Abstract

In this paper we investigate Feldstein Horioka puzzle for 14 CEE countries (Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Greece, Hungary, Kosovo, Latvia, Lithuania, Macedonia, Estonia, Poland, Romania, Serbia). In our paper when we investigate the whole sample of 14 CEE countries we find less positive association between investment and savings meaning that capital is highly mobile. While when we regress the subsample of those countries from the sample which are EU members we find the lowest coefficient of association between investment and saving therefore capital is highly mobile in those countries. While in the Non-EU members from this CEE countries the coefficient is highest 0.13 , meaning there is lowest capital mobility. Unit root tests proved that in this sample of countries savings are I(1) or I(2) process, and investments are stationary.

Keywords: Investment savings correlation, stationarity, capital mobility, macroeconomic puzzles
Introduction

A well known stylized fact in international macroeconomics is the high correlation between domestic savings and investment in major industrial countries.\(^1\) Feldstein and Horioka’s (1980) seminal work, they interpret this high savings-investment correlation as an indicator of capital immobility. This interpretation, however, poses an uncomfortable puzzle\(^2\), the so-called Feldstein-Horioka (hereafter FH) puzzle, as the conventional wisdom in the field of international macroeconomics is that the rich countries have a high degree of capital mobility. The literature on Fedlstein Horioka puzzle is extensive the original FH article has been cited 142 times\(^3\) between 1988 and 1995. From the CA identity:

\[
CA_t = S_t - I_t = -Financial Account_t \Rightarrow I_t = FA_t + S_t
\]

FH argued that if there is perfect \(K\) mobility, we should observe low correlation between domestic \(I\) and \(S\). Investors in one country do not need the funds from domestic savers and can borrow from international markets at world rates. By the same token, savers can lend to foreign investor the entirety of the domestic savings. This concept related to long-term real capital flows. Frankel (1995) came up with the distinction between this measure of capital mobility and the financial capital flows measured by real interest parity, covered and uncovered interest parities. F-H estimated:

\[
\frac{I_t}{Y_t} = \alpha + \beta \frac{S_t}{Y_t} + u_t \quad \text{for each country}
\]

With perfect capital mobility, the null hypothesis is that the slope coefficient would be zero for small open economies. For large economies the slope coefficient would be larger than zero. For the small economy result to hold, we would also need \(\text{Corr}(r^*, S) = 0\), interest parity must hold \((r = r^*)\) and \(\text{corr}(S, u) = 0\). In the next section will review empirical literature on this topic.

---

\(^2\) Since the conventional wisdom in most exchange rate and open-economy macroeconomic models was that capital mobility was high.

Empirical literature review

Existing empirical studies on the savings-investment relationship can be split into two broad groups according to their estimation methodologies. The first group takes a non-time-series approach. The second group uses time series techniques. In the next table we present some of the most important studies.

4 Kevin Grier, Shu Lin, Haichun Ye, (2008), Savings and Investment in the USA: Solving the Feldstein Horioka Puzzle, University of Colorado Denver
Data and methodology used in this paper

The data are collected from the World Bank data site\(^5\). Data are for 14 countries. We investigate Feldstein Horioka puzzle for 14 CEE countries (Albania, Bosnia and Herzegovina, Bulgaria, Croatia, Greece, Hungary, Kosovo, Latvia, Lithuania, Macedonia, Estonia, Poland, Romania, Serbia). Variables of interest here are: Domestic investment to GDP, Domestic savings to GDP, Current account balance, and income per capita. Definitions are given in Appendix 1. Descriptive statistics is presented in Table 1. From the six plots in Appendix 0 we can see that savings and investment are I (1) variables and heteroscedasticity and normality is not a problem.

</tbody>
</table>

From the table we can see that domestic savings constitutes on average 10.75% of GDP, while domestic investment is 21.37% of GDP. Current account Balance on average is negative -6.8354 of GDP. In the tables is given also the descriptive statistics for the credit spread and income per capita. In the following Table 2 we present the results from the Feldstein Horioka equation. F-H model is presented with the following regression:

Feldstein-Horioka regression: \( \frac{I}{GDP} = \alpha + \beta \frac{NS}{GDP} + \nu \)

Feldstein (1980) argued that if capital were perfectly mobile, he would find \( \beta = 0 \). Instead, \( \beta \) was much closer to 1. The coefficient (“saving retention”) fell a bit subsequently, but still high. Three “puzzles”, if the saving –investment coefficient is to be measured as a measure of barriers to international financial integration:

\(^6\) See Also Appendix 0 six plots for variables of interest Domestic savings and Domestic investment
1. The coefficient is statistically far above zero (the original Feldstein-Horioka finding),
2. it is even higher for industrialized than for developing countries, and
3. There is little observed tendency for it to decline over time.

</tbody>
</table>

Here it should be noted that even though we expect F-H coefficient\(^7\) to be between 0 and 1, there are some deviations from this range, which implies that this model describes very simplified behaviour of savings and investment. P-value is probability of significance of this coefficient. Real interest rate volatility is the standard deviation of the interest rate spread.

Regression we use here or the second model is: $$SDIR = \alpha + \beta FH + \nu$$

Result is represented in the following *aplot*

---

\(^7\) Standard deviations of interest rate

\(^8\) Feldstein Horioka coefficient measures capital mobility. The higher this coefficient is means that capital is less mobile in that country or countries, the lower this coefficient is it is interpreted as capital mobility.
In our model higher F-H coefficient is associated with lower real interest rate volatility or vice versa. This implies that higher level of financial integration is not associated with higher volatility of interest rate spread. This is opposite for the Results presented in (Giang Lee, 2000) for instance for his paper on financial integration in Asian economies. From the table 2 we can see that standard deviations of interest rates are high. So in this period interest rates in CEE countries are highly volatile. They are more volatile than in the sample of Asian countries in (Giang Lee, 2000), but for the period 1976-1996. The small countries like CEE countries take anchor LIBOR or EURIBOR\(^9\), so it is likely that the source of fluctuations is in the outside economy than in the home country itself. On the next plot is presented the cross section OLS regression for the CEE countries. In the table 3 below graph is presented the result from the Panel regression. From the aaplot (scatter) we can see positive linear trend between domestic savings and investment\(^{10}\).

\[
\text{investme} - \text{o} = 18.198 + .14679 \text{savingst} - p \quad R^2 = 27.0\%
\]

9 Euribor and LIBOR are comparable base rates. Euribor is the average interbank interest rate at which European banks are prepared to lend to one another. LIBOR is the average interbank interest rate at which a selection of banks on the London money market are prepared to lend to one another. Just like Euribor, LIBOR comes in 15 different maturities. The main difference is that LIBOR rates come in 10 different currencies. We would like to refer to current LIBOR interest rates and background information on LIBOR, in case you are interested in additional information on LIBOR.

10 See Appendix 3 Feldstein Horioka regression for every CEE country.

**Current account balances and economic integration (Blanchard, Giavazzi, 2002)**

As Olivier Blanchard wrote in his working paper with Giavazzi\(^{12}\), a country borrower must take into account when it wants to borrow, interest rate and the price cuts it will have to make in order to generate revenues to repay the debt in the future. In the case of increased integration Blanchard argues borrower countries will borrow more, and lender countries will lend more. If we define \( \alpha \) as current account balance to national income than \( \alpha \) is defined as:

\[
\alpha_t = \frac{1}{2} \left( 1 - \left[ \frac{Y_{rt} Y_t}{R(1+x)} \frac{1}{P_{rt} P_t} \right] \right)
\]

So, from the equation above the determinants of the current account balance are: Income the higher is output in the next period relative to this period the higher will be current account deficit. Second the larger the interest rate the lower will be current account deficit (it will be more costly to borrow). Third, The larger the fall in the price of the domestic good required next period to sell domestic goods and repay the debt, the more expensive it is to borrow, the lower the current account deficit.

\[
\frac{Ca}{Y} = \alpha + b_Y \frac{Y/N_t}{Y/N_t} + X_t \beta + \epsilon_{it}
\]

Table 7 Panel between effects linear model (whole sample)\textsuperscript{13}

<td>0.000</td>
</tr>
</tbody>
</table>

Number of observations: 283
Number of groups (panels): 14
R\textsuperscript{2}(between panels): 0.4043

\[ Ca / GDP = -15.75 + 0.069Y / N \]

P-value=0.000 P-value=0.012

As expected the coefficient on the income per capita is positive and statistically significant. In the next Table we introduce the same regression but for the EU members between CEE countries 8 countries\textsuperscript{14}.

Table 8 Panel between effects linear model -EU members \textsuperscript{15}

<table>
<thead>
<tr>
<th>Dependent variable</th>
<th>Current account balance</th>
<th>Coef.</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Independent variables</td>

<td>0.029145</td>
<td>0.043</td>
</tr>
<tr>
<td></td>
<td>Constant</td>
<td>-9.72245</td>
<td>0.000</td>
</tr>
</tbody>
</table>

Number of observations: 152
Number of groups (panels): 8
R\textsuperscript{2}(between panels): 0.3573

Second subsample: \[ Ca / GDP = -9.72 + 0.029Y / N \]

P-value=0.000 P-value=0.043

Here we can see that the difference from the whole sample model is that the coefficients are smaller in size, while the signs are the same. In the next table we present the same model for Non-EU members from CEE countries.

\textsuperscript{13} See Appendix 4 Between effects panel estimation current account balance on income per capita

\textsuperscript{14} Bulgaria, Greece, Hungary, Latvia, Lithuania, Estonia, Poland, Romania

\textsuperscript{15} See Appendix 5 Panel between effects linear model -EU members
Table 9 Panel between effects linear model NON-EU members\textsuperscript{16}

\begin{center}
\begin{tabular}{|l|l|l|}
\hline
Dependent variable & Current account balance & Coef.  \\
\hline
Independent variables & Income per capita & 0.13546  \\
& Constant & -25.3208  \\
\hline
Number of observations & 131  \\
Number of groups (panels) & 6  \\
$R^2$ (between panels) & 0.9313  \\
\hline
\end{tabular}
\end{center}

Third subsample: \[ Ca/GDP = -25.32 + 0.136Y/N \]

\[ \text{P-value}= 0.000 \quad \text{P-value} = 0.000 \]

So on average in the three subsamples we find positive relationship between current account balance and income per capita but this relationship is of bigger size in non-EU members of CEE countries\textsuperscript{17}. The difference is not very significant because these countries have similar current account balances and income per capita when clustered together.

**Conclusion (Resume)**

In our paper when we investigate the whole sample of 14 CEE countries we find less positive association between investment and savings meaning that capital is highly mobile. While when we regress the subsample of those countries from the sample which are EU members we find the lowest coefficient of association between investment and saving therefore capital is highly mobile in those countries. While in the Non-EU members from this CEE countires the coefficient is highest 0.13 , meaning there is lowest capital mobility. Unit root tests proved that in this sample of countries savings are I(1) or I(2) process, and investments are stationary.
