# Trends in reproductive parameters of North Sea plaice and cod: implications for stock assessment and management advice 

Grift, R.E., M.A. Pastoors, and A.D. Rijnsdorp ${ }^{1}$

#### Abstract

In many stock assessments within the ICES area, the proportion of mature fish at age is kept constant at some loosely defined values. However, given that a number of stocks is under severe fishing pressure, we expect that maturity at age changes in a non-random fashion. North Sea plaice and cod are severely over-exploited. In this paper, trends in maturity, sex ratio and age at first maturation of North Sea plaice and cod are analysed based on Dutch market sampling data and International Bottom Trawl Survey (IBTS) data. Implications of the observed trends in maturity at age on stock assessment and management advice are explored. The results indicate that the maturity at age for North Sea plaice and cod, significantly increased in recent years. The implications, as far as they have been analysed in this paper, are that the perception of the current stock may change but that the biological reference points are relatively robust to these changes.

## Introduction

[^0]North Sea plaice and cod are two demersal stocks that experience high fishing pressure and are both harvested outside safe biological limits (ICES 2001a). Given the depleted state of these stocks it is all the more important to make sure that the basic biological data and assumptions underlying the stock assessment models (Darby and Flatman 1994; Shepherd 1999) are valid and robust. Stock assessment results are generally presented in terms of fishing mortality and spawning stock biomass (SSB) where the latter is defined as the number of fish at age, times the mean weights at age, times the proportion mature at age. Trends in weight at age have been reported elsewhere (Rijnsdorp and Van Leeuwen 1996; Cook et al. 1999) and will not be investigated here. We want to focus the analysis on the proportion mature at age.

Current practice in many stock assessment working groups within ICES, is to assume a certain proportion mature at age and to keep this constant over years (ICES 2001b). Often the biological basis for the maturity assumptions is at best weak, but sometimes almost absent. However, biological reference points like Fmed, F0.1 and Fmax are to a certain extent dependent on the maturity assumptions because they are related to the stock-recruitment relationship. Therefore, it seems appropriate to investigate the changes in maturity for the two stocks considered here and to explore the implications of those changes on stock assessments and management advice.

## Materials en methods

## Plaice

Data used in this study comprised samples from commercial landings (market samples) of the Dutch beam trawl fishery. The market samples consist of a fixed number of fish randomly selected from the landings by market category. Apart from the date of landing and the position of the catch, the following data were recorded for each fish: body size (mm), body weight (g), sex, maturity stage and age (years, January 1 as birthday). Age determination was done at the laboratory based on the pattern of growth zones in the otolith assuming that each growth zone corresponds to one year. The ageing method has been validated (Rijnsdorp et al. 1990).

Male and female plaice were considered to be mature when they had reached maturity stage 2-7 in the 1st quarter (Rijnsdorp 1989).

The method to determine the length at first maturation is described below. The analysis was restricted to samples obtained from the spawning period ( $1{ }^{\text {st }}$ quarter) and from the spawning areas in the southeastern North Sea (between 51 oN and 55 o 30 ' N and east from 2 o E). The sex ratio
was estimated from the Dutch market samples over the whole year. The population maturity was then calculated using the proportion males and females mature at age combined with the sex ratio data. To smooth the year-to-year variations in maturity at age, a three-year running mean was used.

## Cod

For cod, age and maturity data from the International Bottom Trawl Survey from 1980-2000 were used. Only data from roundfish areas 1-7, collected in the first quarter were analysed (Figure 1). No distinction was made between males and females as they were both included in the dataset.

## Length and age at first maturity

The fraction of mature fish at a certain age or length was modelled using a logistic model. In the generalized linear model, the response variable p was defined as:

$$
\begin{equation*}
\mathrm{p}=\mathrm{n}(\text { mature }) /(\mathrm{n}(\text { mature })+\mathrm{n}(\text { immature })) . \tag{1}
\end{equation*}
$$

Where $\mathrm{p}=$ response variable (fraction mature fish), $\mathrm{n}=$ number of mature or immature fish. The response variable $\mathrm{p}_{\mathrm{j}}$ has a binomial distribution. A logit function $\mathrm{g}(\mathrm{m})$ was used to link the expected value of the response variable (p) to the linear predictor:

$$
\begin{equation*}
\mathrm{g}(\mathrm{~m})=\ln (\mathrm{p} /(1-\mathrm{p})) \tag{2}
\end{equation*}
$$

Where $g(m)=$ expected value of fraction of mature fish and $m=$ overall mean.
The size at first maturity in plaice was estimated using the following model:

$$
\begin{equation*}
G(m)=a+b L \tag{3}
\end{equation*}
$$

For each year separately. The size at $50 \%$ maturity is given by: Lmat $=\mathrm{a} / \mathrm{b}$;
To predict the fraction of mature cod per roundfish area, the linear predictor for the expected fraction of non-zero catches was defined using the following model:

$$
\begin{equation*}
\mathrm{g}(\mathrm{~m})=\mathrm{m}+\mathrm{A}+\mathrm{Y}+\mathrm{R}_{\mathrm{i}}+\left(\mathrm{A} * \mathrm{R}_{\mathrm{i}}\right)+(\mathrm{A} * \mathrm{Y})+\left(\mathrm{Y} * \mathrm{R}_{\mathrm{I}}\right) \tag{4}
\end{equation*}
$$

Where A is the age of fish (years), Y is the year of sampling and R is the roundfish area ( $\mathrm{i}=1$ to 7). To predict the faction of mature fish for the North Sea, over all roundfish areas, the expected
value was weighted for the abundance of cod in each roundfish area. Only age, year and the interaction between age and year were used as explanatory variables.

The procedure was implemented using PROC GENMOD of the SAS software package (SAS 1990). $95 \%$ approximate confidence limits of the fitted value were calculated as described in the GENMOD procedure manual. If a term did not reduce deviance significantly ( $\alpha=0.05$ ), it was removed from the model.

## Assessment

For both plaice and cod, XSA assessments (Darby and Flatman 1994) were carried out using the same settings as in the 2000 WG (ICES 2001b), but with new maturity data. A 10-year tuning window was used without tapering. Results were then further investigated using the so-called PA-software (CEFAS 1999) and an equilibrium model analysis (Reeves and Cook 1994; Cook et al. 1999). Biological reference points were calculated and compared with the WG2000 results.

## Results

## Plaice

Trends in maturity for female plaice are shown in Figure 2, based on the analysis of the $1^{\text {st }}$ quarter Dutch market sampling data from 1958 to 1999. Maturity at age has increased for ages 3 to 5 over the last 10 years. However, maturity at age 3 appears to have a cyclic nature and maturity in recent years appears to have declined again. The strongest increase in maturity was observed for age 4 where the proportion mature increased from $40 \%$ in the 1960 's to around $80 \%$ in the late 1990's.

Trends in maturity for male plaice could not be analysed because almost all plaice above the minimum landing size of 27 cm are mature. For the youngest age groups in the landings, these results will be biased because an important part of these young age-groups are not well represented in the commercial landings. For the subsequent analysis it was assumed that all males from age 2 were mature.

The sex ratio of the stock could not be estimated directly. As a proxy, the sex ratio in the Dutch landings were used as observed in the market samples collected during the whole year. (Figure 3). No apparent trends in sex ratios were observed although there may be a slight increase in the
number of females over the recent years. In the youngest age groups represented in the market samples, the proportion males and females are similar. In older age groups the proportion of males declines. The population maturity was estimated taking account of the observed sex ratio and the maturity at age for females (estimated) and males (assumed). Results, indicate the same pattern as for females, but slightly moderated by the inclusion of the males in the population (Figure 4, Table 1). The increases in maturity at age 3 and 4 are still apparent. The overall increase in the percentage mature females at age is related to an overall decrease in the size at which $50 \%$ of the females becomes mature (Figure 5).

Differences in SSB between estimates from 'old' and 'new' maturity data, can be observed in periods of a relatively high SSB (e.g. 1960s and 1980s), where the stock is estimated lower when the new maturity data are used (Figure 6). No detectable difference, however, can be found in recent years. The reduced estimates in the two periods of high biomass results in a decrease of the range of estimated SSB values and in a more dome shape Shepherd stock recruitment curve (ICES 1998). The equilibrium analysis for plaice is shown in Figure 7. Since the equilibrium analysis is dependent on the stock recruitment curve, and since these curves are relatively similar when either using the WG estimates of maturity or the 'new' maturity estimates, the results of the equilibrium analysis are also rather similar. Estimates of biological reference points (Table 2) are also similar although the estimate of Floss (Cook 1997), which may be seen as a proxy for Fcrash, is $13 \%$ lower when using the new maturity data.

## Cod

The analysis of the proportion mature at age for North Sea cod (sexes combined) was based on 44000 individuals collected in the $1^{\text {st }}$ quarter international IBTS surveys over a time-span of 20 years (Table 3). Results of the analysis by roundfish area indicate an increase in the proportion mature, predominantly at ages 3 and 4 (Figure 8). The increase is most clear for roundfish areas $1-5$. Age, year and region, as well as the interaction between age*region significantly contribute to the variance (Table 4). The interactions between age*year and between year*region are also significant, but these only explain a minor proportion of the variance.

The maturity at age by roundfish area was transformed into a population estimate of maturity by weighting over the IBTS index values by area and year (Figure 9, Table 5). Since the IBTS data were only available from 1980 onwards, no estimates could be given for maturity before that
year. Therefore, the ICES WG estimates were used for this period (ICES 2001b). When both the results for maturity from the logistic model and from the running mean are considered, maturity at age is higher at present than assumed in the ICES WG (Table 6 and Table 7).

As the maturities estimated from the IBTS data tend to be higher compared to the WG estimates of maturity, SSBs are higher when implementing the new series (Figure 10). The estimates of SSB in 1999 ranged from 66000 tonnes (WG2000 data) to 98000 tonnes (using a 3-yr mean maturity). The stock recruitment plots and the equilibrium analysis presented in Figure 11 are very similar and the estimates of biological reference points indicate that both Fmed and Floss are estimated to be higher when using the new maturity data (Table 8). However, as the time series of maturity data only extends from 1980 onwards, the years which could be affected mostly (i.e. the years at high stock numbers as in the early 1970s) could not be included in the analysis and it is likely that a revision of the maturity characteristics for this period may affect the estimated reference points even more.

## Discussion

The results presented in this paper indicate that the maturity at age for North Sea plaice and cod, tends to increase in recent years. This is consistent with findings by Cook et al (1999) and Bromley (2000).

There are several factors that may be related to the observed changes in maturation in plaice and cod. First, fishing may act as a strong selection factor towards earlier maturation (Rijnsdorp 1993b; Stokes et al. 1993; Law 2000). Second, fishing will reduce the stock biomass and may enhance the food availability per capita, leading to an increase in growth and an earlier maturation (Rijnsdorp 1993a; Trippel 1995). Thirdly, the increase in temperature in the North Sea may explain (part) of the observed change in maturation. For plaice, Rijnsdorp (1993a) showed that both growth and temperature conditions were significantly related to maturation.

Whatever the causes, the observed change in maturation will affect the perception of the trends in spawning stock biomass estimated by VPA and will affect the Stock - Recruitment relationship, which may affect the equilibrium analysis and on the biological reference points. The estimated effect of the changes in maturation explored in this paper should be considered preliminary, because the analysis of the data for both species shows some caveats. A number of caveats should be taken into account. First, the analysis of North Sea plaice, has been restricted to the Dutch
market sampling data. As the Dutch fleets generates between $30-60 \%$ of the total landings of plaice, this may be regarded as a substantial sample, but there is still a need for a more comprehensive, international analysis (Bromley 2000). Second, the maturity at age for males needs to be revisited, as they are only partly selected by the fishing gear when they are two years old, so that those fish may present a biased sample of the population. Rijnsdorp (1989) showed that in 1985-86, about $50 \%$ of the 2 -year old males, and $75 \%$ of the 3 -year old males were sexually mature. As in females, the age at maturation in males has changed since the beginning of the $20^{\text {th }}$ century. Because males become mature at a size that is well below the minimum landing size, no data are available to detect changes in the age at maturation of male plaice in the period over which the VPA results are available. Third, the analysis for North Sea cod has been restricted to the period 1980-1999 whereas the stock-recruit plot for that stock also heavily dominated by the high stock abundances in the early 1970s. Therefore, the effects on the equilibrium analysis may be underestimated if maturity at age in those years differed substantially from the assumed maturity.

Despite these caveats, our study indicates that changes in maturation should be taken into account in the stock assessment carried out annually by the ICES Working Group. Further work on the reconstruction of changes in maturation, and an analysis of the factors underlying these changes may provide a significant improvement of the assessment and the management advice for these stocks.

## Acknowledgements

We want to thank the ICES secretariat for kindly making the cod IBTS index values available at very short notice.
