ABSTRACT

Indications of a GeV component in the emission from GRBs are known since the EGRET observations during the 1990’s and they have been confirmed by the data of the Fermi satellite. These results have, however, shown that our understanding of GRB physics is still unsatisfactory. The new generation of Cherenkov observatories and in particular the MAGIC telescope, allows for the first time the possibility to extend the measurement of GRBs from several tens up to hundreds of GeV energy range. Both leptonic and hadronic processes have been suggested to explain the possible GeV/TeV counterpart of GRBs. Observations with ground-based telescopes of very high energy photons (E>30 GeV) from these sources are going to play a key role in discriminating among the different proposed emission mechanisms, which are barely distinguishable at lower energies. MAGIC telescope observations of the GRB 090102 (z = 1.547) field and Fermi Large Area Telescope (LAT) data in the same time interval are analyzed to derive upper limits of the GeV/TeV emission. We compare these results to the expected emissions evaluated for different processes in the framework of a relativistic blastwave model for the afterglow. Simultaneous upper limits with Fermi and a Cherenkov telescope have been derived for this GRB observation. The results we obtained are compatible with the expected emission although the difficulties in predicting the HE and VHE emission for the afterglow of this event makes it difficult to draw firmer conclusions. Nonetheless, MAGIC sensitivity in the energy range of overlap with space-based instruments (above about 40 GeV) is about one order of magnitude better with respect to Fermi. This makes evident the constraining power of ground-based observations and shows that the MAGIC telescope has reached the required performance to make possible GRB multiwavelength studies in the very high energy range.

Key words: radiation mechanisms: non-thermal – gamma-rays bursts: general

1 INTRODUCTION

Since the discovery of Gamma-Ray Bursts (GRB) in the late 1960’s [Klebesadel et al.1973], these energetic and mysterious phenomena have been targets of large observational efforts. The discovery of their afterglow in late ‘90 [Costa et al.]1997; Van Paradijs et al.1997] provided a great boost in GRB studies at all wavelengths. The wealth of available information put severe constraints on the various families of interpretative scenarios, showing an unexpected richness and complexity of possible behaviours (see e.g. Gehrels et al.2009). The first observations at MeV-GeV energies with the Energetic Gamma-Ray Experi-
The launch of the Fermi Telescope (EGRET) on board the Compton Gamma-Ray Observatory (CGRO; Hurley et al. 1994, Dingus 1995), showed that the high energy (HE: 1 MeV-30 GeV) and very high energy range (VHE: 30 GeV - 30 TeV) can be powerful diagnostic tools for the emission processes and physical conditions of GRBs. The launch of the Fermi Telescope (LAT; Atwood et al. 2009), showed that, at least for the brightest events, GeV emission from GRBs is a relatively common phenomenon (Granot et al. 2010). However, a satisfactory interpretative framework of the GeV emission is still lacking. In this context, ground-based imaging atmospheric Cherenkov telescopes (IACTs), such as MAGIC, H.E.S.S. and VERITAS, despite the reduced duty cycle of ground-based facilities, provide access to the ~100 GeV to TeV energy interval for GRB observations. Furthermore, the energy range down to ~80 GeV, which was accessible almost exclusively with space-based instruments, has been opened to ground-based observations by the MAGIC observatory (Aliu et al. 2008, Schweizer et al. 2010). Together with the multiwavelength coverage provided by the LAT instrument, this makes possible the complete coverage of the 1-100 GeV energy range with the advantage, in the VHE domain, of an increase in the sensitivity relative to space-based instruments. Moreover, the low energy trigger threshold of MAGIC makes less relevant the effect of the source distance. The flux above ~100 GeV is attenuated by pair production with the lower energetic (optical/IR) photons of the diffuse Extragalactic Background Light (EBL; Nikishov 1962; Gould & Schreder 1966). The resulting cosmic opacity to VHE γ-rays heavily affects Cherenkov observations, especially for GRBs which are sources with an average redshift slightly larger than 2 (Fynbo et al. 2009). Therefore, the higher the redshift, the lower the likelihood of detection at a given energy (i.e., about a 90% of flux reduction at 100 GeV for a z = 2 source following Dominguez et al. 2011)). In addition, the transient and unpredictable nature of GRBs makes it difficult for large ground-based instruments such as IACTs to point them rapidly enough to catch the prompt emission and the early afterglow phases, when these sources are expected to be observable at high energies (see e.g. Covino et al. 2009a, for a discussion about IACTs perspectives for GRB observations). MAGIC has the advantage, compared to the other IACTs, in its low-energy sensitivity and pointing speed (e.g. Garaszyk et al. 2009). Several attempts to observe GRB emission have been discussed (Albert et al. 2006, 2007, Aleksić et al. 2010). In all cases only upper limits have been derived. Similar results have also been reported by other IACTs (Tam et al. 2006, Aharonian et al. 2009, Acciari et al. 2011). As discussed above, the two most limiting factors are the redshift of the source and the delay of the observation.

In this paper we report and discuss the MAGIC observation of GRB 090102, a GRB at a redshift about 1.5 observed at low zenith angle and good weather conditions. These observations permitted data-taking with an energy threshold of about 30 GeV. However, no gamma-ray signal was detected and hence only upper limits could be derived. Section 2 gives general information about GRB 090102. In Sections 3 and 4 we discuss the MAGIC and LAT data sample respectively, while sections 5 and 6 introduce and develop the interpretative scenario. In Sect. 7 we evaluate the effect of the EBL absorption on the lowest energy bins allowed by our observation and finally, we discuss our results in a general theoretical scenario in the last section.

We assume a ΛCDM cosmology with Ω_m = 0.27, Ω_L = 0.73 and h_0 = 0.71. At the redshift of the GRB the proper distance is ~4.5 Gpc (~1.38 × 10^28 cm). Throughout this paper the convention Q_0 = Q/10^4 has been adopted in CGS units.

2 GRB 090102

GRB 090102 was detected and located by the Swift satellite (Gehrels et al. 2004) on January 2nd, 2009 at 02:55:45 UT (Mangano et al. 2009) and also by the Fermi-GBM detector. The prompt light curve was structured in four partially overlapping peaks (Sakamoto et al. 2009) for a total T_90 of 27.0 ± 2.0 s. Since the burst was also detected by Konus Wind (Golenetskii et al. 2009) and Integral (Mangano et al. 2009), it has been possible to obtain a very good reconstruction of the prompt emission spectral parameters. The time-averaged spectrum can be modeled with the classical Band function (Band et al. 1993) with peak energy E_p=451 +175 \ -188 keV and a total fluence in the 20 keV - 2 MeV range of 3.09 +0.24 \ -0.23 σ (Golenetskii et al. 2009). Early optical follow-up measurements were performed by many groups like TAROT (Klotz et al. 2009) at T_90+40.8 s, the REM robotic telescope at T_90+53 s (Covino et al. 2009) and GROND telescope (Afonso et al. 2009) at T_90+2.5 h. Optical spectroscopy was rapidly obtained with the NOT telescope by De Ugarte Postigo et al. (2009). They found evidence of several absorption metal lines, including Fe II, Mg II, Mg I, Al II, Al III and C IV, at a common redshift of z = 1.457. The resulting isotropic energy value E_iso = 5.75 × 10^{53} erg and the rest frame peak energy E_p=1149 +186 \ -144 keV are in good agreement with the Amati relation (Amati et al. 2009). The multlwavelength light curve is shown in Fig. 1 in which, data in the R and H band.

MAGIC upper limits on the GRB 090102 afterglow

3 MAGIC FOLLOW UP OBSERVATION AND ANALYSIS

The MAGIC telescope located at Roque de los Muchachos (28.75°N, 17.89°W, La Palma, Canary Islands) performed a follow-up measurement of GRB 090102. The data presented in this paper were taken when MAGIC was operating as a single telescope. The MAGIC telescope was autonomously repointed and started the observations at $T_\text{Grb} + 255$ s, following the GRB alert from Fermi-GBM.

Later on, the shift of the operating telescope realized that the GBM coordinates (RA: 08°35′06″; DEC: 37°16′48″) differed from the BAT coordinates (RA: 08°33′02″; DEC: 33°05′29″) by more than 4 degrees. Consequently, the telescope was re-pointed to the BAT coordinates and re-started observations by $T_\text{Grb} + 1161$ s. After this burst, the alert system was modified to cope with this situation. First data runs were taken at very low zenith angles from 5° reaching 52° at the end of data taking at 06:54:01 UT after 13149 s of observation. MAGIC upper limits above 80 GeV have already been published for this GRB (Gaug et al. 2009), while arrival directions of the photons is reconstructed using the DISP algorithm (Fomin et al. 1994). The alpha parameter is then used to evaluate the significance of the signal in six energy bins. In spite of the low energy analysis threshold, no significant excess of gamma-rays have been detected from a position consistent with GRB 090102.

Differential upper limits (ULs) assuming a power-law γ-ray spectrum with spectral index of $\Gamma = -2.5$ and using the method of Rolke et al. (2005) were evaluated with a 95% confidence level CL and 30% estimation of systematic uncertainties and are reported in Tab. 3 and Fig. 2.

4 LAT OBSERVATION AND ANALYSIS

The Fermi observatory is operating in a sky survey mode and the Swift localization of GRB 090102 was observable by the LAT instrument approximately 3300 sec after trigger and remained within the LAT field-of-view ($\Theta_{\text{beaming}} \lesssim 60°$) for a duration of ~2300 sec. We analyzed the Fermi-LAT data using the Science Tools 09-30-01 with Pass7V6 ‘Source’ event class. We used the publicly-available models for the Galactic and isotropic diffuse emissions, gal\textit{2yearp7v6}rimg\textunderscore 0, fits and iso\textunderscore p7v6source\textunderscore txt, that can be retrieved from the Fermi Science Support Center. No significant excess was found in this observation, so we computed upper limits in 3 different energy bands: [0.1-1 GeV], [1-10 GeV], and [10-100 GeV]. We first fit the broad energy range (from 0.1 to 100 GeV) using the unbinned likelihood analysis, which was then used

http://fermi.gsfc.nasa.gov/ssc/data/access/lat/BackgroundModels.html
to constrain the background model. Then we froze the normalizations of the isotropic and Galactic diffuse templates, and independently fit the source in the 3 different energy bands, using the unbinned profile likelihood method to derive 95% LAT upper limits. The following upper-limit values were derived for the [0.1 - 1 GeV], [1 - 10 GeV], [10 - 100 GeV] energy ranges respectively: $2.73 \times 10^{-10}$, $4.58 \times 10^{-10}$, $3.45 \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$ and are depicted in Fig. 2. These ULs are more constraining than the ones reported in Inoue et al. (2013). The reason for that is the usage of P7V6 'Source' instead of P6V3 'Diffuse', and also the usage of a different procedure to parametrize the diffuse background in the three differential energy bins. Even if observed with a considerable time delay, the achieved energy threshold of MAGIC permits a better overlap with LAT in the GeV range when compared with previous results on GRB by MAGIC and other IACTs. Thus, it has been possible to derive simultaneous upper limits with a complete coverage of the energy range from 0.1 GeV up to TeV using MAGIC and Fermi-LAT. Furthermore, it is worth stressing that, in the energy range where the two instruments overlap (range [25-100 GeV]), the upper limits derived by MAGIC are about one order of magnitude lower than those from Fermi-LAT.

5 THE LOW ENERGY SCENARIO

In a commonly accepted scenario (see e.g. Mészáros 2004, for a review), GRB dynamics during the prompt phase are governed by relativistic collisions between shells of plasma emitted by a central engine (internal shocks). Similarly, the emission during the afterglow is thought to be connected to the shocks between these ejecta with the external medium (external shocks). Several non thermal mechanisms, indeed, have been suggested as possible sources of HE and VHE photons. They include both leptonic and hadronic processes, (see e.g. for a review Zhang & Mészáros 2001; Gupta & Zhang 2007; Fan & Piran 2008; Ghisellini 2010). In the most plausible scenario, electron synchrotron radiation is the dominant process in the low energy regime. Within this scenario, the GRBs spectra are usually approximated by a broken power law in which the relevant break energies are the minimum injection $\nu_\text{in}$ and the cooling $\nu_c$. The first one refers to emission frequency of the bulk of the electron population (where most of the synchrotron emission occurs), while the cooling frequency identifies where electrons effectively cool. Both are strongly dependent on the microphysical parameters used to describe the GRB environment and, for a constant density $n$ of the circumburst diffuse interstellar medium (ISM) they are given by (Zhang & Mészáros 2001):

$$\nu_\text{in} = 8.6 \times 10^{17} \left(\frac{p - 2}{p - 1}\right)^2 \left(\frac{\epsilon_e}{\zeta_e}\right)^{3/2} E_3^{1/2} t_b^{1/2} (1 + z)^{1/2} \text{ [Hz]} \quad (1)$$

$$\nu_c = 3.1 \times 10^{13} (1 + Y_e) \zeta_e E_3^{3/2} \epsilon_B^{1/2} n_b^{1/2} t_b (1 + z)^{1/2} \text{ [Hz]} \quad (2)$$

where $\epsilon_e$ and $\epsilon_B$ are the energy equipartition parameter for electrons and magnetic field, $E_3$ is the energy per unit solid angle, $t_b$ is the observer’s time in hours, $\zeta_e$ is fraction of the electrons that enter in the acceleration loop and $Y_e$ is the ratio between synchrotron and Inverse Compton (IC) cooling time, known as Compton factor (see e.g. Sari & Esin 2001; Panaitescu & Kumar 2000). As a matter of fact, we have explicitly assumed that the contribution of the Compton scattering is not negligible in the afterglow at the considered time and, as a consequence, the cooling break is reduced by a factor $(1 + Y_e)$. It is important to remark that the change in slope of the optical decay observed in GRB 090102 suggests that the standard model cannot adequately describe the dynamics of this event. The steep-to-shallow behaviour could be interpreted as due to a termination shock, locating the end of the free-wind bubble generated by a massive progenitor at the position of the optical break. However, it is also possible to hypothesize that the early steeper decay is simply due to the superposition of the regular afterglow and a reverse shock present only at early times. It is not our purpose to analyze and discuss the several physical scenarios that are proposed to describe the afterglow, so we continue to model the burst emission assuming the afterglow could be described in the standard context of a relativistic shock model.

6 MODELING THE VHE EMISSION

Any attempt to a meaningful modeling of the possible VHE emission component both during the prompt emission and the afterglow, must rely on information coming from the low energies (see e.g. Aleksić et al. 2010). At the same time, the modeling of the low-energy afterglow can furthermore help in limiting the intrinsic degeneracy or even, to some extent, arbitrariness in the choice of the various possible HE and VHE afterglow parameters. Following Gendre et al. (2010) we assume that the cooling frequency at the time of MAGIC observation is located between optical and X-ray band. Thus, we can estimate the slope of the energy particles distributions which is correlated with the optical de-
Since electrons are ultrarelativistic \((p \approx 1)\), they easily reach the GeV-TeV domain. Following Zhang & Mészáros (2001), produced in the standard synchrotron emission are the seed photons \(\nu\). In the previous case, the predicted SSC spectrum is characterized by the decay index. With the observed optical spectral index of 0.97 ± 0.03 (Gendre et al. 2014), we obtain a value for \(p\) from the relation \(4(p - 1) = 0.97\) of \(p = 2.29 ± 0.04\) in good agreement with numerical simulations which suggest a value of \(p\) ranging between 2.2-2.3 (Achterberg et al. 2001; Vietri 2003). We will assume that at the time of the MAGIC observation, the outflow expands into a diffuse medium with a constant density of the order \(n \sim 1\) cm\(^{-3}\) and we will further assume that all electrons are accelerated in the shocks \((\zeta_e \sim 1)\). At the same time, from the available data, we can only constrain the values of \(\epsilon_B\) and \(\epsilon_e\). Assuming that the optical light curve time break \((\text{Melandri et al.} 2010)\) is less than the start time of the shallow decay phase \((T_{\text{break}} \lesssim 10^3\) s\)), we obtain \(0.04 \leq \epsilon_e \leq 0.2\) and \(7 \times 10^{-4} \leq \epsilon_B \leq 0.05\) which only barely fix the \(\epsilon_B, \epsilon_e\) values. We thus assume, within these limits, \(\epsilon_B \sim 0.01\) and \(\epsilon_e \sim 0.1\) which correspond to typical values for the late afterglow (Panaitescu & Kumar 2002; Yost et al. 2003). The most plausible process producing VHE photons is the IC mechanism in the variant of Synchrotron Self Compton (SSC) (Zhang & Mészáros 2001, Sari & Esin 2001). Within this process, the low energy photons produced in the standard synchrotron emission are the seed photons that are pushed into the VHE band by IC scattering. Similarly to the previous case, the predicted SSC spectrum is characterized by the two typical frequencies \(\nu^{\text{SSC}}_{\text{in}} = \gamma_{m}^{2} \nu_{\gamma}\) and \(\nu^{\text{SSC}} = \gamma^{2} \nu_{\gamma}\) where \(\gamma_{m}\) and \(\gamma_{e}\) are the Lorentz factor for the electrons of frequencies \(\nu_{\gamma}\) and \(\nu_{\gamma}\). Since electrons are ultrarelativistic \((\gamma_{m} \sim 10^{5})\), SSC radiation can easily reach the GeV-TeV domain. Following Zhang & Mészáros (2001) and according to Eqs. (1) and (3) we have:

\[
\nu^{\text{SSC}}_{\text{in}} = 1.3 \times 10^{22} \left(\frac{\epsilon_{\nu}}{\epsilon_{\gamma}}\right)^{\frac{1}{2}} \left(\frac{1 + z}{1}\right)^{\frac{5}{4}} \text{Hz} \tag{3}
\]

\[
\nu^{\text{SSC}}_{\text{e}} = 1.2 \times 10^{25} (1 + Y_{p})^{\frac{1}{4}} \left(\frac{\epsilon_{\nu}}{\epsilon_{\gamma}}\right)^{\frac{1}{4}} \left(\frac{1 + z}{1}\right)^{\frac{3}{4}} \text{Hz} \tag{4}
\]

while the expected maximum flux density is \((\text{Zhang & Mészáros 2001})\):

\[
F^{\nu}_{\nu_{\text{max}}} = 17 \left(\frac{\epsilon_{\gamma}}{\epsilon_{\nu}}\right)^{\frac{3}{4}} \left(\frac{nE_{52}}{b_{h}}\right)^{\frac{1}{4}} (1 + z)^{\frac{3}{4}} \text{[nJy]} \tag{5}
\]

Basically, the new spectral feature has the same shape of the underlying synchrotron component with a new break in the spectrum \((E_{\text{break}})\) due to the decreasing of the IC cross-section with energy \((\text{Fragile et al.} 2004)\). However, this cut-off is found to be above a few tens of TeV in our case, securing that MAGIC upper limits stay below this limit.

We also consider proton synchrotron emission as an hadronic-originated component (Böttcher & Dermis 1998, Pe’er & Waxman 2005). Although protons are poor emitters with respect to the electrons due to their high mass, they can be accelerated in internal or external shocks in the same way as electrons producing synchrotron radiation. However, the peak flux for the two particle emission components is determined by the mass ratio \(\frac{m_{p}}{m_{e}}\) which implies that hadronic component is usually much smaller with respect to the electron emission. Nevertheless, while electrons cool quickly, protons cooling times are much longer since

\[
\frac{\nu_{\nu}}{\nu_{\gamma}} = \left(\frac{1 + Y_{p}}{1 + Y_{\nu}}\right)^{2} \left(\frac{m_{e}}{m_{p}}\right)^{6} \tag{6}
\]

where \(Y_{p} = \gamma_{p} \epsilon_{p}\) and \(\sigma_{p, \gamma}, \sigma_{p, \nu}\) are the proton-gamma interaction and Thomson cross section respectively. We note that since \(\sigma_{p, \gamma} \gg \sigma_{p, \nu}\), \(Y_{p} >> 1\) and proton’s energy is mostly lost in p-\(\gamma\) interaction rather than synchrotron emission. However, Eq. (6) implies that in the same cases proton synchrotron emission can exceed the electron component in the MAGIC energy band. In Sec. 8 we will briefly discuss the relative importance of the above described emission components.

7 EXTRAGALACTIC BACKGROUND LIGHT ATTENUATION

Gamma ray absorption by pair production with EBL plays a key role in VHE astronomy since it significantly limits the IACTs capability in detecting sources at redshift \(z>1\). The optical depth \(\tau\) is strictly connected to the light content of the Universe and the source distance. In the past years, several EBL models have been proposed providing a wide range of values for \(\tau\) from 1 up to 6 for a \(z=1\) source at 100 GeV (see e.g. Kneiske et al. 2004, Stecker et al. 2006, 2008), which gives an attenuation in the expected flux ranging between 1/3 to more than 1/100. However, the more recent EBL models (Franceschini et al. 2008, Domínguez et al. 2011), although based on different assumptions, are converging to stable results. Within this context, Domínguez et al. (2011) have used real data on the evolution of the galaxy population taken from the AEGIS catalogue to evaluate EBL intensity for a wide range of redshift. The reliability of the results have been tested on the three most distant object observed by MAGIC (Domínguez et al. 2011b). Moreover, the EBL intensity evaluated using this model matches the minimum level allowed by galaxy counts which leads to the highest transparency of the universe to VHE \(\gamma\) rays. We used the model of Domínguez et al. (2011) to evaluate the EBL absorption obtaining a value for \(\tau\) of 0.218 \pm 0.075 at about 40 GeV. This gives an attenuation of the flux at the same energy of the order of \(\sim 20\%\), a value that does not significantly compromise detection capability of MAGIC. However, the optical depth increases quickly with energy reaching the values of \(\sim 1.5\) and \(\sim 14.4\) at 100 GeV and 500 GeV respectively and this makes necessary to lower the energy threshold of the observation. In the case of GRB 090102, MAGIC shows its capability to perform observation at very low energy limiting the \(\gamma\) absorption even for moderate redshift sources.
Although only upper limits have been obtained, the possibility of having simultaneous observations with \textit{Fermi}-LAT in the energy range 0.1-100 GeV and MAGIC in the energy range that starts at 25 GeV (hence overlapping with LAT) make the GRB 090102 a good case study in spite of its relatively high redshift. However, it has to be remarked that GRB 090102 can be considered as a common GRB in terms of both energetics and redshifts. Higher expected fluxes can be foreseen in case of more energetic events that are not so rare accordingly to \textit{Fermi} results. We have used the equations of relativistic shock model in order to predict, in a reliable way, the expected VHE emission in the LAT and MAGIC energy range. From numerical results it is evident that for the chosen parameters and at our observation time, leptonic components are the dominant mechanisms from the low to the very high energy. Following Eq. (6), the cooling frequency for protons is usually located well above the very high energy range (> TeV) and this make the process potentially interesting for MAGIC observations. However, to make the two emissions comparable in the low energy regime, and the proton component to dominate the leptonic one at high energies, a fine tuning in the parameters choice is needed implying \( \gamma_{ep} \approx \frac{m_p}{m_e} \approx 10^3 \). Similar results can be obtained for the IC component. In both cases, however, a higher total energy release of \( \approx 10^{51} \) erg and a circumburst density medium of \( \approx 100 \text{ cm}^{-3} \) are needed to maintain the low energy flux at the observed level. This makes the possibility of observing the hadronic emission component with the MAGIC telescope unrealistic, at least for a canonical model. A sketch of the scenario described above is shown in Fig. 3.

Here, we did not take into account other hadronic-induced processes such as \( \pi^0 \) decay (Böttcher & Dermer 1998). However, it has been shown that they could have a non negligible effect at higher energies. For our parameters, the SSC process looks the most reliable mechanism in the VHE range. Indeed, we obtain \( E_{\text{max}}^{\nu_{\text{ssc}}} \approx 1 \text{ MeV and } E_{\text{esc}}^{\nu_{\text{ssc}}} \approx 50 \text{ MeV}. \) We conclude that MAGIC observation (> 40 GeV) was carried out in the SED region where \( \nu F_{\nu} \propto \nu^{2-p}/2 \) (Wei & Fan 2007) so that it is possible to evaluate the expected SSC emission following (Zhang & Mészáros 2001):

\[
\nu F_{\nu} = \nu F_{\nu,\text{max}} \nu_{\text{esc}}^{1/2} \nu_{\text{obs}}^{(p-1)/2} \nu^{2-p}/2
\]

which gives (for MAGIC first energy bin and taking into account the EBL absorption) \( \nu F_{\nu,\text{esc}} (40 \text{ GeV}) \approx 3.4 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}. \) This result lies about one order of magnitude below the corresponding upper limits. However, a change in the microphysical parameters can influence the VHE emission giving scenarios with substantially higher flux. One of the most critical variables is the intensity of the magnetic field, which influences the relative importance between synchrotron and SSC emission. It is of particular importance for this event, since the most striking observational feature of GRB 090102 was the observation of \( \approx 10\% \) polarization in the optical at early times (about 3 min after the GRB; Steele et al. 2009). One of the most plausible interpretations is that the outflow generating the GRB is driven by a large scale ordered magnetic field, which generates polarized optical synchrotron emission in the optical observable during the reverse shock phase (Steele et al. 2009). Large values of the magnetic field affect in a significant way the HE emission since it reduces the importance of the IC component. However, the regular forward-shock emission should not be affected by this ordered magnetic field (Covino 2007; Mundell et al. 2007). The time-scale of the MAGIC observations are indeed likely late enough not to require this further parameter in the modeling. Such a delay, in association with the moderate source distance, militate against performing constraining observations with MAGIC. Indeed, we estimated that \( \nu F_{\nu} \propto \nu^{1/2}. \) This implies that lowering the temporal delay of the observations can make the expected emission higher by one order of magnitude as illustrated in Fig. 4 where the expected SSC emission at different time is showed.

### 9 Future Prospects

Catching VHE signal from GRBs is one of the primary target of the MAGIC telescope and future IACTs like the Cherenkov Telescope Array (CTA). Our estimates show that for this particular GRB, MAGIC follow-up observations made within the first 1-2 minutes from the trigger time would have the potential to detect the VHE component or at least to evaluate constraining upper limits (see Fig. 5). This demonstrates both the capabilities of the system and the necessity of a fast-response observations.

As GeV emission is found to be relatively common in \textit{Fermi} GRBs (see e.g. Abdo et al. 2009g), the unique opportunity of having simultaneous follow-up with LAT and the MAGIC telescope will make accessible the end of the electromagnetic spectrum of GRBs and will have an important role in constraining different emission mechanisms and the space parameters. Moreover, the recent technical improvement of the Stereo MAGIC system (Aleksić et al. 2011), will bring an improvement in the instrument sensitivity in its low energy range. The steeper decay of the flux makes in any case difficult late time (> 200s) detections for such moderate high-redshift event (see Fig. 5). On the other hand, such a timescale is well within the pointing capabilities of the present generation of IACTs (e.g. MAGIC) that are able to perform follow-up measurements within few hundreds of seconds. Basing on the preliminary sensitivity of the future CTA⁶, a detection will instead be possible, within the

Figure 5. Integrated \( \sigma_{\text{LiMa}} \) significance as a function of observation time in the 63-158 GeV for the MAGIC stereo system in the case of a GRB event similar to the one reported in this paper. Significance curve evolutions are showed for different starting of observation times after GRB onset: 180 sec. (green), 600 sec. (blue), 1100 sec. (red). In this latter case (inner plot), the foreseen performance for CTA assuming the preliminary sensitivity achieved with MC simulations in the same energy range is showed. The colored areas show the assumed 50% systematic errors in the effective area evaluation as explained in Lombardi et al. (2013).

ACKNOWLEDGMENTS

We acknowledge an anonymous referee for useful comments

We would like to thank the Instituto de Astrofísica de Canarias for the excellent working conditions at the Observatorio del Roque de los Muchachos in La Palma. The support of the German BMBF and MPG, the Italian INFN, the Swiss National Fund SNF, and the Spanish MICINN is gratefully acknowledged. This work was also supported by the CPAN CSD2007-00042 and MultiDark CSD2009-00064 projects of the Spanish Consolider-Ingrevio 2010 programme, by grant D002-353 of the Bulgarian NSF, by grant 127740 of the Academy of Finland, by the DFG Cluster of Excellence “Origin and Structure of the Universe”, by the DFG Collaborative Research Centers SFB823/C4 and SFB876/C3, and by the Polish MNiSzW grant 745/N-HESS-MAGIC/2010/0.

The Fermi-LAT Collaboration acknowledges support from a number of agencies and institutes for both development and the operation of the LAT as well as scientific data analysis. These include NASA and DOE in the United States, CEA/IRFU and IN2P3/CNRS in France, ASI and INFN in Italy, MEXT, KEK, and JAXA in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the National Space Board in Sweden. Additional support from INAF in Italy and CNES in France for science analysis during the operations phase is also gratefully acknowledged. This research is partially supported by NASA through the Fermi Guest Investigator Grants NNX09AT92G and NNX10AP22G.

This work made use of data supplied by the UK Swift Science Data Centre at the University of Leicester.
