Abstract

This is a protocol for a Cochrane Review (Intervention). The objectives are as follows:

1. To identify the effects and assess the effectiveness of interventions to reduce sedentary behaviour (total sedentary time and the pattern of accumulation of sedentary time) in older adults.

2. To summarise the effects of interventions to reduce sedentary behaviour on quality of life, depression, and health status in older adults.

3. To summarise any evidence on the cost-effectiveness of interventions that reduce sedentary behaviour in older adults.

Background

Description of the condition

Sedentary behaviour has been defined as an activity where the predominant posture is sitting or lying and energy expenditure is low (Chastin 2013; SBRN 2012). Sedentary behaviour is distinctly different from inactivity: inactivity is often regarded as not meeting physical activity guidelines for health, or too little exercise - sedentary behaviour is too much sitting (Owen 2010). So, standing for long periods would be considered inactivity, sitting or lying down (except sleep) for long periods would be sedentary behaviour. Going for a slow walk would not be considered being sedentary (as the person is not sitting) and if the person never or rarely gets warmer or out of breath (moderate activity) they would
be categorised as being inactive. To reduce sedentary behaviour, we need to get people on their feet (if able) as often as possible in their waking hours but we are not necessarily asking them to perform activity to a level that is moderate or vigorous. Evidence is increasing to suggest that sedentary behaviour, especially when accumulated in prolonged and continuous bouts, is detrimental to physical health (de Rezende 2014; Dunstan 2012; Henson 2013), mental health (Lauder 2006), quality of life (Laforge 1999), and bone health (Chastin 2014), in addition to being associated with all-cause mortality, disease incidence and hospitalisation (Biswas 2015). Prolonged screen-based sedentary activities, for example watching television, have been shown to be associated with depressive symptoms (Teychenne 2010), whilst metabolic syndrome has a significant correlation with lengthy sedentary periods (Bankoski 2011). Sedentary behaviour is also associated with lower odds of successful ageing (Dogra 2012). These deleterious health effects of sedentary behaviour are different to those of physical inactivity and largely independent of an individual’s physical activity levels (Bankoski 2011). In fact, the latest meta-analysis reveals that over one hour of daily moderate-intensity activity is required to attenuate the association between sedentary time and mortality (Ekelund 2016). Spending on average 80% of their time in a seated posture and with 67% being sedentary for more than 8.5 hours per day (Harvey 2013), older adults are the most sedentary segment of society and seldom engage in such high level of daily moderate-intensity activity. The UK and other countries have now issued recommendations to reduce sedentary time as part of their physical activity guidelines (DoH 2011). These guidelines recommend reducing sedentary time in addition to engaging in moderate-intensity physical activity. The reasoning is that solely promoting physical activity does not necessarily reduce sitting time as one may achieve the recommended physical activity guidelines, yet still sit for large periods of the day (Dogra 2012; Katzmarzyk 2010). Indeed, the latest reviews indicate that interventions aimed at promoting physical activity are ineffective at reducing sedentary time (Martin 2015; Prince 2014). Experimental work indicates that time spent in moderate-intensity activity tends to displace time that individuals usually spend in light activity and activities incidental to daily living but not sitting time (Gomersall 2015). Interventions devised specifically to reduce sedentary behaviour are needed and are the next step in this field of research (Owen 2011). The aim of this review is to both synthesise and compare the current evidence on the effectiveness of interventions to reduce sedentary time amongst the older adult population.

Description of the intervention

This review will assess the effectiveness of interventions aimed specifically at reducing sedentary behaviour in community-dwelling older adults. Sedentary behaviour is ubiquitous and occurs throughout the day. In order to reduce sedentary time, inter-ventions must specifically promote more time spent in upright postures throughout the day. Interventions can specifically focus on sedentary behaviour or be part of physical activity programmes which include a component specifically addressing sedentary behaviour (Martin 2015; Prince 2014). The type and components of interventions developed in adults (18 years and over) have varied widely and have been mapped against the taxonomy of behaviour change strategies (Gardiner 2016; Michie 2013).

Some interventions target individuals on a one-to-one basis, or may look at a wider reach through communities; some provide feedback using monitors; and some just rely on general awareness raising. With advances in body-worn sensors and self-tracking technology the use of promoting devices is starting to appear in the literature. Finally some interventions are now considering environmental restructuring, such as standing desks and outdoor spaces.

Some of these interventions have been delivered via online media, for example using email messages (Adams 2013), whilst face-to-face consultations have also been shown to provide fruitful outcomes in decreasing sedentary periods (Gardiner 2011). Modification of individual modalities, for example targeting cognitive behavioural therapy, has been the focus of numerous interventions (de Greef 2010).

The majority of interventions have focused on the individual, but others are attempting to modify more distal determinants of sedentary behaviour or even target a different level of determinants (Owen 2011). For example, environmental restructuring interventions modifying home and workplace layout or implementing outdoor spaces and facilities have all been acknowledged as potentially potent ways of reducing sedentary time (Gardner 2016; Tandon 2012).

Recent reviews of interventions in adults found that interventions that targeted sedentary behaviour specifically instead of physical activity were more successful in reducing sedentary time (Martin 2015; Prince 2014). A systematic review identified that interventions based on environmental restructuring, persuasion, or education were more successful in reducing sitting time and that self-monitoring, problem solving, and restructuring the social or physical environment were particularly useful behaviour change techniques (Gardner 2016).

There are some limitations in interventions attempting to reduce sedentary time in older adults. Primarily, some sedentary activities older adults participate in, for example reading and socialising (Leask 2015), provide a mental health benefit (Alpass 2003), and facilitate cognitive function in ageing (Hertzog 2009). Therefore, although prolonged sedentary time may have a detrimental effect on physical health, some instances provide a positive mental health benefit and should not be decreased. Further activities, for example eating and resting, are essential for daily living and should not be altered.
How the intervention might work

Interventions to reduce sedentary time in adults have been either interventions with a specific goal of increasing physical activity levels alongside reducing sedentary time or interventions aimed at reducing sedentary time only (Martin 2015; Prince 2014). Those focusing on reducing sedentary behaviour have resulted in a greater reduction of sedentary time (Martin 2015; Prince 2014). Indeed the determinants of sedentary behaviour are distinct from those of physical activity (Chastin 2015b), and the intervention must specifically address these determinants. There are a number of different ways that sedentary behaviour interventions are predicted to decrease sedentary time or break up prolonged sitting time in older adults.

- Providing information: interventions could be used to educate individuals on the benefits of decreasing their overall sedentary time and breaking up prolonged sedentary periods, by using consultations/interviews, reviewing their own behaviour (self-monitoring by diary) or employing a feedback system. An example of such a feedback system would be the use of objective monitors to detect sedentary behaviour and print out feedback to be discussed with the individual to identify times when prolonged sitting could be reduced (i.e. by avoiding preferred seated activities such as social events, reading and knitting).

- Prompting: real-time behaviour prompts using wearable sensor and mobile technology that detect prolonged sedentary periods and prompt the individual to rise and move. Less frequent reminders by email and phone message may act as a less regular prompt system.

- Environmental restructuring: interventions may alter indoor or outdoor spaces to attempt to decrease individuals’ sedentary time. More specifically, home or care setting layout changes might be considered, to encourage individuals to sit less. Standing desks and perching stools rather than comfortable seats are some potential examples of this.

- Policy change: organisations which provide services and care for older adults might change working practices to encourage individuals to sit less by, for example, using chair movement monitors, or encouraging staff to mobilise patients on a more regular basis.

Why it is important to do this review

The benefits of being physically active for older adults’ health are well established (Kerr 2012; King 2001); and evidence suggesting the effectiveness of several intervention types to increase physical activity has been summarised in several review articles (King 1998; Van der Bij 2002). Despite these findings, older adults spend large periods of the day being sedentary, regardless of whether they are physically active (Harvey 2013; Harvey 2015). Increased sedentary time is associated with poorer health outcomes in older adults (de Rezende 2014), including physical function (Rosenberg 2015), onset of frailty (Song 2015), and less successful ageing (Dogra 2012). There is now robust epidemiological evidence showing that the effect on health of prolonged sedentary time cannot be compensated for by adherence to physical activity and any exercise protocol (Biswas 2015). Consequently, interventions that specifically target sedentary behaviour have been advocated in this population in addition to promoting physical activity (Sparling 2015; Manns 2012). Older adults are potentially the population that might benefit the most from a reduction of sedentary time, because they are the most sedentary group and have the highest chronic disease burden (Harvey 2013; Harvey 2015). In addition, qualitative research reveals that older adults consider interventions to reduce sedentary behaviour more acceptable and desirable for them to adhere to than exercise programmes (Greenwood-Hickman 2015). To date, no reviews are available which have summarised study findings which aim to reduce or change sedentary patterns in older adults. Recently two reviews summarised the evidence in adults, including older adults (Martin 2015; Prince 2014). They included studies with a control or comparison group and identified four studies in older adults, but none with a sole focus on sedentary time. Compiling this information may help inform future interventions regarding the most successful and efficient methods to be found in the literature to decrease sedentary time in the population group with the largest amount and highest prevalence of sedentary time (Harvey 2015).

OBJECTIVES

1. To identify the effects and assess the effectiveness of interventions to reduce sedentary behaviour (total sedentary time and the pattern of accumulation of sedentary time) in older adults.

2. To summarise the effects of interventions to reduce sedentary behaviour on quality of life, depression, and health status in older adults.

3. To summarise any evidence on the cost-effectiveness of interventions that reduce sedentary behaviour in older adults.

METHODS

Criteria for considering studies for this review

Types of studies

Due to the early nature of interventions to reduce sedentary time or change prolonged sitting patterns, this review will be not be
restricted to randomised controlled trials. Despite the potential for bias in other study designs, the following study types will be included.

- Randomised controlled trials (RCTs).
- Cluster RCTs.
- Non-randomised controlled trials (NRCTs).
- Controlled before-after (CBA) studies with at least two intervention sites and two control sites.
- Cross-over studies.
- Interrupted Time Series (ITS) with a clearly defined point in time when the intervention occurred and at least three datapoints before and three after the intervention).

**Types of participants**

The inclusion criteria for data from studies will be as follows.

1. Adults aged 60 years and over.
2. Community-dwelling at home or living in a place of residence that does not provide nursing care, for example sheltered housing or residential complexes and not care or nursing homes.
3. Participants may have multiple co-morbidities or be disease free.
4. Studies investigating interventions in specific clinical populations only (e.g. stroke survivors) will be excluded.

**Types of interventions**

The review will include studies that report the following interventions (population-, community- or individual-based) designed to reduce sedentary time and particular sedentary behaviours, for example sitting time and watching television.

1. Interventions targeting the raising of awareness and provision of information. This might include interventions which use IT and social networks in addition to peer support networks.
2. Interventions which use prompting on multiple occasions (vibration monitors, phones, emails) to raise awareness and provide feedback on sedentary behaviour.
3. Interventions which attempt to alter the environment, for example modifying the layout of indoor and outdoor spaces and furniture.
4. Interventions that aim to change policy and practice in people’s work with older people, for example motivating staff to encourage older people to move more frequently.

Interventions will be categorised as short term (up to 3 months in duration), medium term (3 months to 1 year in duration) or long term (longer than 1 year in duration).

The review will not consider interventions aimed solely at increasing physical activity; however interventions that target both an increase in physical activity and a reduction in sedentary behaviour will be included but presented separately.

We will compare the interventions described above with no intervention or with standard care or with other active interventions.

**Types of outcome measures**

**Primary outcomes**

1. Time spent sedentary (measured by self-reported measures or objective measures).
2. Time spent in specific sedentary behaviour (e.g. time spent watching TV) as defined by the International Classification of Sedentary Behaviours (Chastin 2013).
3. Pattern of accumulation of sedentary time (e.g. number of breaks in sedentary time (Chastin 2015a, Healy 2008), distribution of bouts of sedentary time (Chastin 2010)).

**Secondary outcomes**

1. Quality of life.
2. Depression.
3. Health status (improvement in physical function, cardiovascular and metabolic outcomes, and improvement in cognition).

**Search methods for identification of studies**

The draft search strategy for MEDLINE will be used as the basis for search strategies in the other databases.

The search string is presented in Appendix 1.

**Electronic searches**

We will search all potentially eligible published studies. We will create a comprehensive search strategy, derived from terms related to sedentary behaviour, study design type, and population of study participants. Search criteria will be informed by reviews by Martin and colleagues and Prince and colleagues (Martin 2015; Prince 2014). We will search the following electronic databases to identify a list of potential articles that are written in English.

1. Cochrane Central Register of Controlled Trials (CENTRAL) in the Cochrane Library.
2. Embase (Embase.com).
3. MEDLINE (PubMed).
4. World Health Organization (WHO) International Clinical Trials Registry Platform (ICTRP) search portal (apps.who.int/trialsearch).
5. CINAHL EBSCO (Cumulative Index to Nursing and Allied Health Literature).
6. ClinicalTrials.gov (ClinicalTrials.gov).
7. PsycINFO (ProQuest).
Searching other resources

We will consult the reference list of articles for additional studies. We will also contact experts in the field through the International Physical and Environment Network (www.ipenproject.org/index.html), International Society for Physical Activity and Health (www.ispah.org), Sedentary Behaviour Research Network (www.sedentarybehaviour.org) and other leading international research networks in order to identify any additional work which is unpublished.

Data collection and analysis

Selection of studies

Two authors will review studies independently through three stages: 1) title screening; 2) abstract screening; 3) full-text screening. Authors will code the studies at each stage of the review process as ‘included’ or ‘excluded’. If they encounter any inclusion or exclusion discrepancies, the two authors will either resolve them by discussion, or consult a third author who will act as arbitrator. We will exclude duplicate studies. We will record and present the inclusion process in a PRISMA flow diagram (Moher 2009).

Data extraction and management

We will extract the following data from all studies using the Cochrane Public Health extraction template.

1. Methodological information: study design, intervention duration, follow-up duration, study date, context.
2. Participant information: inclusion and exclusion criteria, sample size, age range, pre-intervention and post-intervention sitting time, health status, socioeconomic status.
4. Intervention information: intervention description, length and if a comparison intervention or control group was used.
5. Outcome information: reporting both primary and secondary outcomes.
6. Additional information: conflicts of interest; intervention fidelity (whether the intervention was delivered as planned); information on the nature and extent of any additional actions given as part of the intervention (co-interventions); intervention costs; source of study funding.

We will resolve any disagreements regarding data extraction by discussion or, if needs be, by consulting a third author. They will initially enter all extracted information into a spreadsheet before one author transfers it to Review Manager 5 (RevMan 5). A second author will double check the data once it is transferred to ensure correct data entry.

We will present these data in a ‘Characteristics of included studies’ table.

Assessment of risk of bias in included studies

Two review authors will independently assess the included studies with respect to risk of bias. We will assess RCTs using Cochrane’s ‘Risk of bias’ tool (Higgins 2011). This tool assesses five domains: selection bias (sequence generation and allocation concealment); performance and detection bias (blinding); attrition bias (incomplete outcome data, withdrawals, dropouts, protocol deviations); reporting bias; and an open ‘other bias’ category (such as baseline comparability for age, gender and occupation).

For the other study designs, we will use study-appropriate risk of bias domains as developed by the EPOC group (EPOC 2017): similar baseline characteristics, similar baseline outcome measures, reliable primary outcome measures and adequate protection against contamination. For ITS studies we will consider the following domains: was the intervention independent of other changes, was the shape of the intervention effect pre-specified, was the intervention unlikely to affect data collection, was knowledge of the allocated intervention adequately prevented during the study, were incomplete outcome data adequately addressed, was the study free from selective outcome reporting and was the study free from other risks of bias? For cluster RCT we will consider (i) recruitment bias; (ii) baseline imbalance; (iii) loss of clusters; (iv) incorrect analysis; and (v) comparability with individually randomised trials.

We will resolve any disagreement in the assessment between the two review authors by discussion or consensus with a third review author. We will assess the likely magnitude and direction of the bias on the findings.

We will assess each potential source of bias as high, low or unclear and provide a justification for our judgment in the ‘Risk of bias’ tables. We will not consider blinding of participants and personnel for risk of bias assessment as it is not possible to blind them in studies trying to modify sedentary behaviour. We will consider each blinding of outcome assessment differently when sedentary time is assessed objectively or by self-report. Studies will be deemed to have a high risk of bias if we judge the study to have a high risk of bias in any of the criteria (excluding blinding of participants and personnel).

Measures of treatment effect

In order to calculate treatment effects, we will enter outcome data from all included studies into RevMan 5. We will use risk ratio
Unit of analysis issues
If a selected study includes multiple trial arms, then we will include only the relevant arms. If trials with multiple relevant intervention arms incorporate a standard care or placebo or control arm to their trial, we will include them and compare each arm to the control. For cluster-randomized studies that report sufficient data to be included in the meta-analysis but do not correct for the design effect, we will calculate the design effect based on a fairly large assumed intracluster correlation coefficient of 0.10. If the study used a cluster design, we will assess whether the reported results were properly adjusted to account for clustering effects and what method was used.

Dealing with missing data
If there are missing numerical outcome data, we will contact study authors in an attempt to retrieve them. In the event that we are unable to gather these data then a risk of bias might be introduced, and we will conduct a sensitivity analysis to assess the impact of including the study. Two authors will then discuss whether the study should be included in the analysis or excluded due to a high potential risk of bias.

If outcome data such as standard deviations are missing and we cannot obtain them from the authors, we will derive them from other available statistics following the methods described in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011).

Assessment of heterogeneity
We will class studies as homogeneous when the results are similar with regards to participants, interventions and outcomes. We will analyse heterogeneity using the I² and Chi² statistic and corresponding P value, as well as Tau² for random-effects meta-analysis. We will report degrees of heterogeneity as a low degree of heterogeneity (25% to 50%), a moderate degree of heterogeneity (50% to 75%) or a high degree of heterogeneity (75% or higher).

Assessment of reporting biases
Provided that we are able to pool more than 10 trials in any meta-analysis, publication bias will be assessed using the funnel plot and Egger’s test methods (Egger 1997).

Data synthesis
We will sort the included studies according to the intervention, measures and comparisons made. We will assess results for each comparison and collate them separately. The findings of the studies will be systematically examined and integrated across studies. The included studies will be described and grouped by study design, population, outcomes, and setting. We will tabulate data and use them to explore relationships within and between included studies in a narrative summary.

If population, study design, intervention and outcome measures are similar enough across studies, we will conduct meta-analyses using RevMan 5. If outcomes within a comparison are obtained from several study designs, we will present results from non-randomised designs separately.

We will use RevMan 5 to gather homogeneous data (including economic data) from studies. We will perform meta-analysis if appropriate. We will use a fixed-effect model for homogeneous data, whilst if we find data to be statistically heterogeneous we will use a random-effects model. We will analyse intervention effects according to primary intervention categories: self-reported sitting time, television viewing, miscellaneous sedentary time, and objectively measured sitting time.

If we do not consider meta-analysis to be meaningful or appropriate, we will present descriptive data in text and tables and synthesise narratively in the main text of the review. We will structure the narrative synthesis according to study design or study quality and intervention setting.

Quality of the evidence
We will present the main outcome measures in a ‘Summary of findings’ table and will assess the quality of evidence for each of the outcomes using the GRADE methodology (Guyatt 2011). Using GRADE, we will reflect the extent to which we have confidence that the estimates of effect are correct. Our confidence will be presented as either high, moderate, low or very low. We will assess the results for each outcome measure against eight criteria. The first five criteria are considered for possible downgrading of the quality of documentation: study quality (risk of bias); consistency (consistency between studies); directness (the same study participants, intervention and outcome measures in included studies is for the people, measures and outcomes we wanted to study); precision of results; and reporting biases. Results can be upgraded by three criteria: strong or very strong associations between intervention and outcome; large or very large dose-response effects; and where all plausible confounders would have reduced the effect.

Subgroup analysis and investigation of heterogeneity
If there are sufficient data, we will explore subgroup analysis on the primary research objective. The following subgroups will be examined using the outcomes of self-reported sitting time, television viewing, miscellaneous sedentary time and objectively measured sitting time.
1. Gender.
2. Geographical location (e.g. difference between urban and rural settings).
3. Socioeconomic status.

Sensitivity analysis
We will assess the robustness of our conclusions by performing a sensitivity analysis in which we will exclude studies judged to have a high risk of bias from the meta-analysis on primary outcomes.

ACKNOWLEDGEMENTS
The authors wish to acknowledge the editorial team of the Cochrane Public Health Group and the librarians at Glasgow Caledonian University who will create and execute the search strategies for the electronic databases. No funding was used to prepare this protocol.
