NEUROSCIENCE

Robots with insect brains

A literal approach to mechanistic explanation provides insight in neuroscience

By Barbara Webb

It is an engineer's dream to build a robot as competent as an insect at locomotion, directed action, navigation and survival in complex conditions. But as well as studying insects to improve robotics, in parallel, robot implementations have played a useful role in evaluating mechanistic explanations of insect behavior, testing hypotheses by embedding them in real world machines. The wealth and depth of data coming from insect neuroscience holds the tantalizing possibility of building complete insect brain models. Robotics has a role to play in maintaining a focus on functional understanding – what do the neural circuits need to compute to support successful behavior?

Insect brains have been described as “minute structures controlling complex behaviors” (1): compare the number of neurons in the fruit fly brain (~135,000) to the mouse (70 million) or human (86 billion). Insect brain structures and circuits evolved independently to solve many of the same problems faced by vertebrate brains (or a robot's control programme). Despite the vast range of insect body types, behaviors, habitats and lifestyles, there are many surprising consistencies across species in brain organization, suggesting these might be effective, efficient and general-purpose solutions.

Unravelling these circuits combines many disciplines, including painstaking neuroanatomical and neurophysiological analysis of the components and connectivity. An important recent advance is the development of neurogenetic methods that provide precise control over the activity of individual neurons in freely behaving animals. However, the ultimate test of mechanistic understanding is the ability to build a machine that replicates the function. Computer models let us copy the brain's processes, and robots allow these models to be tested in real bodies interacting with real environments (2). The following examples illustrate how this approach is now being used to explore more sophisticated control problems including predictive tracking, body coordination, navigation and learning.

The visual target tracking of dragonflies has been replicated on a (wheeled) robot platform performing active pursuit (3), giving

new insight into the neural mechanisms. The starting point was neurophysiological characterization of the responses of small target motion detector (STMD) neurons in the dragonfly brain. These show a distinctive facilitation profile, that is, a slow build up of activity to targets that move on consistent trajectories in the visual field. A computational neural model incorporating such facilitation properties was shown to improve - tracking performance in the presence of clutter and distractors, even outperforming state-of-the-art computer vision algorithms (4). The implementation on the robot included insect-like early visual processing, including resolution, spectral sensitivity, and temporal and spatial high-pass filtering such that the receptors respond most to rapid changes in the stimulus. - The passage of fast-moving small objects against the background can be detected from a local rise followed by a fall (or vice-versa) in intensity of receptor activation. In a retinotopic array of such detectors, centre-surround inhibition and a winner-take-all process (suppressing all but the strongest signal) select a single target position, and its direction and rate of motion are used to facilitate the activation of model STMDs in the predicted future location. The facilitation enhances pursuit and may explain selective attention responses observed in downstream neurons (5).

When the robot makes a quick movement (a saccade) to visually pursue the target, this will change the relative position of the target in the visual field (e.g., to keep it centered). Hence the position in the neural map to which the facilitation should be propagated depends not only on the target's motion, but on the robot's (or dragonfly's) own motion. This means the target pursuit system must receive some information about the motor command. In addition, the implementation on a robot demonstrated the robustness of the model to challenges such as changing illumination and unexpected motor disturbance (bumps). It also confirmed that the optimal time constant for facilitation depends on the specific circumstances (target velocity and background clutter), suggesting STMD neurons should exhibit dynamic modulation of facilitation. The neural model on the robot thus allowed neural data that had been collected from an

immobilized insect to be understood in the context of continuous behavioral control in natural conditions, predicting that further experiments should reveal inputs from motor systems and dynamic modulation of the STMD response.

Insect target tracking behavior has also been examined in the praying-mantis inspired ‘mantisbot’ (6). Here the focus is on how the detected position of a visual target can be translated into the complex coordination of head, body and leg joints in a hexapod to make a successful orienting movement. The solution implemented on the robot exploits a detailed, distributed leg control network based on local reflexes (also used to model walking control for the stick insect (7)) that can be modulated by relatively simple high-level signals to alter the stepping motion towards a given target direction. The same network can also, through a simple switch, be used to control posture changes instead of walking, corresponding to the animal tracking the target with its head and body only. The tuning of the network in the mantisbot was based on (robotic) methods of inverse kinematics, in which the geometric relation of joint angles to the end-of-limb position is used to derive, inversely, for a desired end-of-limb position, the required values for joint angles. This method allowed a deterministic setting of the synaptic values in the model that would have been set by evolution in the animal.

The mantisbot controller demonstrated that descending information from the insect brain to motor circuits can be in the simple form of a desired vector of motion. Additionally, it showed that it is crucial even for simple saccades that the brain maintains a short-term memory of the position of the prey. Other insect behaviors require more sophisticated directional memory, such as the ability of ants, bees and wasps to maintain an estimate of their home location during long and convoluted foraging excursions, by continuous integration of their velocity (path integration). The underlying neural circuitry for this advanced spatial capacity has been unraveled (8). The insect central complex (CX) receives celestial compass inputs (9) and encodes heading direction relative to visual targets and self-motion (10). Identified neurons that have the required connectivity to combine this in-

1 formation with the speed (estimated from
2 the motion of the visual surrounding) could
3 form the basis of a distributed vector
4 memory, constantly updated to reflect the
5 geocentric location of the animal relative to
6 its starting point (β). Moreover, the precise
7 and highly regular connectivity pattern be-
8 tween these neurons and specific output
9 neurons of the CX provides a mechanism for
10 steering the animal home, essentially by
11 evaluating (before acting) whether turning
12 left or right would most improve alignment
13 to the target. A neural model that copies CX
14 neuroanatomy at the single neuron level
15 can thus explain the path integration capa-
16 bility of insects (β).

17 This model has recently been extended
18 with a proposal for how insects could re-
19 turn to a discovered food source and take
20 efficient routes between multiple sources
21 (11). This would require that a snapshot of
22 the state of the vector memory could be
23 stored for salient locations in the world, and
24 then reactivated – to interact with the same
25 steering circuitry – when the animal wants
26 to revisit the location. As yet, the neural ba-
27 sis for such a memory is unknown.

28 The CX model has been demonstrated to
29 work for path integration on both wheeled
30 and flying robots. However, the key ‘robotic’
31 contribution to understanding this circuit
32 was mostly conceptual. Taking a robotic
33 perspective meant that, rather than focus-
34 ing on how the CX neurons ‘represent’ ex-
35 ternal stimuli, the question became – how
36 do the neurons transform the stimuli into
37 the control of action? For example, accumu-
38 lating speed in 8 directions, following the 8-
39 fold columnar structure in each half of the
40 CX, is a redundant Cartesian encoding (us-
41 ing more axes than required) of the home
42 vector. However, it greatly simplifies the
43 subsequent calculation of the desired turn-
44 ing direction, allowing a simple column shift
45 to the right or left to ‘rotate’ the vector by 90
46 degrees.

47 Where next? Another prominent subcir-
48 cuit, found in the brains of all insects, that is
49 coming under increasing scrutiny is the
50 mushroom body (MB). This region is known
51 to be involved in associative learning of the
52 value of olfactory stimuli. Its distinctive ar-
53 chitecture, which has been compared to the
54 vertebrate cerebellum (12), has been shown
55 in multiple modelling studies, and some ro-
56 bot applications (13), to support pattern
57 learning by encoding inputs as sparse acti-
58 vation of a small subset of a larger neural
59 population and correlating with a reward
signal. A recent study directly evaluated the
effectiveness of an augmented MB model on

robot benchmark data sets for real world
place recognition (14). This work suggests a
key function of the MB is to produce an effi-
cient and compact re-encoding of stimuli (in
this case, outdoor images from a moving
platform over a long route) which can be
exploited for recognition, even in changing
conditions. The results show that the insect-
inspired network produces comparable per-
formance to state-of-the-art deep-learning
approaches for autonomous navigation,
with a much smaller and faster computa-
tional footprint (14).

However, currently modellers have not
converged in their accounts of the key MB
learning mechanisms. Most (but not all) fo-
cus on a change in synaptic weight between
the parallel fibres of the Kenyon cells (KCs),
encoding the stimulus, and the output neu-
rons. The output neurons are sometimes in-
terpreted as encoding the response, and
sometimes the predicted stimulus value. In
some models, the synaptic change depends
on coincident firing of KCs and output neu-
rons, in other models on delivery of a re-
ward signal (or alternatively, a prediction
error signal) by dopaminergic neurons that
target the synapse, and some models com-
bine both mechanisms. Moreover, there is a
cornucopia of new information emerging
about the precise anatomy and individual
neural function of the MB, particularly for
neurogenetic model systems such as the
fruitfly (*Drosophila melanogaster*), which
has yet to be incorporated in computational
or robot models. For example, the MB is di-
vided into multiple compartments in which
specific reward inputs target specific output
neurons, and the KCs, output and dopamin-
ergic neurons form distinct tripartite synap-
ses, suggesting a more complex flow of in-
formation between them.

What about modelling the whole insect
brain? Several groups, inspired by detailed
D. melanogaster brain wiring diagrams, are
now pursuing this target (15). But just in-
cluding more detail in brain models for its
own sake is unlikely to lead to insights un-
less it is grounded in understanding behav-
ior. For example, the MB seems over-
engineered for forming simple odor-value
associations – indeed, it evolved to deal with
the dynamic complexity of actively respond-
ing to fluctuating stimuli streams in real en-
vironments. Posing such a problem for a ro-
bot should be an effective way to illumina-
te the key computations involved, and to rig-
orously evaluate new models. It could also
result in smarter robots.
