation.

At low *RH* ranges (i.e. 40–50%, 50–60%, 60–70%) we see that the model calculated AOD is too low when compared to AERONET. This indicates that the concentrations of (inorganic) aerosols is too low for this areas. The larger standard deviations for El Arenosillo at low *RH* is due to the presence of aerosol dust, leading to higher AOD peak values. The high AOD model value for Oristano at *RH* 40–50% is based on a few hours only and therefore not statistically robust.

At higher *RH* ranges (70–80%, 80–90%) larger standard deviations are found when compared to AERONET, indicating the non-linear effect of *RH* on aerosol water calculations, which contribute to the overestimation of the AOD values.

We evaluated the effects of assuming the “water-soluble aerosol accumulation/aitken mode” according to the Whitby distribution with 2 other distributions as presented in Table 4.2 in the d’Almeida climatology ($r=0.0285\ \mu\text{m}$ and $\sigma=2.239$) and Putaud et al. (2003) who present a host of log-normal fits to observed size distributions at various locations in Europe. E.g. at the rural location Ispra Mode 2 parameters $r=0.024\ \mu\text{m}$ and $\sigma=1.91$. Using these parameters we calculate that the extinction coefficient would differ from the assumed Whitby distribution by 3% (higher) and 15% (lower), respectively.

6 Conclusions

Based on the analysis presented above it appears that the AEROCOM inventory overestimates the emissions of aerosol precursor gases SO_2 and NO_x and NH_3 emissions, especially in June. This overestimate is the combined effect of a lack in seasonal variation in the AEROCOM inventory and the different vertical distribution of emissions (SO_2 and NO_x). For NH_3 it seems that the inclusion of recent abatement measures in the EMEP inventory (see Sect. 2.3.3) indeed leads to a better agreement with measured concentrations.

The height distribution of the emissions is obviously a less important factor for AOD values than for surface concentrations.

We evaluated the impact of the EMEP and AEROCOM emission inventories on aerosol concentrations and aerosol optical depth (AOD) in Europe for June and December 2000. There are substantial differences between annual emissions

included in the two inventories, e.g. mineral dust emissions are 40% lower and NH_3 emissions are 18% higher comparing AEROCOM and EMEP emissions. The differences between AEROCOM and EMEP emissions are in general augmented in June (factors of 1.00–2.48) compared to December (factors 0.71–1.21).

Especially for SO_2 and NO_x differences occur also in the vertical distribution profile of the emissions. Despite these differences, for most aerosol species and aerosol precursor gases TM5 simulates the spatial and temporal distribution over Europe relatively well. Spatial correlations, based on monthly mean concentrations are often quite high and many EMEP measurement stations show high temporal correlation with S_{EMEP} and S_{AERO} .

However, a better agreement of surface concentrations of aerosol precursors SO_2 , NO_x and aerosol NH_4^+ are calculated with the EMEP emissions inventory for June, while SO_4^{2-} for both simulations compares well to observations. Similar discrepancies are found in December, with the difference that SO_4^{2-} is underestimated by a factor of two using both inventories. At the only station available in 2000 for comparison (Ispra), black carbon concentrations calculated with both inventories agree within $\pm 40\%$ with the measured concentrations in June and December, respectively; a comparison with measurements from other years/locations indicated in general a large underestimate of computed BC.

The large differences in surface concentrations between the simulations are not equally reflected in corresponding differences in computed column aerosol and AOD. In June, model AOD computations using the AEROCOM and EMEP emission inventories reveal good agreement with surface based AERONET sun photometer observations and AOD retrieved from MODIS. Spatial patterns over Europe of AOD differ due to the varying contributions of mineral dust and inorganic aerosol, as observed by satellite and confirmed by model simulations. An evaluation of the impact on aerosol of the temporal distribution (daily, weekly and seasonal) of emissions reveals that the concentrations of most aerosol components are not strongly influenced by introduction of a high temporal resolution of emissions. The exception is aerosol nitrate and its precursor gases NO_x , and NH_3 .

However, seasonal temporal variation of the emissions do play an important role for all gas and aerosol calculations, and need to be included to accurately calculate aerosol concentrations and its influence on climate.

Global scale emission inventories such as used for AEROCOM may provide a reasonable first estimate for computation of aerosol precursor and aerosol concentrations. However, global inventories will strongly benefit from information from regional scale inventories, such as EMEP, especially with regard to knowledge on seasonality of emissions, and spatial and vertical distribution of these emissions. The challenge for future global inventories will be to include this regional knowledge, while maintaining the global consistency and transparency.

Acknowledgements. We acknowledge S. Metzger who provided the EQSAM_v03d aerosol module and O. Boucher for providing his Mie code.

Monthly and daily emission distributions have been prepared by the Institute of Energy Economics and the Rational Use of Energy, University of Stuttgart (D). The hourly variations are provided by TNO Environment, Energy and Process Innovation (NL).

We would like to thank EMEP for compiling the emission inventory, as used in the EURODELTA exercise (<http://aqm.jrc.it/eurodelta>). The AERONET principal investigators are acknowledged for their continuous effort in collecting AOD data. We thank Goddard Distributed Active Archive Center (DAAC) for providing MODIS data.
