24 **ABSTRACT**

25

26 Climatic influence (global warming and decreased rainfall) could lead to an increase in the  
27 ecological and toxicological effects of the pollution in aquatic ecosystems, especially  
28 contamination from agricultural nitrate ( $\text{NO}_3^-$ ) fertilizers. Physicochemical properties of the  
29 surface waters and sediments of four selected sites varying in  $\text{NO}_3^-$  concentration along La  
30 Rocina stream, which feeds Marisma del Rocio in Doñana National Park (South West, Spain),  
31 were studied. Electrical conductivity, pH, content in macro and microelements, total organic  
32 carbon and nitrogen, and dissolved carbon and nitrogen were affected by each the sampling site  
33 and the sampling time. Contaminant  $\text{NO}_3^-$  in surface water at the site with the highest  $\text{NO}_3^-$   
34 concentration (ranged in 61.6-106.6  $\text{mg L}^{-1}$ ) were of inorganic origin, most probably from  
35 chemical fertilizers, as determined chemically (90% of the total dissolved nitrogen from  $\text{NO}_3^-$ )  
36 and by isotopic analysis of  $\delta^{15}\text{N-NO}_3^-$ . Changes in seasonal weather conditions and hydrological  
37 effects at the sampling sites were also responsible for variations in some biological activities  
38 (dehydrogenase,  $\beta$ -glucosidase, arylsulphatase, acid phosphatase and urease) in sediments, as  
39 well as in production of the greenhouse gases  $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{N}_2\text{O}$ . Both organic matter and  $\text{NO}_3^-$   
40 contents influenced rates of gas production. Increased  $\text{NO}_3^-$  concentration also resulted in  
41 enhanced levels of potential denitrification measured as  $\text{N}_2\text{O}$  production. **The denitrification  
42 process was affected by  $\text{NO}_3^-$  contamination and the rainfall regimen, increasing the greenhouse  
43 gases emissions ( $\text{CO}_2$ ,  $\text{CH}_4$  and especially  $\text{N}_2\text{O}$ ) during the driest season in all sampling sites  
44 studied.**

## 49 1. Introduction

50

51 Anthropogenic influence on the biogeochemical N cycle can produce important alterations  
52 of the cycle leading to concomitant environmental risks such as increased concentration of  
53 greenhouse gases, acidification of soils, streams and lakes, transfer of nitrogen through rivers to  
54 estuaries and coastal oceans, accelerated losses of biological diversity and human health and  
55 economy problems (Vitousek et al., 1997; Galloway et al., 2008; Mulholland et al., 2008). In  
56 aquatic ecosystems, water acidification, eutrophization, including occurrence of toxic algae, and  
57 toxicity of ammonia ( $\text{NH}_3$ ), nitrite ( $\text{NO}_2^-$ ), and nitrate ( $\text{NO}_3^-$ ) are the three major environmental  
58 problems due to inorganic nitrogen pollution (Camargo and Alonso, 2006). Furthermore,  
59 increasing global warming and decreased rainfall in some continental areas may increase  
60 ecological and toxicological effects of this type of environmental contamination (Camargo and  
61 Alonso, 2006). Abuse in utilization of nitrogenous chemical fertilizers have been shown to  
62 enhance emission of carbon dioxide ( $\text{CO}_2$ ), methane ( $\text{CH}_4$ ), and nitrous oxide ( $\text{N}_2\text{O}$ ) greenhouse  
63 gases (Thornton and Valente, 1996; Merbach et al., 1996, 2001; Davidson et al., 2000; Liu and  
64 Greaver, 2009). In addition to chemical fertilizers, release of greenhouse gases to the atmosphere  
65 can be induced by changes in precipitations, temperature, seasons, drought, regional  
66 deforestation, global warming, and El Niño events (Christensen et al., 1990; Smith et al., 2003;  
67 Davidson et al., 2004).

68 Wetlands are among the most important ecosystems on Earth **because of their role in**  
69 **regulating global biogeochemical cycles**. Climate change and anthropogenic effects may have  
70 significant impacts on coastal and inland wetlands (Mitsch and Gosselink, 2007; Olías et al.,  
71 2008). Accordingly, physicochemical and biological monitoring are needed for assessment of  
72 ecological risks due to freshwater pollution and to provide maximal information for adequate

73 protection of aquatic ecosystems (Camargo, 1994). Several authors and reports have shown that  
74  $\text{NO}_3^-$  contamination of soils and surface and groundwater is becoming more intense and frequent  
75 due to the great consume of inorganic nitrogen, mainly nitrate and ammonium salts from  
76 agrochemicals, of the intensive farming (Spalding and Exner, 1993; European Comission, 2002).  
77 Denitrification is the biological process by which  $\text{NO}_3^-$  can be transformed into molecular  
78 nitrogen ( $\text{N}_2$ ) via formation of  $\text{NO}_2^-$  and nitric oxide (NO). Thus, it represents the major pathway  
79 by which  $\text{NO}_3^-$  can be removed from soils and waters to avoid  $\text{NO}_3^-$  accumulation and  
80 contamination. And yet, incomplete denitrification results in production of the greenhouse gases  
81 NO and  $\text{N}_2\text{O}$  (Aulakh et al., 1992; Conrad, 1996; Groffman et al., 2006).

82  
83 The European directive 91/676/CEE concerning  $\text{NO}_3^-$  contamination from agricultural  
84 sources defines the so called “nitrate vulnerable zones” as reference areas of special  
85 environmental protection to prevent soil and water nitrate contaminations. An example is Doñana  
86 National Park (DNP), one of the most important wetlands in Europe covering an area around  
87 60,000ha in a marshy area of SW Spain, in the estuary of the Guadalquivir River. These water  
88 flows are susceptible of  $\text{NO}_3^-$  contamination from small urban areas in the surrounding of the  
89 park and agricultural practices allowed in the ecotone, where organic farming of strawberries and  
90 rice is common. This area is the most fertile and productive zone of Doñana as a result of its  
91 permanent humidity and of the fertilization it receives from the animals either living there or  
92 crossing it (Suso and Llamas, 1993).

93 Several authors have noted that surface and groundwater of DNP wetland are becoming  
94 polluted during the last 20 years. Suso and Llamas (1993) remarked that some wetlands and small  
95 streams could be depleted by groundwater extraction for agricultural reclamation, affecting  
96 negatively the quality of surface and groundwater. Olías et al. (2008) evaluated the water quality

97 of the Almonte-Marismas aquifer (upon which DNP is located) and showed that it was affected  
98 by pollution of both agricultural and urban origins. They detected some shallow points located in  
99 the agricultural zones with high concentrations of  $\text{NO}_3^-$  and sulphates ( $\text{SO}_4^{2-}$ ) from fertilizer  
100 pollution. Finally, Serrano et al. (2006) reviewed the aquatic systems of DNP and they focused  
101 on processes affecting water quality. They noted that there has been a considerable increase of  
102  $\text{NO}_3^-$  concentration in the water-flows of La Rocina and El Partido streams during the past  
103 decade, probably due to the increase in cultivated land and fertilizer applications. They advise  
104 that the influence of this pollution on the eutrophication of the nearby marshes should not be  
105 overlooked.

106 Our research aim was to evaluate the anthropogenic (especially from agriculture) and  
107 seasonal influence in La Rocina stream and how it could be affected by the physicochemical and  
108 biological characteristics of the surface water and its aquatic sediments, focusing in the  $\text{NO}_3^-$   
109 contamination and its influence on the greenhouse gas production ( $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{N}_2\text{O}$ ) and the  
110 denitrification process.

111

## 112 **2. Materials and methods**

113

### 114 *2.1. Description and selection of sampling sites*

115

116 In 1982, DNP was declared a Reserve of the Biosphere by UNESCO and a Wetland of  
117 International Interest per RAMSAR Convention. DNP wetland has three important surface water  
118 inputs (Arambarri et al., 1996; Serrano et al., 2006). Two natural streams called La Rocina and El  
119 Partido, in the north edge of the park, and the Guadiamar River, wich represents the main water  
120 input of the wetlands and suffered the Aznalcollar mine spill in 1998 (Cabrera et al., 1999;

121 Grimalt et al., 1999; Sierra et al. 2003; Olías et al., 2005).

122 The study was performed on La Rocina stream, located in the north of the DNP wetland,  
123 which is one of the main natural streams feeding El Rocío marsh (Fig. 1). Selection of sampling  
124 sites was based on their  $\text{NO}_3^-$  content (in-situ measurements using a Nitrate Test Kit, CHEMetrics  
125 Inc.) after screening of more than 25 points along the course of La Rocina basin ( $462 \text{ km}^2$ ) at the  
126 different sampling times. Four sampling sites along the course of La Rocina stream differing in  
127 their  $\text{NO}_3^-$  concentration were selected (Fig. 1). The Universal Transverse Mercator (UTM)  
128 coordinates for the sites were as follows: 29S 0718632, 4114294 for the lagoon of Palacio del  
129 Acebrón (S1); 29S 0717797, 4113881 for the small stream Arroyo de la Cañada (S2); 29S  
130 0722653, 4111704 for the junction between the stream and the marsh called Vado de la  
131 Canariega (S3); and 29S 0723654, 4111088 for the El Rocío marsh (S4). S1 and S2 had the  
132 lowest and the highest  $\text{NO}_3^-$  concentration, respectively, whereas the values detected in S3 and S4  
133 were between those detected in S1 and S2. Also, differences on hydrological morphology (S1: a  
134 small stream, S2: a lagoon, S3: the union between a stream and a marsh, S4: a marsh) and in  
135 riparian vegetation (not present in S3 and S4) were noted.

136 Samples were taken in October 2008 (T1) and January (T2), April (T3) and July (T4) 2009  
137 in order to represent the pluvial regimen (dry and wet). Rainfall, relative humidity and air  
138 temperature were collected from the Manecorro RM1 meteorological station, which belongs to  
139 the Singular Scientific and Technological Installation (<http://icts.ebd.csic.es/>) of Doñana National  
140 Park located about 200 m away from S3, and from Estación Manual Palacio de Doñana (EM05,  
141 <http://www-rbd.ebd.csic.es>).

142

143 2.2. *Physicochemical properties*

144

145 Four replicates of the surface waters (approximately 1-2 meters from the shore in streams  
146 and 3-4 meters in lagoons for each replicate) and semi disturbed sediments (0-10 cm from the  
147 upper layer using an EIJKELKAMP Peat sampler) were taken at each sampling site, placed in a  
148 portable fridge and processed in the laboratory within 24 h of sample collection. Subsets of  
149 samples from the sediments were lyophilized and kept frozen at -20 °C until use.

150 In water samples, pH and electrical conductivity (EC) were analyzed using a Basic 20  
151 Crison pHmeter and a Basic 525 Crison conductimeter at the laboratory, respectively. After  
152 filtration through 0.45 µm filters, dissolved organic carbon (DOC) and total dissolved nitrogen  
153 (TDN) were determined by using an automatic Shimadzu TOC-VCSN analyser.  $\text{NO}_3^-$  and  $\text{NO}_2^-$   
154 concentration were estimated by ion chromatography (HPLC) using an IC-Pac anion HC  
155 (Waters) column at the facilities of Servicio de Instrumentación (EEZ-CSIC).  $\text{NH}_4^+$  was  
156 determined by a colorimetric method based on Berthelot's reaction (Kempers and Zweers, 1986;  
157 Sommer et al. 1992), adding sodium citrate to complex divalent cations. Macro and  
158 microelements (P, K, Ca, Mg, Na, S, Fe, Cu, Mn, and Zn) were determined by Inductively  
159 Coupled Plasma Optical Emission Spectrometry (ICP-OES) using an IRIS Intrepid II XDL  
160 (Thermo Fisher Scientific Inc.).

161 Texture of the sediments was determined in fresh samples according to the Spanish Official  
162 Methods for Soils and Waters (MAPA, 1974).  $\text{NH}_4^+$ , after 2 h extraction 1:20 (w:v) with 2 N  
163 KCl, and water extracted (1:20, w/v)  $\text{NO}_3^-$  and  $\text{NO}_2^-$  were also analyzed in fresh samples as  
164 indicated above. All other assays were performed in ground samples (0.2 mm) after  
165 lyophilization. pH and EC were measured after water extraction (1:5, w:v) for 2 h. Total organic  
166 carbon (TOC) and total nitrogen (TN) were determined using a LECO TruSpec CN Elemental  
167 Analyser. DOC and TDN were obtained after 2 h water extraction 1:20 (w:v) and estimated as  
168 indicated for surface waters. Macro and microelements were analyzed by ICP-OES after

169 microwave digestion with a mixture (1:1) HF:HCl. Organic nitrogen ( $N_{\text{ORG}}$ ) was calculated as the  
170 difference between either TDN in surface waters or TN in sediments, and the content in inorganic  
171 nitrogen ( $N_{\text{INORG}}$ ), considering  $N_{\text{INORG}}$  as  $N\text{-NO}_3^- + N\text{-NO}_2^- + N\text{-NH}_4^+$ .

172

### 173 | 2.3. Enzymatic analysis in sediments

174

175 A selection of some enzymatic activities related to the metabolic activity and the main  
176 biogeochemical cycles were measured in the freeze-dried sediments. Dehydrogenase was used as  
177 an estimation of overall microbial activity,  $\beta$ -Glucosidase as the enzyme that catalyses the  
178 hydrolysis of disaccharides (C cycle), Arylsulphatase as a measure of the enzymes catalysing the  
179 hydrolysis of organic sulphate esters (S cycle), Acid phosphatase as a measure of the enzymes  
180 responsible for the hydrolysis of phosphate esters (P cycle), and Urease which catalyses the  
181 hydrolysis of urea to  $\text{CO}_2$  and  $\text{NH}_3$  (N cycle) Dehydrogenase was determined according to Garcia  
182 et al. (1997),  $\beta$ -Glucosidase, arylsulphatase and acid phosphatase, were determined as described  
183 by Tabatabai (1982) and urease activity was determined according to Kandeler and Gerber et al.,  
184 (1988). Briefly, these techniques were based on a controlled incubation of the sediments after  
185 adding the initial substrate (INT: 2-*p*-iodophenyl-3-*p*-nitrophenyl-5-tetrazolium for  
186 dehydrogenase, *p*NG: 4-nitrophenyl-beta-D-glucopyranoside for  $\beta$ -Glucosidase, PNPS: *p*-  
187 nitrophenyl sulphate for arylsulphatase, *p*NPP: 4-nitrophenyl phosphate for acid phosphatase and  
188 urea for urease activity respectively) and measuring the ending product of each enzyme reaction  
189 colorimetrically (INTF: iodonitrotetrazolium formazan for dehydrogenase, *p*NP: *p*-nitrophenol  
190 for  $\beta$ -Glucosidase, arylsulphatase, acid phosphatase and  $\text{NH}_4^+$  (measured as described above for  
191 water and sediment samples) for urease activity.

192

193 *2.4. Gas emission (CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O) and denitrification potential of the sediments.*

194

195 The emission of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O were measured after 24 hour aerobic incubation (25°C)  
196 of 20-30 g of the freshly collected sediments in 125 mL glass bottles. Gas concentrations were  
197 analysed in the headspace by a Varian 4900 Gas Chromatograph with a PoraPlot Q column (10 m  
198 length, 0.15 mm internal diameter) and thermal conductivity detector (TCD). Denitrifying  
199 Enzyme Activity (DEA) and Denitrification Potential (DP) were also determined in the fresh  
200 sediments using an acetylene inhibition technique adapted from Šimek et al., (2004). DEA is a  
201 measure of denitrifying enzymes in the sediment and reflects whether the environmental conditions  
202 of the sediments at the moment of sampling would induce the activity of the denitrifying bacteria,  
203 whereas DP represents a long term denitrification potential, allowing the maximum regrowth of  
204 denitrifying bacteria (Tiedje, 1994). DEA was determined using an anaerobic slurry prepared by  
205 mixing 25 g moist sediment and 25 ml of a solution containing 1 mM glucose, 1 mM KNO<sub>3</sub> and  
206 1 g L<sup>-1</sup> chloramphenicol (to prevent protein synthesis and growth) in a 125 mL glass bottle. The  
207 headspace was evacuated and flushed four times with He and 10 ml of acetylene were added. The  
208 samples were shaken at 25°C and the concentration of N<sub>2</sub>O was measured in the headspace after  
209 30 and 60 min of incubation by gas chromatography, as previously described. DEA was calculated  
210 from the N<sub>2</sub>O increase during a half an hour incubation (60–30 min) and using the Bunsen  
211 coefficient for the N<sub>2</sub>O dissolved in water. DP was determined by mixing 6 g moist sediment  
212 with 5 mL of a solution containing 1 mM KNO<sub>3</sub> and 1 mM glucose in a 125 mL glass bottle.  
213 After evacuating and flushing the headspace four times with He, 10 ml of acetylene were added  
214 and the samples were incubated at 25°C during 48 hours. DP was calculated from the N<sub>2</sub>O  
215 increase in the headspace after the second day of incubation and using the Bunsen coefficient for  
216 the N<sub>2</sub>O dissolved in water.

217

218 *2.5. Isotope measurements*

219

220  $\delta^{15}\text{N}$  of  $\text{NO}_3^-$  was determined [following the methodology](#) described by Silva et al., (2001) with  
221 modifications. Water samples (10–30 l) were first filtered through Whatman filter paper and then  
222 passed through 0.45  $\mu\text{m}$  filters (High Capacity GWV, Groundwater Sample Filter). Possible  
223 interferences from sulphate and phosphate in the samples were eliminated by adding an excess of  
224  $\text{BaCl}_2$ , and dissolved  $\text{CO}_2$  was removed by adding HCl and gentle heating. Water samples were  
225 then eluted through a cation exchange resin (AG 50W X8 100-200 mesh, Bio-Rad) to remove  
226 dissolved organic matter and the excess of  $\text{Ba}^{2+}$ , and passed through an anion exchange resin  
227 (AG1 X8 100-200 mesh, Bio-Rad) to retain  $\text{NO}_3^-$ . Finally, nitrate was eluted from the column by  
228 adding 1N HCl, and the solution containing  $\text{HNO}_3$  and HCl was neutralized with  $\text{Ag}_2\text{O}$  (Merck).  
229 The resulting AgCl precipitate was removed by filtration (0.45 mm membrane filter) leaving only  
230  $\text{Ag}^+$  and  $\text{NO}_3^-$  in solution. The solutions were freeze dried yielding a pure, dry  $\text{AgNO}_3$  precipitate.

231 Nitrogen isotope ratios and total nitrogen contents of  $\text{AgNO}_3$  precipitates were determined  
232 by thermal de-composition in a Carlo Erba NC1500 elemental analyser on line with a Delta Plus  
233 XL (ThermoQuest) mass spectrometer (EA-IRMS). The overall precision of analyses was  $\pm 0.1$   
234 ‰ for  $\delta^{15}\text{N}$ . The stable composition is reported as  $\delta$  values per mil:  $\delta = (\text{R}_{\text{sample}}/\text{R}_{\text{standard}} - 1) \times$   
235 1000, where  $\text{R} = {}^{15}\text{N}/{}^{14}\text{N}$  for  $\delta^{15}\text{N}$ . Nitrogen contents of the  $\text{AgNO}_3$  samples were typically  $\sim 8\%$ ,  
236 indicating that no major contaminants were present in the precipitate. Commercial  $\text{N}_2$  was used as  
237 the internal standard for the nitrogen isotopic analyses, contrasted with the international standard.  
238  $\delta^{15}\text{N}$  values for all samples were normalized against internationally accepted reference materials  
239 (IAEA N1,  $\delta^{15}\text{N} = + 0.4$  ‰, IAEA N2,  $\delta^{15}\text{N} = + 20.3$ ‰). The nitrogen isotope ratios of  $\text{AgNO}_3$

240 generated from dissolved IAEA-NO-3 potassium nitrate were within + 4.65 ‰ (n = 12), similar  
241 to the accepted value. Duplicate nitrogen isotope ratio determinations on AgNO<sub>3</sub> from laboratory  
242 nitrate samples were performed with a precision generally better than ± 0.2‰. δ<sup>15</sup>N values are  
243 reported with respect to air.

244

## 245 *2.6. Statistical analysis*

246

247 Differences between the different physicochemical parameters were checked out using the  
248 analysis of variance (ANOVA) and the Tukey post-hoc test at P<0.05. Pearson coefficients were  
249 calculated to obtain correlation between variables using the SSPS 17.0 program for Windows  
250 XP. A principal component analysis (PCA) was performed to analyse relationships among  
251 parameters concerning physicochemical characterization of the sediments, their enzymatic  
252 activities and gas production.

253

## 254 **3. Results**

255

### 256 *3.1. Meteorological data*

257

258 Total rainfall at DNP during the period of study was 299.9 mm, a value which is lower than  
259 that of 477.5 mm, which represents the mean rainfall for the previous 5 years. Main rainfall was  
260 registered in October 2008 (119.25 mm) and March-April 2009 (49.49 and 30.90 mm)  
261 respectively, coinciding with T1 and T3 sampling times. T2 (January 2009) presented 9.3 mm  
262 and T4 (July 2009) 0.11 mm, being the driest season. This pluvial regimen affected water  
263 dynamic in the sampling places studied especially at T4, transforming the stream and lagoon

264 waters sampled in swamps (especially in S3 that presented a high eutrophization rate). Relative  
265 humidity was higher in autumn and winter seasons (T1: 73.79 % and T2: 79.69 %) than in spring  
266 and summer seasons (T3: 65.38 % and T4: 48.68 %), decreasing with air temperature (T1:  
267 18.04°C, T2: 9.73°C, T3: 14.55°C and T4: 25.31°C).

268

### 269 *3.2. Surface waters: Physicochemical characterization and isotopic analysis.*

270

271 Surface water showed in general a slightly basic pH values, especially in S2, S3 and S4  
272 (average values of 7.94 and 7.83 in S2, S3 and S4 respectively, Table 1a). EC was related directly  
273 to total K, Ca, Mg, Na and S concentration in waters, and also to the sampling season. EC values  
274 typically varied within the range from 0.12 and 1.22 dS cm<sup>-1</sup> depending on the sampling season.  
275 The highest EC values were generally recorded during rainy the season (T1), with the exception  
276 of the large EC value (3.11 dS cm<sup>-1</sup>) registered in S3 during the driest season (T4), due to the  
277 eutrophization caused for the swamp water. In general, soluble organic matter was high at T1  
278 (S1: 17.7, S2: 28.3 and S4: 77.7 mg L<sup>-1</sup> of DOC) for all sampling sites studied with the exception  
279 of S3, that presented 135.2 mg L<sup>-1</sup> of DOC at T4, due to the high water eutrophication (the P  
280 concentration at this location was the highest value for all sampling sites and seasons) which  
281 produced an elevated suspended algae content (green water colour by visual observation).

282 S2 presented higher TDN concentrations (in the range 21.6 and 9.4 mg L<sup>-1</sup>) than the other  
283 three locations S1, S3 and S4 that presented an overall of 0.5, 6.2 and 2.3 mg L<sup>-1</sup> respectively  
284 (Table 1b). In S3 at the driest season (T4), TDN showed a value of 18.1 mg L<sup>-1</sup> especially due to  
285 the high NH<sub>4</sub><sup>+</sup> content (Table 1a and b). S2 presented a large NO<sub>3</sub><sup>-</sup> concentration (61.6, 106.6,  
286 101.6 and 68.8 mg L<sup>-1</sup> at T1, T2, T3 and T4 respectively) respect to the other sampling sites  
287 studied (less than 6 mg L<sup>-1</sup>, Table 1a). These NO<sub>3</sub><sup>-</sup> concentrations represented between 90 and

288 97% of the TDN of the surface waters (Table 1b). Also, this fact was noticed in DOC/TDN ratio  
289 values, being smaller in S2 (average of 0.6) than in S1, S3 and S4 (23.7, 12.9 and 10.2  
290 respectively). These sampling sites presented an important organic nitrogen fraction (average of  
291 74.6, 68.9 and 50.1% respectively), not in S2 that was predominantly inorganic (average of  
292 92.4% of  $\text{NO}_3^-$  respect to TDN content).

293 With the procedure used in this study, isotopic analysis of N- $\text{NO}_3^-$  could be carried out only  
294 in S2, the site with the highest  $\text{NO}_3^-$  concentrations. Values of  $\delta^{15}\text{N}$  ranged from -1.6 ‰ to +6 ‰  
295 (AIR) with an average of -0.78 ‰ (AIR). This relatively low value, closed to that of the  
296 atmosphere air, indicates that contaminant  $\text{NO}_3^-$  were of inorganic origin because atmospheric air  
297 is used for their synthesis (Vitoria et al. 2004). Moreover, since mean average values of  $\delta^{15}\text{N}$  for  
298 most inorganic Spanish fertilizers vary between -1 and +2 ‰ (AIR), being the total range  
299 between -4 and +6 ‰ (Otero et al. 2005), the stable isotopes of nitrogen indicate an origin related  
300 with fertilizers used in agricultural practices.

301

### 302 *3.3. Sediments: Physicochemical characterization, enzymatic activities and gas production*

303

304 Sand constituted more than 85% of the components of the sediments. According to the  
305 corresponding contents in clay and silt, S1 and S2 were classified as loamy sand sediments, those  
306 from S3 as sand, and sandy loam for S4. Similar to surface waters, values of pH, EC and content  
307 in macro and microelements in sediments from the four sampling sites varied both among the  
308 sites and with the sampling time (Table 1b). Despite these differences, the values of TOC and TN  
309 were always higher in S1 than in the remaining sampling sites (Table 2b). Regardless of the  
310 sampling sites and sampling times, more than 90% of the nitrogen content in the sediments was  
311 of organic origin and, accordingly, the greatest values of DOC and TDN were also found in S1

312 (Table 2b). Similarly,  $\beta$ -glucosidase, dehydrogenase, urease acid phosphatase and arylsulphatase  
313 activities varied greatly with both the sampling sites and the sampling times (Fig. 2). Whereas S4  
314 showed the highest values of dehydrogenase (mean average value of  $10.26 \mu\text{g INTF g}^{-1} \text{h}^{-1}$ ), acid  
315 phosphatase (mean average value of  $23.5 \mu\text{g pNP g}^{-1} \text{h}^{-1}$ ), urease (mean average value of  $600 \mu\text{g}$   
316  $\text{pNP g}^{-1} \text{h}^{-1}$ ) and arylsulphatase (mean average value of  $400 \mu\text{g pNP g}^{-1} \text{h}^{-1}$ ) activities, S1 was the  
317 site with the greatest values of  $\beta$ -glucosidase activity (mean average value of  $90 \mu\text{g pNP g}^{-1} \text{h}^{-1}$ )  
318 (Fig. 2).

319 The mean average value of  $\text{CO}_2$  produced at sampling sites S1, S2, S3 and S4 were 112, 89,  
320 13, and  $41 \mu\text{g C-CO}_2 \text{g}^{-1} \text{day}^{-1}$ , respectively (Fig. 3). Methane production from the sediments was  
321 also higher in S1 (mean average value of  $9.7 \mu\text{g C-CH}_4 \text{g}^{-1} \text{day}^{-1}$ ) than in S3 and S4 (mean  
322 average values of 0.2 and  $0.3 \mu\text{g C-CH}_4 \text{g}^{-1} \text{day}^{-1}$ , respectively). Methane production occurred in  
323 S2 was in general low. Unexpectedly, values for S2 detected at T3 were the highest for all  
324 samples analyzed ( $34.9 \mu\text{g C-CH}_4 \text{g}^{-1} \text{day}^{-1}$ ) (Fig. 3). S2, the site with the highest  $\text{NO}_3^-$  contents in  
325 its surface water, and S4 showed maximal values of  $\text{N}_2\text{O}$  production with mean average values of  
326 500 and  $310 \text{ ng N-N}_2\text{O g}^{-1} \text{day}^{-1}$ , respectively. Potential denitrification as assayed by DEA and  
327 DP showed that S1 and S2 have the highest potential for denitrification compared to S3 and S4.  
328 The highest values for DEA were obtained during the driest season (T4) with 1115, 2246 and 719  
329  $\text{ng N-N}_2\text{O g}^{-1} \text{h}^{-1}$  in S1, S2 and S4 respectively. Despite fluctuations at the sampling times, S1 and  
330 S2 also showed maximal values of DP with mean average values of 218, 164, 58 and  $89 \mu\text{g N-}$   
331  $\text{N}_2\text{O g}^{-1} \text{d}^{-1}$  for S1, S2, S3 and S4, respectively.

332

### 333 3.4. Statistical analysis

334

335 Pearson correlation matrix revealed that TOC, TN,  $\text{NH}_4^+$ , DOC and TDN were positive and

336 significantly ( $p \leq 0.01$ ) correlated with CO<sub>2</sub> production and with  $\beta$ -glucosidase activity (Table 3).  
337 After PCA analysis, except for NO<sub>3</sub><sup>-</sup> and pH, the remaining parameters analyzed clustered in 3  
338 main groups (Figure 4a). The first cluster contained most of the parameters related with the  
339 organic fraction of the sediments (TOC, TN, DOC, TDN, NH<sub>4</sub><sup>+</sup>, CO<sub>2</sub>, CH<sub>4</sub>, DP and  $\beta$ -glucosidase  
340 activity), the second cluster included the inorganic components (K, Ca, Mg, Fe, Cu, Mn and Zn),  
341 and the third cluster was composed of the enzymatic activities dehydrogenase, acid phosphatase,  
342 urease and arylsulphatase. The first principal component (PC1) explained 36.79% of the total  
343 variance of the data, whereas the second principal component (PC2) was responsible for 20.34%.  
344 According to these two axes, the sampling sites were ordered as a function of the three clusters  
345 mentioned above (Figure 4b). Consequently, S1 showed the highest values for the organic  
346 fraction and S4 for the enzymatic fraction. Nevertheless, sizes of the clusters indicated that  
347 seasonal variation affected much more to S1 and S4 than to S2 and S3.

348

349

### 350 **3. Discussion**

351

352 Although to a different extent depending on the sampling site, physicochemical properties  
353 of the surface waters sampled along La Rocina stream were influenced **by seasonal variation**  
354 **(especially rainfall regime)**. These results agree with those of Espinar and Serrano (2009) which  
355 indicate that development of temporary wetlands in DNP are influenced by climate and geology  
356 of the region. This is especially important in wetlands located in semiarid areas such as the South  
357 of Spain, where the climate is unpredictable and produces a wide range of hydrological  
358 conditions (Serrano et al., 2006). Thus, it is possible that rainfall, evaporation, groundwater  
359 discharge, biogeochemical interactions at the sediment-water interface affected chemical

360 composition of the surface waters along the course of La Rocina stream. Hydrological dynamic at  
361 each sampling site was affected by the sampling time. That was clearly visible in S3 at T4, the  
362 driest sampling time, where stream waters were transformed into swampy waters, and in S4  
363 where desiccation almost emptied the El Rocio marsh.

364 Several authors have reported continuous increases in pollution (Suso and Llamas, 1993;  
365 Olías et al., 2008), and more precisely in  $\text{NO}_3^-$  content, in surface- and ground-waters of DNP  
366 during the last two decades (García-Quesada et al., 1987, Serrano et al., 2006). Recently,  
367 contamination due to  $\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  in the Doñana aquifer has been linked to utilization of  
368 agrochemicals during the agricultural practices that take place in the ecotone of the Park (Olías et  
369 al., 2008). Values of  $\text{NO}_3^-$  content in S2 were higher than the  $50 \text{ mg L}^{-1}$  defined by the European  
370 directive 91/676/CEE as the upper limit for  $\text{NO}_3^-$  contamination from agricultural sources  
371 (European Commission, 1991). At that site, concentration of inorganic N represented more than  
372 90% of the TDN. In this study, based on isotopic analysis of the contaminant  $\text{NO}_3^-$  in surface  
373 waters of La Rocina stream, we show that, at least in S2, they were of inorganic origin, more  
374 probably from chemical fertilizers.

375 The interpretation of the nutrients dynamic in aquatic ecosystems could be biased by the  
376 strong effects of hydrology on physicochemical (Espinar and Serrano, 2009). For that,  
377 microbiological processes involved in the principal biogeochemical cycles are needed  
378 (Faulwetter et al., 2009). Soil microorganisms mediate many processes that are of particular  
379 interest in freshwater wetland ecosystems where nutrient cycling is highly responsive to  
380 fluctuating hydrology and nutrients and soil gas releases may be sensitive to climate warming  
381 (Gutknecht et al., 2006). Determination of enzymatic activities in sediments of La Rocina stream  
382 varied both among sampling sites and sampling times. Although determinations of enzymatic  
383 activities in sediments are relatively scarce, previous analyses have shown they vary widely

384 across the different wetland ecosystems examined (Gutknecht et al., 2006). In our study, dryness  
385 and temperature positively affected dehydrogenase, as values of activity were always greater at  
386 T4. Similarly,  $\beta$ -glucosidase activity correlated significantly with the content of the organic  
387 matter fraction, as the highest values of activity were detected in S1 and S2, the sites with the  
388 highest TOC concentrations. Similar results were reported by Williams and Jochem (2006) who  
389 showed that, despite the complex relationships between biological and environmental parameters,  
390 the kinetic of several ectoenzymes, among them  $\beta$ -glucosidase, were controlled by organic  
391 matter availability.

392 Wetlands play an important role on carbon cycle and on global climate change. The  
393 emission of greenhouse gases, especially  $\text{CO}_2$ , and  $\text{CH}_4$ , shows a large spatial and temporal  
394 variation due to the complex interactions between environmental variables and the  
395 microbiological processes leading to gas production. The carbon flux is related to many external  
396 factors, including soil environment, hydrological conditions, vegetation type and exogenous  
397 nitrogen (Ma and Lu, 2009). As revealed by Pearson correlation matrix (Table 3),  $\text{CO}_2$  and  $\text{CH}_4$   
398 fluxes showed a strong seasonal influence, especially at S1 and S2, the sampling sites with the  
399 highest TOC concentrations. There is to note, however, that  $\text{NO}_3^-$  contamination increased  
400 production not only of  $\text{N}_2\text{O}$ , but also of  $\text{CO}_2$  and  $\text{CH}_4$ . These results agree with those which show  
401 that alterations in the biogeochemical cycles in nature may lead to altered biogenic fluxes of  $\text{CO}_2$ ,  
402  $\text{CH}_4$  and  $\text{N}_2\text{O}$ , the three main gases contributing to global warming (Liu and Greaver, 2009).

403 In addition to  $\text{NO}_3^-$ , denitrification correlated positively with the content of organic matter  
404 in the sediments. Accordingly, increased potential denitrification was observed at sites with the  
405 highest TOC values. Similar results were obtained during studies on denitrification and its  
406 relationship with organic carbon quality in three coastal wetland soils (Dodla et al., 2008). Also,  
407 Sirivedhin and Gray (2006) found that the sediment denitrification potential showed a positive

408 relationship with the biodegradable organic carbon concentration produced by the periphytic  
409 algae in wetlands. Denitrification was also affected by the pluvial regime, as the highest values of  
410 DEA were registered during the driest season at each sampling time. **Hernández and Mitsch**  
411 **(2007)** founded that soil temperature, flood frequency and nitrate availability were important  
412 factors controlling denitrification in created wetlands. Davidson, (1991) observed an increase  
413 N<sub>2</sub>O production in dry season, and specially during drying and wetting cycles, caused by a  
414 temporal accumulation of mineral nitrogen into soil surface, which will become rapidly available  
415 to microbial biomass when dry soil is wetted.

416

#### 417 **4. Conclusions**

418

419 The surface water of La Rocina stream showed NO<sub>3</sub><sup>-</sup> contamination, probably to  
420 agricultural sources. This contamination decreased along La Rocina basin and apparently, the  
421 superficial water body of DNP wetland was not affected. More research is needed to evaluate  
422 how the NO<sub>3</sub><sup>-</sup> pollution could affect DNP groundwater. The environmental conditions such as  
423 precipitation rate, hydrological morphology and organic matter content greatly influenced the  
424 physicochemical characteristics of the surface waters of DNP wetland. The biological activity  
425 and greenhouse gas production in their aquatic sediments was also affected by these  
426 environmental parameters, specially the hydrology which had a major effect during the driest  
427 season. The denitrification process was affected by anthropogenic activity (nitrate contamination  
428 from agricultural practices) and the rainfall regimen, increasing the GHG emissions (CO<sub>2</sub>, CH<sub>4</sub>  
429 and especially N<sub>2</sub>O) during the driest season in all sampling sites studied.
