20 **Abstract:**

21 Despite the growing interest in ecosystem services provided by intertidal wetlands, we lack
22 sufficient understanding of the processes that determine the seaward extent of salt marsh
23 vegetation on tidal flats. With the present study, we aim to establish a globally valid demarcation
24 between tidal flats and salt marsh vegetation in relation to tidal range.

25 By comparing results from a regional GIS study with a global literature search on the salt marsh-
26 tidal flat border, we are able to define the global critical elevation, above which salt marsh plants
27 can grow in the intertidal zone. Moreover, we calculate inundation characteristics from global
28 tide gauge records to determine inundation duration and frequency at this predicted salt marsh -
29 tidal flat border depending on tidal range.

30 Our study shows that the height difference between the lowest elevation of salt marsh pioneer
31 vegetation and mean high water increases logarithmically with tidal range when including
32 macrotidal salt marshes. Hence, the potentially vegetated section of the tidal frame below mean
33 high water does not proportionally increase with tidal range.

34 The data analysis suggests that inundation frequency rather than duration defines the global
35 lower elevational limit of vascular salt marsh plants on tidal flats. This is critical information to
36 better estimate sea level rise and coastal change effects on lateral marsh development.

37

38 **Introduction**

39 Coastal salt marshes worldwide provide important ecosystem services to society as the
40 final terrestrial frontier facing the open tidal flats. Upon submersion, the vegetation buffers
41 waves and currents to stabilise the coast and trap sediment to increase surface elevation [*Cahoon*
42 *et al.*, 1996; *Temmerman et al.*, 2013; *Möller et al.*, 2014]. Salt marshes often front coastal
43 infrastructure such as dikes making them an important part of coastal protection measures
44 [*Temmerman et al.*, 2013; *Möller et al.*, 2014] while storing large amounts of carbon in their soil
45 [*Duarte et al.*, 2013]. The biogeomorphic feedbacks, arising from interactions between sediment
46 transport and vegetation growth, lead to complex self-organized landscapes and a non-linear
47 response to environmental forcing [*van de Koppel et al.*, 2005; *Marani et al.*, 2010; *Balke et al.*,
48 2014]. The border between salt marsh vegetation and the tidal flat is of general ecological
49 importance as it determines the ratio of vegetated and bare intertidal area within the intertidal
50 zone and hence e.g. the length over which salt marsh vegetation can attenuate waves or the
51 available area for foraging birds on tidal flats. Although regional definitions of the critical
52 elevation above which salt marsh pioneer plants are able to survive, can be found in the scientific
53 literature (see e.g. *Hinde*, 1954; *Mckee and Patrick*, 1988; *Castillo et al.*, 2000; *Morris et al.*,
54 2002; *Suchrow and Jensen*, 2010), a global data driven comparison is lacking. This is surprising,
55 as scientists have been very successful in testing and developing general ecological principles in
56 the intertidal zone especially regarding species zonation [*Adams*, 1963; *Bertness et al.*, 2002;
57 *Costa et al.*, 2003]. Accelerated sea level rise, changes in tidal range, changing weather pattern
58 and increasing anthropogenic pressure on the coastal zone worldwide however call for a global
59 definition of this marine-terrestrial border and influences thereon.

60 Despite their adaptive nature, salt marsh and also mangrove ecosystems have increasingly

61 gained attention in recent years as rising sea levels may pose a threat through drowning (i.e.
62 sediment accretion rates $<$ rates of SLR, [Reed, 1995; McKee *et al.*, 2007; Mariotti and
63 Fagherazzi, 2010; Kirwan and Megonigal, 2013]) and wetlands are ‘squeezed’ between rising
64 sea levels and coastal infrastructure [Doody, 2004]. Kirwan *et al.*, [2016], however, recently
65 highlighted that focusing on vertical salt marsh development is not sufficient to predict future
66 development and identified lateral marsh development as one of the main knowledge gaps. The
67 influence of changing tidal range on salt marsh functioning has gained much less attention than
68 effects of changes in mean sea-level (but see modelling study by Kirwan and Guntenspergen
69 [2010]). Sea-level rise is however known to positively and negatively affect tidal range locally
70 with unknown consequences for salt marsh development [Woodworth *et al.*, 1991; Pickering *et*
71 *al.*, 2012]. These changes are reinforced by deepening of shipping channels, the construction of
72 dikes and closures that increase tidal range, or on the contrary, by storm surge barriers reducing
73 tidal range behind them, even while they remain open [Woodworth *et al.*, 1991; Pickering *et al.*,
74 2012]. The Dutch coast is a prime example of a highly modified coastline. After the construction
75 of the storm surge barrier in 1987 at the Oosterschelde (SW Netherlands), tidal range has
76 decreased by 12% within the former estuary [Louters *et al.*, 1998] (see Fig. 1 A station
77 Stavenisse). Closing-off of the Zuiderzee in the Netherlands in 1932 has led to a sudden increase
78 in tidal range in front of the new dike by up to 50 cm [Jonge *et al.*, 1993] (see Fig. 1A station
79 Harlingen). Deepening of estuaries to allow the passing of increasingly big vessels to the major
80 harbors have led to an increase in tidal range of several decimeters for example in the
81 Westerschelde (SW Netherlands) and the Elbe estuary (Germany) [Meire *et al.*, 2005; Kerner,
82 2007] (see Fig. 1A, station Terneuzen). Natural variability of tidal range due to the 18.6 year
83 nodal tidal cycle (see e.g. Fig. 1A station Terneuzen) will affect the salt marsh inundation

84 regime on top of such anthropogenic changes and is often not accounted for due to its long return
85 time [Beefink, 1985]. With increasing development of coastal infrastructure (e.g. tidal power
86 stations, storm surge barriers, dikes) and an increasing need for flood defence due to climate
87 change (e.g. with new embankments in subsiding deltas [Syvitski *et al.*, 2009]) anthropogenic
88 impact on low lying coastal areas will further increase. China for example is currently
89 establishing new large scale embankments for their economic growth in coastal areas [Ma *et al.*,
90 2014].

91 Scientific reports in coastal ecology and coastal engineering often quote the general
92 lowest elevation of salt marsh pioneer vegetation from regional studies [Hinde, 1954; Adams,
93 1963; Redfield, 1972; Gordon *et al.*, 1985; Castillo *et al.*, 2000; Costa *et al.*, 2003; Silvestri *et*
94 *al.*, 2005]. Most of those studies define the marsh - tidal flat border with tidal benchmarks. This
95 border was for example defined to be at Mean Low Water (MLW) (e.g. in Spring Harbour
96 [Hinde, 1954] or at microtidal sites along the U.S. Atlantic coast [Mckee and Patrick, 1988]), at
97 Mean Sea Level (MSL) (e.g. used in a model by D'Alpaos *et al.*, 2007) or at a certain elevation
98 below Mean High Water (MHW) (e.g. 20 - 40 cm below MHW in the Dutch Waddensea [Bakker
99 *et al.*, 2002]). Few studies attempt to make general statements across tidal ranges about the salt
100 marsh – tidal flat border, often not supported by data. Odum [1988] for example limits salt marsh
101 occurrence to the upper 2/3rd of the tidal frame whereas others use Mean High Water of Neap
102 tides (MHWN) as the lower limit for salt marsh occurrence [Adam, 2002; Doody, 2008; Plater
103 and Kirby, 2011]. Mckee and Patrick [1988] provide to our knowledge the only data driven
104 study comparing a number of sites from a literature review along the Atlantic U.S. coast. They
105 showed that the lowest elevation of *Spartina alterniflora* occurrence relative to MLW increases
106 with greater tidal range, whereas they found no differences along the climatic/latitudinal

107 gradient. This study however is lacking a global comparison and sites with tidal ranges above 3
108 m.

109 The mechanisms limiting survival of salt marsh vegetation in the intertidal zone differ
110 between small seedlings and mature vegetation. Initial establishment of salt marsh pioneer plants
111 from seed may be limited by tidal currents and waves as seedlings require 2-3 days free from
112 inundation to anchor against subsequent flooding (i.e. Window of Opportunity) [Wiehe, 1935;
113 *Balke et al.*, 2014]. After seedlings surpass the critical seedling stage [Corenblit *et al.*, 2015]
114 increased rooting depth and attenuation of hydrodynamic energy within a dense vegetation cover
115 lead to higher tolerance to physical disturbance by tides, even during storm events [Spencer *et*
116 *al.*, 2015]. Establishment from seed can lead to sudden colonization of large areas even several
117 tens of meters away from the marsh edge in only one growing season when the conditions are
118 favourable and dispersal is not limited [Balke *et al.*, 2014]. Other expansion mechanisms such as
119 clonal growth and establishment from displaced marsh fragments but also lateral erosion of salt
120 marshes generally act on longer time scales and only affect the current marsh edge [van der Wal
121 and Pye, 2004; van de Koppel *et al.*, 2005; Mariotti and Fagherazzi, 2010]. Morphological
122 adjustments such as cliff retreat occur at maximum rates of a few meters per year [van der Wal
123 and Pye, 2004]. Direct dieback of mature salt marsh vegetation may largely be caused by
124 exceeded physiological tolerance to flooding [Hinde, 1954; Morris *et al.*, 2002; Langley *et al.*,
125 2013], although drought and potential hypersalinity may also be lethal to plants [Hughes *et al.*,
126 2012]. Generally, it is important to note that the lowest elevation suitable for seedling
127 establishment may not be the same as the lowest elevation at which established salt marsh plants
128 can survive flooding or clonally expand. Especially in meso- to macrotidal marshes, tidal flats
129 may remain bare although the inundation-duration at the tidal flat is far below the physiological

The global seaward salt marsh extent

130 limits to flooding (e.g. < 80% of time flooded for *Spartina* spp. [Hinde, 1954; Langley et al.,
131 2013]. We hypothesize that the lowest possible elevation for salt marsh establishment is
132 generally limited by inundation frequency as salt marsh vegetation will immediately colonize
133 large areas if disturbance is below a critical threshold [in the sense of Balke et al., 2014]. The
134 contrasting drivers and rates of change of marsh progradation and marsh retreat may have
135 important implications on how we predict salt marsh resilience and lateral development in times
136 of changing tides and accelerated sea-level rise.

137 In this synthesis, we compare data from remote sensing and monitoring studies along the
138 Dutch and German North-Sea coast with a global literature search to correlate tidal range with
139 the lower limit of salt marsh vegetation relative to tidal datums. A global tide gauge dataset is
140 analyzed to calculate inundation characteristics in relation to the theoretical elevation of the
141 transition zone from the tidal flat to the pioneer vegetation. Finally, we discuss how changes in
142 tidal range due to sea level rise and coastal engineering may affect lateral salt marsh
143 development worldwide.

144

145 **Materials and Methods**

146 *Elevation of the Salt Marsh – Tidal Flat Border:*

147 The elevation of the salt marsh-tidal flat border is defined here as the lowest elevation of
148 the pioneer vegetation of the genera *Salicornia* spp. and *Spartina* spp.. This border was
149 determined from i) a global literature search and from ii) a GIS analysis of monitoring and
150 remote sensing data from a) the German Waddensea area within the federal state of Schleswig-
151 Holstein (mesotidal, average salinity: 22-30), b) the Dutch Oosterschelde (mesotidal, average

The global seaward salt marsh extent

152 salinity: 28-33) and c) the Dutch Westerschelde estuary (meso- to macrotidal, average salinity:
153 13-28) up to the Belgian border. These three study sites (see Fig. 2) were chosen because LiDAR
154 (Light detection and ranging) data are available from the same year as vegetation survey data
155 based on aerial photographs. Moreover, the sites span over meso- to macrotidal environments
156 whereas the pioneer species are the same at all sites. Data from contrasting locations are
157 necessary because the tidal range gradient is also always a spatial gradient (e.g. from North to
158 South in the Schleswig-Holstein dataset and from West to East in the Westerschelde dataset)
159 along which many other important parameters such as wave fetch and salinity may change.
160 Hence, we pooled the GIS study data with the global literature data for further analysis (see
161 supporting information).

162

163 *German Data Set*

164 *Vegetation:* Vegetation survey data following the classification of the *Trilateral*
165 *Monitoring and Assessment Programme* (TMAP) [Petersen, et al., 2014] were available for the
166 entire coast of the federal state of Schleswig-Holstein. This vegetation data are based on
167 classified near infrared aerial photographs (< 40cm resolution) and ground truthing from 2006
168 and was provided by the LKN-SH (Landesbetrieb für Küstenschutz, Nationalpark und
169 Meeresschutz Schleswig-Holstein). Polygons with pioneer vegetation were selected based on
170 TMAP vegetation classification: S1.1 *Spartina anglica* type pioneer vegetation (Natura 2000
171 type 1320), S1.2 *Salicornia* spp./*Suaeda maritima* type pioneer vegetation (Natura 2000 type:
172 1310) and S1.0 unspecific salt marsh pioneer vegetation. The minimum vegetation cover for an
173 area to be declared pioneer vegetation was 10%.

The global seaward salt marsh extent

174 *Elevation:* LiDAR data from 2005 to 2006 with a resolution of 1m and absolute vertical
175 accuracy of better than 20 cm was available for the entire North-Sea coast of Schleswig-Holstein
176 and provided by LKN-SH (Landesbetrieb für Küstenschutz, Nationalpark und Meeresschutz).

177 *Tidal data:* Data on averaged recent tidal conditions (hydrological years 2001-2010) were
178 provided by the LKN-SH for 18 stations along the North-Sea coast of Schleswig-Holstein. Mean
179 High Water of Neap tides (MHWN) along the Schleswig-Holstein coast for 2007 were provided
180 by the BSH (Bundesamt für Seeschifffahrt und Hydrographie). For the analysis of yearly Mean
181 Tidal Range (MTR), long-term time series of High Water (HW) and Low Water (LW) from
182 Schleswig-Holstein were analyzed for Wittdün (1934-2012), provided by LKN-SH. MTR was
183 also analysed for two tide gauges in Lower Saxony with data from Norderney (1935-2012) and
184 Cuxhaven (1900-2012) provided by the BfG (Bundesanstalt für Gewässerkunde) and WSV
185 (Wasser- und Schifffahrtsverwaltung des Bundes).

186

187 *Dutch Data Set*

188 *Vegetation:* Vegetation surveys of the salt marshes are regularly conducted in the
189 Netherlands based on 1:5000 false colour aerial photographs and were provided by RWS
190 (Rijkswaterstaat) for the Oosterschelde (2007) and the Westerschelde (2010). Salt marsh pioneer
191 vegetation was defined based on percentage cover as >5% cover of *Spartina* spp. and/or
192 *Salicornia* spp. when no other vegetation was present and >50% cover of *Spartina* spp. and/or
193 *Salicornia* spp. when other vegetation was present in the same polygon.

194 *Elevation:* LiDAR data from the same year as the vegetation survey were provided by
195 RWS for the Westerschelde (2010) and the Oosterschelde (2007) with a 2m resolution raster and

196 absolute vertical accuracy better than 20 cm.

197 *Tidal data:* Data on averaged recent tidal conditions ('Slotgemiddelden 2011') were
198 provided by RWS for 7 tide gauges in the Schelde Estuary. For the analysis of yearly MTR,
199 long-term time series of HW and LW in the Netherlands were analyzed for Terneuzen (1900-
200 2012), Stavenisse (1957-2012), Harlingen (1900-2012) and Delfzijl (1900-2012).

201

202 *GIS Analysis of Regional Data Sets:*

203 ArcGIS was used to determine the elevation of the tidal flat just in front of the mapped
204 pioneer vegetation (Fig. 3). A 10 m buffer was created around all polygons with pioneer
205 vegetation defined as described above. These buffer polygons were then erased by the polygons
206 of all other vegetation types (erase function) leaving only the seaward areas outside the
207 vegetation cover. This was necessary since the LiDAR scans do not always penetrate the
208 vegetation, hence surface elevation readings should be taken on the tidal flat just outside the
209 pioneer vegetation. All LiDAR datasets were reduced to 5 m resolution using the nearest
210 neighbour reclassification method prior to the extraction of height information. Two readings of
211 the original LiDAR raster dataset were taken from the tidal flat 0-10 m in front of the pioneer
212 vegetation for every 5 m width of salt marsh edge. Problems however remain where pioneer
213 vegetation borders tidal creeks, dikes and groins. These areas were manually removed from the
214 analysis based on the topography of the LiDAR raster (see Fig. 3B).

215 Twenty-five Thiessen polygons (i.e. polygons in which each point is closer to its
216 associated point than to any other point) were created for the tidal stations close to the vegetation
217 surveys (see dots in Fig. 2B,C for distribution of tide gauges). Between 860 and 32000 data

The global seaward salt marsh extent

218 points (see supporting information Table 1) at the seaward salt marsh - tidal flat border were
219 extracted from the LiDAR raster for each Thiessen polygon depending on the covered area and
220 the shape of the coast. The elevation data were spatially joined to the tidal information for each
221 polygon. Linear mixed models were applied separately to the Dutch and the German dataset (R
222 Package: nlme), with the Thiessen polygon as random effect. The model describes the best
223 statistical fit and determines the correlation between tidal range and elevation of the tidal flat -
224 salt marsh transition relative to MHW. Median, upper and lower quantile of elevation data were
225 calculated for each polygon. The lower quantile was defined as the ‘lowest possible elevation’ of
226 salt marsh pioneer vegetation for comparison with the literature review data.

227 *Literature Review on Elevation of the Pioneer Vegetation:*

228 A literature search was performed with scopus and google scholar for studies that report
229 mean tidal range, elevation of mean high water (i.e. as a reference tide level) and the lowest
230 elevation of salt marsh pioneer vegetation in the intertidal zone (Fig. 2A). We limited the search
231 for the genera *Spartina* spp. and *Salicornia* spp., both globally distributed salt marsh pioneers in
232 the temperate zone. Whereas *Salicornia* is absent from South America and Australasia [Kadereit
233 *et al.*, 2007], *Spartina anglica* and *Spartina alterniflora* are invasive in many parts of the world
234 [Nehring and Hesse, 2008]. Surprisingly few studies report site specific information on elevation
235 of the seaward salt marsh border relative to a tidal datum and tidal range. A total of 37 locations
236 from 15 scientific articles were derived from literature after the search had been narrowed down
237 to 70 peer reviewed articles on salt marsh pioneer vegetation. Data points from the study by
238 *Mckee and Patrick* [1988] were included when the lower limit of *S. alterniflora* was reported
239 relative to MHW. The results and coordinates of the sites are available in the supporting
240 information.

241

242 *Global Tide Gauge Data:*

243 Global hourly tide gauge records were downloaded from the GLOSS database
244 (University of Hawaii Sea Level Center: <http://ilikai.soest.hawaii.edu/uhslc/woce.html>) and
245 filtered for stations that are located in areas that support salt marsh vegetation (see supporting
246 information S2). Salt marsh abundance GIS layers were based on *Hoekstra and Molnar* [2010]
247 (supporting information S3). The time series were reduced to a period from January 1990 to
248 December 2010, 155 stations from the database provided data for this period in areas supporting
249 salt marsh vegetation. To calculate MHW and MLW, the data were reduced to daily minimum
250 and daily maximum values. The difference of the averaged daily maximum and minimum values
251 is defined here as mean tidal range. This simplification was applied in order to include data from
252 stations with very low tidal range, where high and low water values are not easily distinguishable
253 from the time series. The inundation duration gradient was calculated for each station in R by
254 counting the hours of inundation for each centimeter increment along the inundation gradient.
255 Frequency of inundation events was analyzed by counting the events at which sea level
256 surpassed a certain elevation along the inundation gradient. Data presentation was done using the
257 rgl package in R.

258 *Inundation Model*

259 Two 30 day simulated tidal signals were generated to calculate the same inundation
260 characteristics (i.e. inundation duration and inundation frequency) as performed for the GLOSS
261 dataset. This analysis aims to illustrate how inundation characteristics differ, especially at the
262 upper intertidal zone (i.e. corresponding to the area above MHWN) when more than one partial

The global seaward salt marsh extent

263 tide is considered in an inundation model.

264 A simple sine curve (equation 1), which is often used in salt marsh modelling studies (see e.g.
265 [Mariotti and Fagherazzi, 2010]) and two superimposed sine curves (equation 2) with a 12.42
266 and a 12 day period representing the M2 and S2 partial tides (i.e. a spring neap tidal cycle) were
267 simulated.

$$268 \quad h_1(t) = 100 * \cos\left(t * \frac{2\pi}{12.42}\right) \quad (1)$$

$$269 \quad h_2(t) = 100 * \cos\left(t * \frac{2\pi}{12.42}\right) + 20 * \cos\left(t * \frac{2\pi}{12}\right) \quad (2)$$

270 **Results**

271 *GIS Study*

272 A linear mixed model for the Schleswig-Holstein dataset provided the best statistical fit
273 and shows that the elevation of the tidal flat- salt marsh border relative to MHW (Pi_{oh} [cm]) is
274 declining with increasing tidal range (MTR [cm] = MHW - MLW) with $Pi_{oh} = -0.11 * MTR -$
275 13.62 (P=0.017). The same analysis for the data from the Dutch Westerschelde and
276 Oosterschelde showed a similar relationship with $Pi_{oh} = -0.26 * MTR + 11.13$ (P=0.066). With
277 each cm increase in MTR, i.e. for each 0.5 cm increase in MHW, the elevation of the tidal flat
278 fronting the marsh decreases by 0.11 cm relative to MHW in Schleswig Holstein and by 0.26 cm
279 relative to MHW in the Dutch Delta. The majority of the elevation derived from the tidal flat
280 fronting the marsh edge for all sites was found to lie below the provided astronomic Mean High
281 Water of Neap tides (MHWN) for each polygon (Fig. 4).

282 *Global Literature Data*

283 The lower quartiles of the elevation data for each polygon from the regional GIS study
284 (Fig. 4) were defined as the lowest possible elevation for marsh vegetation to be compared with
285 the reported lowest elevation of salt marsh vegetation from global literature (Fig. 5). This
286 combined global marsh edge elevation relative to MHW is negatively correlated to tidal range
287 with a logarithmic curve as the best fit ($R^2=0.39$, $P<0.001$) (Fig. 5). Hence, the potential salt
288 marsh area between the pioneer vegetation elevation and MHW does not proportionally increase
289 with tidal range. The dataset does not contain any macrotidal marshes below 45° latitude as none
290 were found in the literature (see supporting information S1). Excluding macrotidal marshes from
291 the regression analysis would result in a linear relationship as the best fit.

292 *Global Tide Gauge Data*

293 Inundation duration calculated from the GLOSS global tide gauge data, increased linearly
294 from 0% at and above MHW to 100% just below MLW (Fig. 6A). The distribution of inundation
295 events, expressed as average number of inundations per day, shows a bell shape with an
296 increasingly wide flat plateau at the maximum value of 2 inundation events per day at larger tidal
297 ranges. Whereas inundation events (i.e. frequency of change from exposed to inundated
298 conditions) at higher elevations were limited due to lack of flooding events, inundation events at
299 lower elevations were limited due to very long inundation duration and hence lack of exposure
300 events. Projecting the results of the global and regional logarithmic regression between tidal
301 range and the salt marsh - tidal flat border (see equation in Fig. 5) onto the inundation
302 characteristics showed that inundation duration at the theoretical border between salt marsh and
303 tidal flat decreased with tidal range (see black dots in Fig. 6a). Inundation frequency at this
304 elevation remained on average just below 2 inundation events per day across the tidal range
305 gradient (Fig. 6b). This is where inundation frequency dropped from its maximum (i.e. at the

306 right side of the curve plateau) which corresponded with mean high water of neap tides.

307 *Inundation Model*

308 The simple model comparing a single sine curve as a simulated tidal inundation with a
309 tidal time-series consisting of two superimposed sine curves (i.e. spring-neap) illustrate the
310 mechanism behind the inundation frequency curve in Fig. 6b. Whereas inundation duration was
311 similar between the two tidal models (Fig. 7b), inundation frequency was reduced at both ends of
312 the elevational gradient when adding a second tidal constituent (i.e. the spring-neap tidal cycle)
313 to the single sine curve (Fig. 7c, right).

314

315 **Discussion**

316 The lowest elevation at which vascular salt marsh plants can still colonize tidal flats has
317 been described by many authors, although mainly without sufficient data to support a global
318 definition and often with regionally varying results. In times of global climate change, however,
319 we need to be able to predict salt marsh development relative to changes in tidal range and sea
320 level at a global scale. We show that globally, the potentially vegetated zone between Mean High
321 Water and the lowest possible elevation for pioneer vegetation does not proportionally increase
322 with tidal range for meso- to macrotidal marshes. Thus, with increasing tidal range the lowest
323 elevation suitable for pioneer vegetation may increase faster than Mean High Water levels.
324 Projecting our GIS and literature search data on a global tide gauge analysis suggests, that the
325 global salt marsh tidal-flat border is generally located at an elevation above which inundation
326 frequency starts to drop below its maximum (Fig. 6b). This critical elevation is defined by the
327 tidal constituents and potentially weather induced sea level variability (see Fig. 7) and elevation

328 roughly corresponds to the mean high water of neap tides. This has important implications for
329 predicting effects of sea-level rise and changing tidal range on lateral marsh development.

330 Apart from tidal range other factors can influence the elevation at which pioneer
331 vegetation is able to settle. This is also apparent from our dataset, as elevation of the tidal flat
332 fronting the salt marsh pioneer vegetation can vary up to 1 m near the same tide gauge at the
333 regional scale (Fig. 4) and up to 1.5 m for sites with the same tidal range at the global scale (Fig.
334 5). This variability may be attributed to factors influencing suitable elevation for marsh
335 establishment such as wave exposure [Callaghan *et al.*, 2010; Balke *et al.*, 2015] and salinity
336 [Odum, 1988] or other environmental factors such as bioturbation, herbivory or soil anoxia [van
337 Wesenbeeck *et al.*, 2007; He *et al.*, 2014]. However, since we did not directly determine the
338 height within the marsh but the tidal flat in front we cannot draw conclusions from the variability
339 of the GIS study results within each Thiessen polygon. Many environmental factors vary
340 spatially with tidal range such as salinity along estuarine gradients and are therefore difficult to
341 detect in a correlative study. It also has to be highlighted that only eight studies on the pioneer
342 zone elevation at sites with a tidal range > 4 m were found in the literature. We therefore suggest
343 further research to disentangle physical and biological reasons for this global demarcation with a
344 global multivariate approach based on locally measured data.

345 At the marine-terrestrial border, organisms that require to be submerged for the
346 majority of the time (e.g. algae) are replaced by organisms that require to be emergent in order to
347 grow and reproduce (e.g. vascular salt marsh plants). It is clear from our study however, that the
348 50% inundation-duration border or mean sea level is not a good estimation for the division
349 between marine and terrestrial life. Salt marsh vegetation may only grow down to around the half
350 tide line (1/2 tidal range) where tidal range is negligible (Fig. 5). In meso- to macrotidal sites the

351 globally averaged salt marsh – tidal flat border is situated several tens of centimetres to a few
352 meters above the half tide line and is thus inundated much less than 50% of the time (Fig. 5 and
353 6). However, our results show that for meso- to macrotidal sites, inundation still occurs twice
354 daily above the half tide line (Fig. 6B). The globally predicted salt marsh border is located at
355 elevations above the half tide line where inundation frequency starts to drop from its maximum
356 of two inundations per day (i.e. for semidiurnal tides), leaving the tidal flat occasionally free
357 from inundation (Fig. 6B). This is also shown by the regional GIS study (Fig. 4) where the
358 pioneer vegetation is situated just below the calculated astronomic MHWN, hence at an elevation
359 where inundation free days start to occur. This critical elevation is created by superimposition of
360 tidal constituents (Fig. 7) and weather induced sea level variability. Such inundation free days
361 are crucial for salt marsh vegetation to establish on tidal flats [Wiehe, 1935; Balke *et al.*, 2014].
362 Our study therefore suggests that inundation frequency and not inundation duration should be
363 used to globally predict the potential seaward salt marsh border, especially for marshes with
364 larger tidal ranges. The deterministic approach used in this study to calculate inundation
365 frequency from real data may serve as a useful tool to estimate elevations of vegetation
366 establishment (e.g. when planning salt marsh restoration). Also mangrove seedling establishment
367 was shown to be limited by inundation frequency [Balke *et al.*, 2011] and further global studies
368 need to show how tidal range affects the lower elevational limits of mangrove establishment and
369 survival.

370 Coastal engineering for safety and for accessibility of the major ports are most likely the
371 main local drivers to changes in tidal range (Fig. 1). However, it is not always clear what has
372 caused a positive or negative trend in tidal range development [Flick *et al.*, 2003]. A modelling
373 study showed that tidal range is directly influenced by sea level rise, whereas some areas may

374 experience an increasing tidal range and other areas may experience a decreasing tidal range
375 [*Pickering et al.*, 2012]. In the Waddensea area tidal range has been altered directly by human
376 activity due to the embankment of many intertidal areas since the 17th century [*Jonge et al.*,
377 1993]. The closure of the Zuiderzee with the construction of the Afsluitdijk in 1932 had a
378 particularly large impact and has led to a sudden increase in tidal range by 50 cm with long
379 lasting effects on the coastal geomorphology and ecology [*Jonge et al.*, 1993; *Dastgheib et al.*,
380 2008]. Our data show that if tidal range would increase (e.g. due to embankment or dredging, see
381 Fig. 1) this would lead to a greater increase in the lowest possible elevation of pioneer vegetation
382 compared to the increase in MHW. This is under the assumption that tidal range increases
383 symmetrically and that increase in MHW is half of the increase in tidal range (Fig. 4 and 5). At
384 the Oosterschelde, where tidal range at Yerseke has suddenly dropped from 3.7 to 3.24 m after
385 construction of the storm surge barrier [*Louters et al.*, 1998] the predicted potential elevation for
386 establishment of pioneer vegetation may have decreased relative to the local geodetic datum
387 (Fig. 4). Such changes are difficult to detect in the field as the tidal flat morphology is also
388 changing with tidal range. Further studies are needed to disentangle long-term morphological
389 response (i.e. decadal time scales [*Dastgheib et al.*, 2008]) and short term vegetation response
390 (i.e. colonization of new areas, see e.g. [*Balke et al.*, 2014]) to changes in tidal range. The
391 absence of new seedling establishment along salt marsh coasts (especially absence of the annual
392 pioneer *Salicornia* spp.) can serve as an early warning signal for changing inundation regimes
393 where the existing marsh may not yet show any signs of drowning or retreat. Our study can be
394 useful to coastal managers as it can help to a) establish a baseline for the possible salt marsh
395 extent, for example within habitat protection legislation and b) detect areas with insufficient
396 surface elevation for marsh rejuvenation and hence reduced resilience.

397 *Conclusions*

398 Ongoing and projected sea-level rise have created awareness of managers and scientists
399 for future threats to coastal ecosystem health. The majority of studies however focus on whether
400 vertical sediment accretion can keep pace with sea-level rise [*Reed, 1995; Kirwan and*
401 *Megonigal, 2013*]. Although there is evidence for changing tidal ranges both due to sea-level rise
402 and coastal engineering worldwide [*Flick et al., 2003; Pickering et al., 2012*] studies about their
403 effects on lateral intertidal wetland development are scarce [*Kirwan et al., 2016*]. Our study
404 highlights the importance of inundation frequency for salt marsh development at the upper part
405 of the tidal frame where inundation is driven by the spring neap tidal cycle and weather induced
406 sea level changes. Lateral marsh development may react very rapidly to decreasing flooding
407 frequencies but more slowly to increasing flooding frequencies. Especially to determine coastal
408 ecosystem resilience future studies should aim to consider both, the threats to vertical and to
409 lateral marsh development and thus the effects of rising mean sea levels versus changes in tidal
410 range and inundation frequency pattern. Local effects on tides due to construction of storm surge
411 barriers or dikes, deepening of shipping channels and land reclamation are still increasing
412 worldwide and their importance to salt marsh dynamics need to be assessed independently from
413 global sea level rise.

575 **Figure legends:**

576 **Fig. 1 A)** Examples of tidal range development along the Dutch and German North-Sea coast.
577 Whereas the closure of the Zuiderzee has lead to a sudden increase in tidal range at Harlingen,
578 the construction of the Oosterschelde storm surge barrier has had the opposite effect at Stavenisse.
579 **B)** Location of the tide gauges, salt marsh area is indicated in black. Colours correspond to the
580 water level time series of each location.

581 **Fig. 2 A)** Location of studies from the literature search on the reported salt marsh – tidal flat
582 border. **B)** Location of the Thiessen polygons and their respective tide gauges (points) of the
583 regional GIS study. Salt marsh pioneer vegetation is marked in black.

584 **Fig. 3 A)** Example of the seaward pioneer vegetation border from the Westerschelde dataset. **B)**
585 Example of the seaward pioneer vegetation border from the Schleswig-Holstein dataset. The
586 yellow to red (low to high elevations) color-coded dots represent the extracted elevation at the
587 seaward edge of the marsh pioneer vegetation.

588 **Fig. 4** Summary of regional GIS study results. Median elevation of pioneer vegetation relative to
589 mean high water per polygon (Pi_{med_h} [cm]) is linearly correlated to Mean Tidal Range (MTR
590 [cm]): $Pi_{med_h} = -0.23 * MTR + 13.17$ ($R^2 = 0.58$; $P < 0.001$). Error bars show upper and lower
591 quartile of pioneer vegetation elevation relative to mean high water for each polygon.

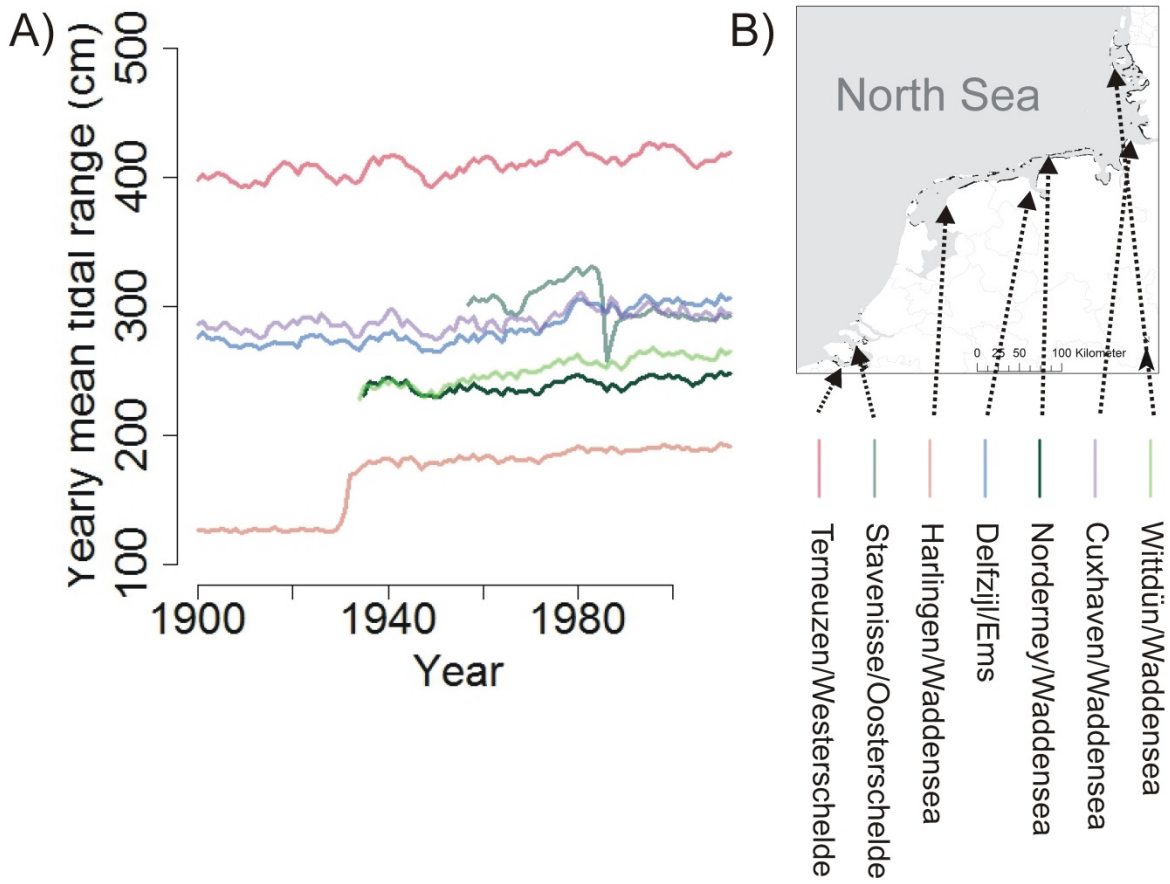

592 **Fig. 5** Global salt marsh - tidal flat border relative to mean high water with data from the global
593 literature search (black) and from the regional GIS study (grey) (data in supporting information
594 S1). Mean Tidal Range (MTR [cm]) is logarithmically correlated to elevation of the pioneer
595 vegetation relative to mean high water (Pi_{o_h} [cm]): $Pi_{o_h} = -108.23 * \log_{10}(MTR) + 163.21$
596 ($R^2 = 0.39$, $P < 0.001$). Dashed lines represent 95% confidence interval.

597 **Fig. 6 A)** 3D plot of the inundation duration gradient for selected tide gauges from the GLOSS
598 (Global Sea Level Observing System) database (data between 1990 and 2010). Black dots
599 represent the theoretical salt marsh – tidal flat border (equation of Fig. 5). **B)** 3D plot of
600 inundation events (expressed as average number of inundation events per day). Black dots
601 represent the theoretical salt marsh – tidal flat border (equation of Fig. 5).

602 **Fig. 7 A)** Simulated tidal sine curve and two superimposed sine curves representing a simplified
603 spring-neap tidal cycle. B) Calculated inundation duration percentage along the elevational
604 gradient. C) Calculated inundation frequency of the simulated tide data. The same analysis was
605 applied to real tide data in Fig. 6.
