Antenatal synthetic glucocorticoids promote fetal maturation in pregnant women at risk of preterm delivery and their mechanism of action may involve other endocrine systems. This study investigated the effect of maternal dexamethasone treatment, at clinically relevant doses, on components of the renin-angiotensin system (RAS) in the pregnant ewe and fetus. From 125 days of gestation (term 145±2 days), ten ewes carrying single fetuses of mixed sex (3 female, 7 male) were injected twice intramuscularly, at 22:00–23:00h, with dexamethasone (2x12mg, n=5) or saline (n=5) at 24-hour intervals. At 10 hours after the second injection, maternal dexamethasone treatment increased angiotensin-converting enzyme (ACE) mRNA levels in the fetal lungs, kidneys and heart, and ACE concentration in the circulation and lungs, but not kidneys, of the fetuses. Fetal cardiac mRNA abundance of angiotensin II type 2 receptor decreased following maternal dexamethasone treatment. Between the two groups of fetuses, there were no significant differences in plasma angiotensinogen or renin concentrations; in transcript levels of renal renin, or AII type 1 or 2 receptors in the lungs and kidneys; or in pulmonary, renal or cardiac protein content of the AII receptors. In the pregnant ewes, dexamethasone administration increased pulmonary ACE and plasma angiotensinogen, and decreased plasma renin, concentrations. Some of the effects of dexamethasone treatment on the maternal and fetal RAS were associated with altered insulin and thyroid hormone activity. Changes in the local and circulating RAS induced by dexamethasone exposure in utero may contribute to the maturational and tissue-specific actions of antenatal glucocorticoid treatment.

In clinical practice, synthetic glucocorticoids, such as dexamethasone, are administered routinely to pregnant women at risk of preterm delivery in order to promote fetal maturation and neonatal survival (1, 2). These drugs mimic the normal rise in endogenous glucocorticoids seen in the fetus near term by promoting structural and functional changes in fetal tissues in preparation for life after birth (3). Over the last forty years, antenatal glucocorticoid therapy has improved survival of the premature infant and has reduced markedly the incidence of many disorders associated with preterm delivery, such as respiratory distress syndrome (RDS) (2, 4). The clear beneficial effects of maternal glucocorticoid treatment have been offset, however, by evidence showing adverse consequences for growth and long-term blood pressure (BP) control, especially in infants exposed to multiple doses in utero (5, 6, 7). It is therefore important to understand the mechanisms of glucocorticoid action in the control of fetal growth and maturation.

Abbreviations:
Some of the effects of the glucocorticoids on the development of fetal tissues are mediated, in part, by other endocrine systems (8, 9). For example, in fetal sheep, endogenous and synthetic glucocorticoids stimulate the production of the active thyroid hormone, triiodothyronine (T₃), and in turn, T₃ promotes hepatic glycogen deposition and gluconeogenic enzyme activity in preparation for blood glucose control at birth (10, 11, 12, 13). The renin-angiotensin system (RAS) is functional in the fetus from relatively early in gestation (14, 15) and is known to have an important role in the growth and development of specific tissues, as well as in the regulation of renal and cardiovascular function in utero (16, 17, 18). A number of maturational changes are observed in the fetal RAS near term, some of which are regulated by the prepartum surge in endogenous glucocorticoids (19, 20, 21, 22). In addition, direct administration of dexamethasone to the sheep fetus increases both pulmonary and circulating concentrations of angiotensin-converting enzyme (ACE) in association with a rise in fetal arterial BP (23). However, the effect of maternal dexamethasone treatment, in a regime similar to that used in clinical practice, on the components of the RAS in the pregnant mother and fetus during late gestation is unknown in any species.

Therefore, the aim of this study was to investigate the acute effect of maternal dexamethasone treatment, in clinically relevant doses, on various components of the RAS in the pregnant ewe and fetus. The study hypothesized that synthetic glucocorticoid administration to the pregnant ewe would stimulate components of both the maternal and fetal RAS with potential consequences for fetal development.

Materials and Methods

Animals

Ten Welsh Mountain ewes carrying singleton fetuses of known gestational age were used in this study. There were 3 female and 7 male fetuses. The ewes were maintained on 200 g kg⁻¹ concentrates daily (sheep nuts #6; 18% protein and 10 MJ/kg; H & C Beart Ltd, King’s Lynn, UK) with free access to hay, water and a salt-lick block. All experimental procedures were carried out in accordance with the UK Animals (Scientific Procedures) Act 1986 and approved by the research ethics committee at the University of Cambridge.

Materials and Methods

From 125 days of gestation, all of the ewes were injected twice intramuscularly (IM) with either dexamethasone (2 × 12 mg in 2 ml 0.9% NaCl, n = 5) or saline (2 ml 0.9% NaCl, n = 5) at 24-hour intervals. The experimental regime of dexamethasone treatment was similar to that recommended in human clinical practice by the Royal College of Obstetricians and Gynaecologists (24). At 10 hours after the second injection, the fetuses were delivered by Caesarean section under general anesthesia (20 mg kg⁻¹ sodium pentobarbitone i.v.). This time point was chosen so that data were obtained when the fetal dexamethasone concentration was comparable to previous studies that examined the cardiovascular effects of (a) maternal dexamethasone treatment and (b) direct fetal dexamethasone infusion in chronically catheterized fetuses (25, 26). The plasma dexamethasone concentration in the sheep fetus at this time point was approximately one-fifth of that measured in umbilical arterial blood samples taken from human infants at Caesarean section after maternal dexamethasone treatment (27). Before anesthesia at between 09:00 and 10:00h, 10 ml blood samples were obtained from the ewes by jugular venepuncture. At delivery, 10 ml blood samples were taken by venepuncture of the umbilical artery, and a number of tissues were collected from the ewes and fetuses after the administration of a lethal dose (LD) of barbiturate (200 mg kg⁻¹ sodium pentobarbitone i.v.). Samples of lung, kidney and heart from the fetus, and lung and kidney, but not heart, from the ewe, were immediately frozen in liquid nitrogen and stored at –80°C until analysis.

Biochemical analyses

Plasma hormone concentrations

All blood samples were immediately placed into EDTA-containing tubes and centrifuged for 5 minutes at 1000g and 4°C. The plasma aliquots were stored at –20°C until analysis. Plasma angiotensinogen and renin concentrations were measured by radioimmunoassay (RIA) as described previously (28, 29). The lower limits of detection were 0.01 μg ml⁻¹ for angiotensinogen and 0.5 pg ml⁻¹ h⁻¹ for renin. Plasma concentrations of cortisol, thyroxine (T₄), T₃ and insulin were measured by RIA or ELISA as detailed and published in these animals previously (12, 30).

RAS protein concentrations

Tissue and plasma ACE concentrations (as a proxy measure of activity) were determined by a spectrophotometric enzyme assay as described previously (20, 22). Tissue ACE concentration was expressed as nanomoles of hippurate generated per min per mg protein, while plasma ACE concentration was measured in U l⁻¹ where 1 U equals 1 μmole of hippurate generated in 1 minute. Protein levels of the angiotensin (All) type 1 and 2 receptor subtypes (AT₁R and AT₂R) were determined in maternal lung and renal cortex, and fetal lung, heart and renal cortex, by Western blotting as detailed previously (31). The primary antibodies used were both rabbit polyclonal antibodies to epitopes on the human AT₁R (0.2 μg/ml 306, sc-579, Santa Cruz Biotechnology, Santa Cruz, USA) and the human AT₂R (0.04 μg/ml H-143, sc-9040, Santa Cruz Biotechnology; Supplemental Table 1). Membranes
were analyzed with Ponceau S to normalize for protein loading as validated previously (32). Proteins were quantified using Image J software (National Institutes of Health, Bethesda, USA; http://rsb.info.nih.gov/ij/) and ratios of protein content were arc-sine transformed prior to statistical analysis.

**RAS mRNA abundance**

Tissue mRNA abundance of renin, ACE, AT$_1$R and AT$_2$R were measured by Taqman quantitative RT-PCR. Frozen samples of tissue (15 mg) were placed in Lysing Matrix-D tubes (MP Biomedicals, Loughborough, UK) with 170 μl lysis/bindng solution from a MagMax96 Total RNA Isolation kit (Life Technologies, Paisley, UK) and 0.75 μl β-mercaptoethanol, and homogenized using a FastPrep-24 (MP Biomedicals, Santa Ana, USA). After homogenisation, 106 μl 100% isopropanol was added to each sample. Samples were placed into a MagMAX96 system (Applied Biosystems, Paisley, UK) where RNA was isolated and DNase treated (TURBO DNase) using the Mag-MAX96 Total RNA Isolation Kit (Life Technologies). Sample RNA yields and purities were assessed by a Nanodrop (Thermo Fisher, Loughborough, UK). Ratios of absorption (260/280nm) of all preparations were between 1.8 and 2.0.

Reverse transcription of mRNA was carried out using a PCR Express machine (Thermo Fisher) and materials from Promega (Southampton, UK) and Invitrogen (Paisley, UK). For each sample, 5 μl of DNase-treated RNA was mixed with 1 μl random primers, 1 μl deoxyribonucleotide triphosphate mix and 5 μl RNase-free water, and incubated at 65°C for 2 minutes. A master reverse transcription mix was made, consisting of 4 μl first strand buffer, 2 μl dithiothreitol, 1 μl RNaseOUT and 1 μl Superscript II enzyme. The samples were incubated at room temperature for 5 minutes, at 42°C for 50 minutes and at 70°C for 15 minutes.

TaqMan qRT-PCR was performed to measure mRNA abundance of target genes in tissue samples. Samples were analyzed using a TaqMan 7900HT and data were acquired and processed using Sequence Detector v.2.3 software (Applied Biosystems). TaqMan Master Mix (5 μl), 0.5 μl target gene probe and primer set, and 3.5 μl water, were added to each well of a 96-well HT plate (Applied Biosystems). In addition, 1 μl tissue cDNA at 1:20 dilution was added to each well apart from the nontemplate controls, where 1 μl of water was added. The sequences of the TaqMan qRT-PCR probes for renin, ACE, AT$_1$R and AT$_2$R are listed in Table 1. Each tissue sample was measured in triplicate and normalized to the geometric mean of two housekeeping genes, GAPDH and cyclophilin A (Table 1). The mRNA levels of these housekeeping genes were not affected by maternal dexamethasone treatment. For each assay, a negative control without cDNA was included to ensure that amplicon contamination had not occurred in the reaction. Cycle thresholds (Ct) determined by qRT-PCR were analyzed by the ddCt method as all standard curves were linear and parallel.

**Statistical analyses**

A sample size of five animals was calculated in order to find a two-fold difference in fetal pulmonary ACE concentration, assuming a standard deviation of 0.26, and to achieve 99% power at the 5% significance level. This sample size calculation was based on mean and standard deviation values measured in previous studies from this laboratory examining the effects of fetal dexamethasone treatment on pulmonary ACE concentration (23; Sigmastat 3.5, Systat Software Inc, Chicago, USA). All data are presented as mean ± SEM. The distributions of data for plasma and tissue measurements were assessed for normality by the Kolmogorov-Smirnov test, and compared between the treatment groups by Student’s unpaired t test (parametric) or Mann-Whitney test (nonparametric), as appropriate. Relationships between the variables measured were determined by Pearson correlation and partial correlation analyses. The Null Hypothesis was rejected where $P < .05$.

**Results**

**Fetus**

Within 10 hours of the second maternal injection of dexamethasone, the fetal plasma concentration of ACE increased significantly (Figure 1A, $P < .05$). Plasma cortisol decreased, and T$_3$ and insulin concentrations increased in the fetuses exposed to dexamethasone compared to those from the saline-treated ewes (Table 2, $P < .05$). There were no significant differences in plasma concentrations of angiotensinogen, renin or T$_4$ between the two groups of fetuses (Table 2, Figure 1A).

Pulmonary ACE mRNA and ACE concentration were significantly greater in the fetuses exposed to dexamethasone compared to the control fetuses (Figure 2A, $P < .05$). The mRNA levels of ACE in the fetal kidney and

heart were also elevated by maternal dexamethasone treatment (Figures 3A and 4A, \( P < 0.05 \)), although renal ACE concentration was unchanged and cardiac ACE concentration was below the limit of assay detection in both groups of fetuses (0.10 nmol min\(^{-1}\) mg protein\(^{-1}\); Figure 3A).

Neither relative mRNA abundance nor protein content for AT\(_1\)R and AT\(_2\)R in the lungs and kidneys were significantly different between fetuses of mothers treated with dexamethasone or saline (Table 3). Renal renin mRNA abundance was also unchanged by maternal dexamethasone treatment (Table 3). In the fetal heart, no significant changes in AT\(_1\)R mRNA level, or protein content of AT\(_1\)R or AT\(_2\)R, were seen following maternal dexamethasone treatment, although cardiac AT\(_2\)R mRNA abundance was reduced in the fetuses exposed to dexamethasone (Table 3, Figure 4B, \( P < 0.05 \)).

When observations from all of the fetuses were considered, a significant positive correlation was observed between pulmonary ACE concentration and circulating ACE levels (\( r = 0.77, P < 0.001, n = 10 \)). Significant negative correlations were observed between plasma cortisol concentration and both pulmonary ACE mRNA abundance and plasma ACE concentration (Table 4). Plasma renin concentration was negatively correlated with plasma ACE concentration in the fetuses (Table 4). In addition, plasma T\(_3\) correlated with plasma insulin concentration and various components of the fetal RAS (Table 4). Significant positive relationships were also seen between plasma insulin concentration and various components of the fetal RAS (Table 4). Partial correlation analyses showed that pulmonary ACE concentration and renal ACE mRNA were positively associated with plasma T\(_3\) concentration (\( r = 0.67, P < 0.05, n = 10 \) and \( r = 0.72, P < 0.05, n = 10 \), respectively), independent of plasma insulin; all other partial correlations failed to identify a single significant independent factor when multiple hormones correlated with RAS components.

### Ewe

In the ewes treated with dexamethasone, plasma concentrations of cortisol, renin, T\(_3\), and T\(_4\) were suppressed, and plasma insulin increased, within 10 hours of the second injection (Table 2, Figure 2B, \( P < 0.05 \)). Plasma angiotensinogen concentration was increased by dexamethasone administration, but this just failed to reach statistical significance (Figure 1B, \( r = 0.059 \)). Maternal dexamethasone treatment had no significant effect on plasma ACE concentration (Figure 1B).

Pulmonary ACE concentration was increased in the dexamethasone-treated ewes compared to those of saline-treated ewes (Figure 1A, \( P < 0.05 \)).

### Table 2. Plasma concentrations of cortisol, thyroid hormones (thyroxine T\(_4\) and triiodothyronine T\(_3\)) and insulin in the ewes and fetuses at 10 h after saline or dexamethasone treatment. Data are presented as mean values (\( \pm \) SEM). *, significantly different from saline-treated group, \( P < 0.05 \).

**Figure 1.** Plasma concentrations of angiotensinogen, renin and ACE in the fetuses (A) and ewes (B) sampled at 10 hours after the second daily injection of either saline (\( \square \), \( n = 5 \)) or dexamethasone (\( \blacksquare \), \( n = 5 \)). Data are presented as mean values (\( \pm \) SEM). Significant difference from saline-treated group, * \( P < 0.05 \), † \( P = 0.06 \).
treated with saline (Figure 2B, $P < .05$); however, there was no significant effect of dexamethasone administration on ACE mRNA abundance in the maternal lungs (Figure 2B). Renal ACE mRNA and ACE concentrations were also unchanged by maternal dexamethasone treatment (Figure 3B). Maternal dexamethasone treatment had no significant effect on the gene transcript or protein levels of the AII receptors in the lungs and kidneys, or renin mRNA abundance in the kidneys of the pregnant ewes (Table 3).

Using data from all ewes, significant inverse correlations were observed between pulmonary ACE concentration and plasma concentrations of both cortisol ($r = -0.89$, $P < .001$, $n = 10$) and T4 ($r = -0.80$, $P < .005$, $n = 10$). Partial correlation analyses showed that pulmonary ACE concentration was inversely associated with plasma T4 concentration ($r = -0.74$, $P < .05$, $n = 10$), independent of plasma cortisol concentration. Plasma renin concentration was correlated with renal renin mRNA abundance ($r = +0.70$, $P < .05$, $n = 10$) in the pregnant ewes. Significant positive relationships were also seen between plasma T3 concentration and both renal renin mRNA abundance ($r = +0.67$, $P < .05$, $n = 10$) and plasma renin concentration ($r = +0.75$, $P < .01$, $n = 10$);

**Discussion**

**Effects of maternal dexamethasone treatment on the RAS in utero**

The present study demonstrates for the first time that maternal dexamethasone treatment, at a dose equivalent (DE) to that used in clinical practice, alters various components of the RAS in both the pregnant ewe and fetus. Administration
of the synthetic glucocorticoid upregulated ACE mRNA abundance in a variety of fetal tissues; it also increased pulmonary ACE concentration in both the pregnant ewe and fetus, and ACE concentration in the fetal circulation. In the pregnant ewe, plasma angiotensinogen tended to increase in response to dexamethasone administration, and plasma renin was suppressed which suggested negative feedback control by activation of the AT1R in the kidney.

In the present study, the increments in circulating and pulmonary ACE concentrations observed in the fetuses after maternal dexamethasone treatment were similar to those seen previously in sheep fetuses infused directly with the synthetic glucocorticoid (23). In addition, both fetal and maternal routes of dexamethasone administration had no significant effect on renal ACE concentration in the sheep fetus (23).

Table 3. Relative protein and mRNA levels of renin, AT1R and AT2R in fetal and maternal lung and kidney at 10 h after saline or dexamethasone treatment. Data are presented as mean fold changes (± SEM) relative to the saline-treated group. NA, not available. Significant difference from saline-treated group, * P < 0.05

Table 4. Correlation coefficients from relationships between plasma hormone concentrations in the fetuses, and ACE mRNA and concentrations in the fetal circulation and tissues. NS, not significant. Pearson correlation, n = 10; *P < 0.05, **P < 0.005

Figure 4. Cardiac ACE (A) and AT1R (B) mRNA levels in the fetus at 10 hours after saline ( ), n = 5) or dexamethasone ( , n = 5) treatment. Data are presented as mean fold changes (± SEM) relative to the saline-treated group. Significant difference from saline-treated group, * P < .05.
The present findings indicate that maternal dexamethasone treatment elevated pulmonary and circulating ACE concentration in utero, at least in part, by increasing ACE mRNA abundance in the lungs and other fetal tissues. At 10 hours after the second injection of dexamethasone to the pregnant ewe, ACE mRNA levels in the fetal kidney and heart had increased without any change in enzyme concentration. The duration of exposure to the synthetic glucocorticoid, and/or the timing of tissue collection, however, may have been too short to observe significant effects on protein translation in these fetal organs.

The changes in plasma and pulmonary ACE concentration, and cardiac ACE mRNA, induced in utero by maternal dexamethasone treatment were similar to the normal maturational changes seen in sheep fetuses close to term (22, 33). In the lungs, ACE is localized to the vascular endothelium and for most of gestation, both pulmonary blood flow and ACE concentration in the fetal lungs are relatively low. However, pulmonary ACE concentration in the fetus increases near term and this appears to be driven by the prepartum glucocorticoid surge as part of the preparation for extrauterine life (22). Neonatal plasma AII concentrations after vaginal delivery are much higher than after Caesarean section in human infants (34), suggesting that the capacity to convert AI to AII is activated by exposure to endogenous glucocorticoids before birth in preparation for pulmonary vasodilatation and increased pulmonary blood flow and delivery of AI after birth.

Developmental changes in AII receptor expression are also seen in the fetus towards term. The relative expression of AII receptor subtypes in a variety of fetal tissues shifts with gestational age from widespread AT$_2$R abundance to tissue-specific and predominant localization of AT$_1$R (35). In the heart of the sheep fetus, mRNA abundance and receptor density of the AT$_2$R receptor are high from at least midgestation and decrease over the perinatal period (36, 37). The reduction in cardiac AT$_2$R mRNA level induced by dexamethasone in the present study indicates that the normal developmental decline in AT$_2$R expression seen in the fetal heart near term may be a glucocorticoid-dependent event.

**Mechanisms of glucocorticoid action on the RAS**

The mechanisms of glucocorticoid action on the RAS in the pregnant ewe and fetus may be direct and/or indirect involving coincident changes in other endocrine systems, such as insulin and the thyroid hormones. The effects of antenatal glucocorticoid treatment on the RAS observed in the present study are unlikely to be the consequence of fetal hypoxaemia or hypotension. In the chronically-catheterized pregnant ewe and fetus, the same protocol of maternal dexamethasone treatment does not influence fetal blood gas status and causes a small, but significant, rise in arterial BP (26, 38).

Dexamethasone may have direct effects on the genes for angiotensinogen, ACE and the AT$_2$R. A glucocorticoid-response element in the angiotensinogen gene is an important regulator of angiotensinogen synthesis (39); thus, the near-significant rise in maternal plasma angiotensinogen may have been directly stimulated by dexamethasone treatment. Glucocorticoid-response elements have also been identified close to a promoter region in the murine angiotensinogen gene which have inhibitory influences on promoter activity and AT$_2$R gene expression (45). Indeed, AT$_2$R mRNA and protein levels in hearts isolated from fetal rats are suppressed by 48 hours of dexamethasone treatment in vitro (45).

The present study was part of a larger project examining the effects of maternal dexamethasone treatment on fetal growth and development and in which plasma concentrations of insulin and the thyroid hormones were measured (12, 30). Significant associations were observed between circulating concentrations of T$_3$ in the fetus and plasma and pulmonary ACE concentrations, and the transcript levels of ACE in the fetal lungs, kidneys and heart. These findings support the suggestion that T$_3$ may have an important role in mediating the regulatory effects of glucocorticoids on tissue and circulating ACE expression in utero (46). Indeed, in fetal sheep, experimental thyroid hormone deficiency prevents the normal developmental rise in pulmonary and renal ACE concentration near term, and exogenous T$_3$ infusion has been shown to increase ACE concentration in the fetal lungs, but not kidneys (46). Previous studies, however, have shown that maternal dexamethasone treatment has differential effects on the thyroid hormone axis in the pregnant ewe and fetus (12). In the sheep fetus, synthetic and endogenous glucocorticoids activate the production of T$_3$, while in the mother, the thyroid hormone axis is suppressed (11, 12). Therefore, the rise in pulmonary ACE concentration seen in the pregnant ewe treated with dexamethasone may be the direct consequence of glucocorticoid, rather than T$_3$, action. Alternatively, dexamethasone and/or T$_3$ may have different and tissue-specific effects on ACE expression in the
fetus and mother. In adult rats, dexamethasone treatment causes a rise in ACE concentration in the lungs, but not renal cortex or medulla, and T3 administration reduces pulmonary ACE, while increasing renal and circulating ACE, concentrations (47).

**Implications of altered RAS activity induced by maternal dexamethasone treatment**

Changes in the activity of the RAS in utero following maternal dexamethasone treatment may contribute to the maturation of fetal tissues induced clinically by synthetic glucocorticoids. In addition, alterations in fetal RAS activity may have both local and endocrine effects on growth and maturation before birth (48). Although a limitation of this study was that circulating and tissue concentrations of RAS, and downstream signaling pathways, were not determined, the increase in pulmonary ACE concentration is likely to result in enhanced production of AII locally in the lungs of the ewe and fetus. Local production of AII in the fetal lungs has been shown to promote maturation of pulmonary structure, including vascularization and airway branching (49, 50) and may mediate, in part, some of the beneficial effects of antenatal synthetic glucocorticoids on the developing lungs.

Activation of ACE mRNA, and suppression of AT2R mRNA, abundances in the fetal heart by dexamethasone may influence the development of cardiac structure and function in utero, if the mRNA levels were to translate to altered protein expression in the longer term. The developmental processes of growth and differentiation in fetal cardiomyocytes are sensitive to glucocorticoids and thyroid hormones (51), and the mechanisms of hormone action may involve changes in local AII activity (52, 53). It is increasingly recognized that, while antenatal synthetic glucocorticoid treatment can be life-saving for the infant when delivery occurs preterm, there may also be adverse sequelae reaching into adulthood (54). Indeed, dexamethasone-induced changes in the fetal RAS, especially within the heart and kidney, may have acute and long-term consequences for the regulation of arterial BP.

Previously, arterial BP was found to correlate with pulmonary ACE concentration in sheep fetuses infused with either dexamethasone or saline (23). Pulmonary ACE is responsible both for the production of vasoconstrictive AII and for the degradation of the vasodilator bradykinin, and the RAS is known to have an important role in the control of fetal BP by peripheral and central mechanisms (55, 56, 57). Furthermore, the RAS has been implicated in the developmental programming of hypertension in sheep and rodent offspring exposed to glucocorticoids in utero (58, 59, 60). In conclusion, antenatal dexamethasone treatment stimulates components of the maternal and fetal RAS, and suppresses fetal cardiac AT2R mRNA levels, in the sheep. These changes may influence maturation of the developing lungs, heart and kidney, and may have acute and long-term consequences for the regulation of arterial BP.
