18 **Abstract**

2  
3  
4 19 The effect of solar radiation on dissolved organic matter (DOM) and the subsequent impact of  
5  
6 20 photo-altered DOM on bacterial activity and community structure were assessed during two  
7  
8 21 experiments in the coastal system of the Ría de Vigo (NW Iberian Peninsula). After exposure of 0.2  
9  
10  
11 22  $\mu\text{m}$  filtered seawater for 3.5 days to dark and full sunlight, an inoculum of the bacterial community  
12  
13 23 collected at the same time as the exposed water was added and the mixture was incubated for 4 days  
14  
15 24 in the dark at 15°C. Changes in bacterial production (BP), diversity (assessed by Fluorescence in  
16  
17 25 situ hybridization) and electron transport system (ETS) activity, dissolved organic carbon (DOC)  
18  
19 26 and nitrogen (DON) and DOM humic-like absorption and fluorescence were followed. The  
20  
21 27 exposure to sunlight had no effect on DOM concentrations while an average ( $\pm$  SD) decrease in  
22  
23 28 DOM humic fluorescence of  $45 \pm 10$  % was found. The incubations with photo-altered DOM had  
24  
25 29 lower BP ( $57 \pm 11$  %), ETS ( $42 \pm 9$  %) and bacterial carbon demand (BCD) ( $42 \pm 8$  %) compared  
26  
27 30 with the dark incubations, while bacterial growth efficiency (BGE) was unaffected. This suggests  
28  
29 31 that DOM photo-alteration had a negative effect on bacterial metabolism in the study system. The  
30  
31 32 bacterial growth on irradiated DOM resulted in a significant enrichment of the  
32  
33 33 *Gammaproteobacteria* group compared with the dark control, indicating that solar exposure of  
34  
35 34 DOM led to rapid changes in the bacterial community composition of the Ría de Vigo.

36 **1. Introduction**

2  
37 Dissolved organic matter (DOM) constitutes the main substrate for heterotrophic bacterial  
4  
5  
68 growth and respiration in marine systems (Hedges, 2002). DOM in coastal waters can be  
7  
89 differentiated according to its origin as autochthonous or allochthonous. Autochthonous DOM is  
9  
10  
1140 produced within the system and originates largely from phytoplankton exudation, cell lysis, and  
12  
1341 grazing (Nagata, 2000), whereas allochthonous DOM primarily originates from terrestrial plant and  
14  
15  
1642 soil materials (Cauwet, 2002).

17  
1843 There is considerable evidence that coloured DOM (CDOM) can be transformed by UV-B  
19  
20  
2144 (280– 320 nm) and UV-A (320–400 nm) solar radiation into reactive oxygen species (ROS) (Scully  
22  
2345 et al., 2003), inorganic carbon species (CO<sub>2</sub> and CO) (Bertilson and Tranvik 2000), labile organic  
24  
2546 and inorganic compounds (Kieber et al., 1989) and further induce the production of biological  
26  
27  
2847 refractory humic substances (Harvey et al., 1983; Kieber et al., 1997). ROS species may enhance  
29  
3048 microbial activity, since they can convert biological refractory DOM into labile forms, while they  
31  
32  
3349 can also lower microbial activity by competing for substrates and causing oxidative stress (Scully et  
34  
3550 al., 2003; Lesser, 2006). The direct photomineralization of DOC to CO or CO<sub>2</sub> does not provide  
36  
37  
3851 new bacterial substrate (Bertilson and Tranvik 2000), while the photochemical conversion of  
39  
4052 biological refractory DOM into new organic and inorganic compounds may stimulate bacterial  
41  
4253 growth (Vähatalo et al., 2003). Contrarily, sunlight can also induce the biological polymerization  
43  
44  
454 and condensation of DOM into refractory materials, representing a source of CDOM (Harvey et al.,  
46  
4755 1983; Kieber et al., 1997). While some studies suggest that autochthonous DOM gets less and  
48  
49  
5056 allochthonous DOM more bioavailable after UV exposure, others studies have found the converse  
51  
5257 (Obernosterer and Herndl 2000; Tranvik and Bertilson, 2001; Sulzberger and Durisch-Kaiser,  
53  
54  
5558 2009).

159 The bacterial community in marine waters is often dominated by a few major bacterial groups:  
2  
3  
60 *Alpha*-, *Beta*- and *Gammaproteobacteria*, and the group *Bacteroidetes* (Giovannoni and Rappé,  
4  
5  
61 2000; Giovannoni and Stingl, 2005). Several studies have shown that the DOM composition  
7  
8  
62 influences the bacterial community composition (Pérez and Sommaruga, 2006; Teira et al., 2009).  
9  
10  
11  
63 However, little is known about the influence of photochemically altered DOM on the bacterial  
12  
13  
64 community composition. A recent study by Piccini et al., (2009) in a coastal lagoon suggests that  
14  
15  
65 photochemical transformation of DOM stimulates the growth of the *Alpha*- and *Betaproteobacteria*  
16  
17  
66 groups. But this finding needs to be investigated in more detail before we can come with general  
18  
19  
20  
67 conclusions.  
21  
22

23  
24  
25  
68 In the present study, we assessed the bacterial community response to irradiated DOM in a  
26  
27  
69 coastal system dominated by autochthonous inputs. We hypothesize that photochemically altered  
28  
29  
70 DOM will have a negative impact on bacterial activity and change the bacterial community  
30  
31  
71 composition.  
32  
33

## 34 35 72 **2. Material and methods**

### 36 37 73 *2.1. Sampling site*

38  
39  
74 The Ría de Vigo is a large coastal embayment, with a length of 33 km, a surface area of 176  
40  
41  
75 km<sup>2</sup>, and a volume of 3.32 km<sup>3</sup>. Its hydrographic regime is dictated by wind-driven upwelling and  
42  
43  
44  
76 downwelling episodes; northerly winds result in upwelling, which prevails from April to October,  
45  
46  
77 with nutrient-rich upwelled water reaching the surface resulting in a high productivity. From  
47  
48  
78 November to March, southerly winds predominate, resulting in downwelling forcing warm and  
49  
50  
79 nutrient-poor shelf surface water into the ría (Álvarez-Salgado et al., 2003). In the winter, the  
51  
52  
80 phytoplankton community consists mainly of small phytoplankton species and diatoms which are  
53  
54  
81 followed by a spring diatom bloom. During upwelling episodes, phytoplankton primary production  
55  
56  
82 reaches a mean value of 2.5 g Cm<sup>-2</sup> d<sup>-1</sup>, which decreases to < 0.3 g Cm<sup>-2</sup> d<sup>-1</sup> during downwelling  
57  
58  
59  
60  
61  
62  
63  
64  
65

episodes (see review by Álvarez-Salgado et al., 2010). The bacterial abundance varies seasonally between  $0.3$  and  $2.7 \times 10^9$  cells  $l^{-1}$  and the bacterial production reaches levels between  $2.8$  and  $66.7$   $mg\ C\ l^{-1}\ d^{-1}$  (Lekunberri et al., 2010; Teira et al., 2013). The bacterioplankton community is dominated by the groups *Bacteroidetes* and *Roseobacter* (Alonso-Gutiérrez et al., 2009; Teira et al., 2008), although SAR11 can become occasionally abundant in this eutrophic system (Teira et al., 2009).

Two separate experiments were conducted during winter (14 February 2008) and spring (24 April 2008) with water samples collected in the middle segment of the Ría de Vigo ( $42^\circ 14.5'N$  and  $8^\circ 45.8'W$ ). Previous studies have shown large differences in DOM concentration and composition between these two periods (Nieto-cid et al., 2005; Lønborg et al., 2010a). Samples were taken at  $5$  m depth using a  $25\ l$  Niskin bottle. Salinity and temperature were measured prior to the sampling with an SBE 9/11 CTD probe. Samples for chlorophyll *a* (Chl. *a*) were collected by filtering seawater ( $100$ -  $200\ ml$ ) through a GF/F filter and analyzed after  $90\ %$  acetone extraction with a Turner Designs 10000R fluorometer (Yentsch and Menzel, 1963).

## 2.2. Experimental design

Filtration of the collected seawater started within  $10$  min of collection; one part was filtered through pre-combusted ( $450^\circ C$  for  $4\ h$ ) GF/C filters to establish a microbial culture, which was kept in the dark at  $15^\circ C$  until used. The second part was gravity filtrated through a dual-stage ( $0.8$  and  $0.2\ \mu m$ ) filter cartridge (Pall-Acropak supor Membrane), which had been pre-washed with Milli-Q water ( $>10\ l$ ).

In the laboratory, the  $0.2\ \mu m$  filtered seawater was divided into two experimental treatments; dark (dark) and full sun light treatment (UV). The dark treatments were established by placing the  $0.2\ \mu m$  filtered seawater in  $500\ ml$  glass bottles covered with aluminium foil and dark plastic bags. The water for the UV treatments was distributed into  $270\ ml$  quartz tubes (diameter:  $5\ cm$ ). No

107 headspace was left in either the glass bottles or the quartz tubes, and all incubators were sealed with  
2  
3  
108 ground glass stoppers. The samples were thereafter placed in a recirculation water bath (water  
4  
5  
109 depth: 2.5 cm) in the terrace of the laboratory and exposed to 100 % natural sunlight for 3.5 days  
7  
8  
110 encompassing the natural light/dark cycle. This exposure time was fixed on basis of the decay rate  
9  
10  
111 constants of coloured dissolved organic matter previously obtained by Nieto-Cid et al., (2006) in  
12  
112 winter ( $0.25 \text{ d}^{-1}$ ) and spring ( $0.40 \text{ d}^{-1}$ ) in the Ría de Vigo. At these rates, a colour loss of 60-75%  
14  
113 would occur in 3.5 days. Before and after sunlight exposure, subsamples were collected for the  
15  
114 analysis of dissolved organic carbon (DOC), total dissolved nitrogen (TDN), dissolved inorganic  
19  
20  
115 nitrogen (DIN:  $\text{NH}_4^+$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ ) and phosphate (DIP:  $\text{HPO}_4^{2-}$ ), and DOM optical properties  
21  
22  
116 (absorption and induced fluorescence). Within 30 min after sunlight exposure, the water was  
24  
117 combined into two different (dark and UV) carboys and the microbial community collected at the  
26  
27  
118 time of sample collection (3.5 days before), was added in a ratio of 1 part of microbial culture to 9  
29  
119 parts of exposed water. The water was thereafter transferred into 500 ml glass bottles and incubated  
31  
32  
120 in the dark at a constant temperature of  $15^\circ\text{C}$ , with four replicate bottles being used for sub-  
34  
121 sampling at incubation times 0, 1, 2, and 4 days. Unfiltered water from these bottles was used to  
36  
37  
122 follow changes in bacterial abundance (BA), production (BP), electron transport system (ETS)  
38  
39  
123 activity and diversity using Catalysed Reporter Deposition-Fluorescence In Situ Hybridisation  
41  
42  
124 (CARD-FISH). Samples for the analysis of DIN, DIP, DOC, TDN and CDOM absorption were  
43  
44  
125 collected in four replicates at day 0 and 4. DOM fluorescence (FDOM) was measured at incubation  
46  
47  
126 day 0, 1, 2, and 4. Samples for the dissolved phase were collected after filtration through  $0.2 \mu\text{m}$   
48  
49  
127 filters (Pall Supor membrane Disc) in an acid-cleaned glass filtration system under low  $\text{N}_2$  flow  
51  
52  
128 pressure. All glassware used was acid washed in 10 % HCl and rinsed with Milli-Q and sample  
53  
54  
129 water prior to use.  
55  
56  
57

### 58 2.3. Sample analysis 59

131 BA was determined on day 0, 1 and 2 by fixing the samples (1-2 h) with formol in the dark,  
2  
32 filtered onto 0.2 µm polycarbonate filters, and stored at -20°C until counted. The samples were  
4  
5  
63 stained with a DAPI-mix before counted on a Leica DMBL microscope equipped with a 100-W Hg-  
7  
84 lamp; more than 800 DAPI-stained cells were counted per sample. Bacterial biomass was calculated  
9  
10  
135 from BA, using a carbon conversion factor of 30 fg C cell<sup>-1</sup>, which is representative for coastal  
12  
136 bacterial assemblages (Fukuda et al., 1998).

15 BP was measured by [<sup>3</sup>H] thymidine incorporation (Fuhrman and Azam, 1980) on days 0, 1 2  
16  
17 and 4. Four replicate 9.9-ml samples and 2 trichloroacetic acid killed samples were added an  
18  
19 aqueous stock solution of [<sup>3</sup>H - methyl] thymidine (40 nmol final concentration). The samples were  
20  
21 incubated in the dark at 15°C for 2 h, 10 ml of ice-cold Trichloroacetat (TCA) was thereafter added  
22  
23 and samples were filtered onto 0.2 µm polycarbonate filters (presoaked in non-labelled thymidine),  
24  
25  
26 washed with 95% ethanol and autoclaved Milli-Q water. The filters were hereafter dried at room  
27  
28 temperature (24 h) and mixed with 10 ml of scintillation fluid (Sigma-Flour). The radioactivity  
29  
30  
31 incorporated into cells was counted using a Beckman spectral liquid scintillation counter.  
32  
33  
34 Thymidine incorporated into bacterial biomass was converted to carbon production using the  
35  
36 theoretical conversion factors 2 x 10<sup>18</sup> cells mol<sup>-1</sup> thymidine (Fuhrman and Azam, 1980) and a  
37  
38 carbon conversion factor of 30 fg C cell<sup>-1</sup> (Fukuda et al., 1998).  
39  
40  
41

42 The ETS activity was measured on days 0, 1, 2 and 4 using the reduction of 2-(4-iodophenyl)-  
43  
44 3-(4-nitro-phenyl)-5-phenyl tetrazolium chloride (INT) (Martínez-García et al., 2009). The activity  
45  
46 was measured using 1 h incubations of 3 replicate samples (10 ml) and 1 formol-killed control. The  
47  
48 incubations were terminated by adding formol and filtering onto 0.2 µm polycarbonate filters. The  
49  
50 filters were hereafter stored frozen (-20°C) until further processing (Martínez-García et al., 2009).  
51  
52  
53 The respiration rates derived from ETS activity ( $R_{ETS}$ , in µmol O<sub>2</sub> l<sup>-1</sup> h<sup>-1</sup>) were obtained by  
54  
55 multiplying the in vivo ETS activity (in µmol INTF l<sup>-1</sup>) by an empirically derived conversion factor  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

155 of 12.8 (Martínez-García et al., 2009). The microbial respiratory quotient (RQ), defined as the ratio  
2  
3  
156 of mol CO<sub>2</sub> production per mol O<sub>2</sub> was calculated using the average RQ values (range 1.35-1.53)  
4  
5  
157 calculated by Lønborg et al., (2010a) for the same sampling period.  
7

158 The bacterial carbon demand (BCD) was calculated as the sum of BP and ETS activity:  
9

$$159 \text{BCD} = \text{BP} + \text{ETS} \quad (1)$$

160 The bacterial growth efficiency (BGE) was calculated as BP divided by the sum of BP and  
14  
15  
161 ETS activity:  
16

$$162 \text{BGE} = \text{BP} / (\text{BP} + \text{ETS}) \quad (2)$$

163 Changes in the bacterial community composition were monitored using CARD-FISH at day 0,  
21  
22  
23  
24  
25  
165 and, subsequently, the samples were stored at 4°C in the dark for 12-18 h. Thereafter, each sample  
26  
27  
28  
29  
30  
167 supported by a cellulose nitrate filter (Millipore, 0.45 µm), washed twice with Milli-Q water, dried  
31  
32  
33  
168 and stored in a vial at -20°C until further treatment. The abundance of different bacterial  
34  
35  
36  
169 populations was determined using a mix of oligonucleotide probes specific for the domain  
37  
38  
39  
40  
41  
42  
172 *Eubacteria* (EUB338, EUB338II, EUB338III) (Daims et al., 1999), the *Beta*- (BET42a) (Manz et  
43  
44  
45  
46  
47  
48  
174 al. 1992) and *Gammaproteobacteria* (GAM42a) (Manz et al., 1992) subclasses and the class  
49  
50  
51  
52  
53  
54  
55  
177 *Flavobacteria* of phylum *Bacteroidetes* (CF319a) (Manz et al., 1996). Additionally, the relative  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65  
178 abundance of the SAR11, *Roseobacter*, and SAR86 clusters was also analysed using the specific

179 amplification (30-40 min) (Teira et al., 2004). We used 55 % of formamide for all probes excepting  
2  
3  
180 for SAR11-441R (45 % formamide). Cells were counter-stained with a 4',6-diamidino-2-  
4  
5  
181 phenylindole (DAPI)-mix (5.5 parts of Citifluor [Citifluor, Ltd.], 1 part of Vectashield [Vector  
7  
8  
182 Laboratories, Inc.] and 0.5 parts of PBS with DAPI (final concentration  $1 \mu\text{g ml}^{-1}$ ). The slides were  
9  
10  
183 examined under a Leica DMBL microscope equipped with a 100-W Hg-lamp and appropriate filter  
12  
13  
184 sets for DAPI and Alexa488. For each microscope field, 2 different categories were enumerated: 1)  
14  
15  
185 total DAPI-stained cells and 2) cells stained with the specific probe. Negative control counts  
16  
17  
186 (hybridization with HRP-Non338) averaged 0.5 % of DAPI-stained cells. The counting error,  
19  
20  
187 expressed as the percentage of standard error between replicates, was, on average, < 5 % for DAPI  
21  
22  
288 counts and < 10 % for CARD-FISH counts. The counting error was relatively higher for the less  
24  
25  
189 abundant groups (*Betaproteobacteria* and SAR86).

27  
290 Inorganic nutrients ( $\text{NH}_4^+$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$  and  $\text{HPO}_4^{2-}$ ) were determined by standard segmented  
29  
30  
391 flow analysis (SFA) as described in Hansen and Koroleff, (1999). DOC and TDN were measured  
31  
32  
392 using a Shimadzu TOC analyser (Pt-catalyst) connected to an Antek-TN measuring unit. Three to  
34  
35  
393 five replicate injections of 150  $\mu\text{l}$  were performed per sample. Concentrations were determined by  
36  
37  
394 subtracting a Milli-Q blank and dividing by the slope of a daily standard curve of potassium  
38  
39  
495 hydrogen phthalate and glycine. Using the deep ocean reference (Sargasso Sea deep water, 2600 m)  
41  
42  
196 we obtained a concentration of  $46.0 \pm 2.0 \mu\text{mol C l}^{-1}$  (average  $\pm$  SD) for DOC and  $22.0 \pm 2.0 \mu\text{mol}$   
43  
44  
497  $\text{N l}^{-1}$  for TDN. DON concentrations were calculated as the difference between TDN and DIN (DON  
46  
47  
198 = TDN – DIN). The DOM consumed over the 4 days incubation was here defined as the bio-  
48  
49  
509 available pool (BDOM), and the remaining as the bio-resistant pool (RDOM).

51  
520 The CDOM absorption was measured in four replicates on a Beckman Coulter DU 800  
53  
54  
501 spectrophotometer using Milli-Q water as a blank. Before analysis samples were warmed to room  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

202 temperature. The absorption was measured at a wavelength of 340 nm using a 10 cm quartz cuvette.

203 The absorption coefficient,  $a_{\text{CDOM}}(340)$ , was calculated as:

$$a_{\text{CDOM}}(340) = \frac{2.303 \cdot A(340)}{L} \quad (3)$$

205 Where  $A(340)$  is the absorbance measured at 340 nm minus the average residual absorbance from  
206 600 to 700 nm ( $\text{m}^{-1}$ ). The factor 2.303 converts from base 10 to base e logarithms and the  
207 denominator  $L$  is the cell path-length in meters.

208 The CDOM fluorescence was measured in four replicates on a Perkin Elmer LS 55  
209 luminescence spectrophotometer equipped with a xenon discharge lamp, equivalent to 20 kW for 8  
210  $\mu\text{s}$  duration. Measurements were performed at a constant temperature of 20°C in a 1 cm quartz  
211 fluorescence cell. Milli-Q water was used as a reference and Excitation/emission (Ex/Em)  
212 measurements were performed at Ex/Em = 340 nm/440 nm (termed  $F(340/440)$ ) characteristic of  
213 humic-like materials (Coble, 1996; Lønborg et al., 2010b).  $F(340/440)$  were expressed in ppb  
214 equivalents of quinine sulphate (QSU), by calibrating the LS 55 Perkin Elmer at Ex/Em: 350  
215 nm/450 nm against a quinine sulphate dihydrate (QS) standard dissolved in 0.05 mol  $\text{l}^{-1}$  sulphuric  
216 acid.

217 In this paper unpaired t-tests as described in Sokal and Rohlf (1995) were used to test the  
218 significance (95% confidence level) of the differences observed in bacterial abundance, activity,  
219 and relative abundance of different phylogenetic groups between the Dark and UV treatments, with  
220 all statistical analysis conducted in Statistica 6.0.

## 221 **3. Results**

### 222 *3.1. Environmental chemical and optical conditions*

223 Contrasting hydrographic conditions occurred during the two study periods: salinities were  
224 35.4 and 25.0, temperatures 13.4 and 15.5 °C and Chl  $a$  concentrations 1.13 and 8.42  $\text{mg m}^{-3}$  during

225 the winter and spring samplings, respectively. Both DIP and DIN concentrations were higher during  
226 winter, while DOC, DON,  $a_{\text{CDOM}}(340)$  and  $F(340/440)$  were higher during spring (Table 1). The  
227  $F(340/440)$  to DOC ratio indicated a larger allochthonous influence and lower DOM quality during  
228 spring (Table 1).

229 Incident irradiance during the UV treatments was taken from the meteorological observatory  
230 of the Cies Islands, ~ 10 km from the base laboratory, showing that over the 3.5 days the UV  
231 samples were exposed to 268 kJ (winter) and 890 kJ (spring) of total solar radiation. These solar  
232 intensities are comparable to average values found for these periods in the NW Iberian Peninsula.

### 233 3.2. Photochemical induced changes in chemical and optical parameters

234 The 3.5 days dark and UV-light exposure did not have any significant impact on nutrient or  
235 DOM concentrations (Table 1). In the dark treatments, significant differences were not found in  
236  $a_{\text{CDOM}}(340)$  and  $F(340/440)$  compared with the field data, while strong changes occurred in the UV  
237 treatments (Table 1). The UV-light degradation led to a decrease of  $a_{\text{CDOM}}(340)$  of  $0.06 \pm 0.02 \text{ m}^{-1}$   
238 (about 20% of the initial absorption) in winter and  $0.36 \pm 0.06 \text{ m}^{-1}$  in spring (about 50% of the  
239 initial absorption). For the case of  $F(340/440)$ , the decrease was  $0.6 \pm 0.2 \text{ QSU}$  (about 40% of the  
240 initial fluorescence) in winter and  $1.6 \pm 0.2 \text{ QSU}$  (about 50% of the initial fluorescence) in spring.  
241 DOM absorption and fluorescence were significantly different in the dark and UV treatments (t-test,  
242  $p < 0.003$ ,  $n = 8$ ). The  $F(340/440)$  to DOC ratio in the dark treatment was not different from the  
243 field measurements, while decreases were found in the UV-light exposed samples (Table 1).

### 244 3.3. Effects of photochemical alterations on the bacterial community

245 After the UV exposure, water samples were inoculated with the original bacterial community  
246 of the exposed water. The bio-available DOC (BDOC) measured over the 4 days incubation period  
247 was  $4 \pm 2 \text{ (UV)}$  and  $12 \pm 3 \text{ } \mu\text{mol C l}^{-1}$  (Dark) in winter and  $13 \pm 4 \text{ (UV)}$  and  $11 \pm 2 \text{ } \mu\text{mol C l}^{-1}$

248 (Dark) in spring (Table 1). Bio-available DON (BDON) varied only slightly (between  $1.4 \pm 0.7$  and  
249  $1.7 \pm 1.0 \mu\text{mol N l}^{-1}$ ), and there was no difference between the dark and UV treatments (Table 1).  
250 During the 4 days incubation,  $a_{\text{CDOM}(340)}$  and  $F(340/440)$  remained constant in both the dark and  
251 UV treatments (data not shown).

252 The UV pre-treatment had a negative impact on the BP compared with the dark treatment  
253 during both experiments (Table 1; Figure 1a, b). The BP peaked in both periods at day 0 or 1,  
254 decreasing thereafter reaching average values of  $0.13 \pm 0.09$  and  $0.02 \pm 0.01 \mu\text{mol C l}^{-1} \text{d}^{-1}$  after 4  
255 days in the dark and UV treatments, respectively (Table 1; Figure 1a, b). The impact of UV pre-  
256 exposure on the BP was evaluated by comparing the average BP measured at each sampling day in  
257 the two treatments, showing a statistical significant difference (t-test,  $p < 0.05$ ,  $n = 8$ ), suggesting a  
258 negative impact of DOM photoalteration on BP.

259 The initial BA was  $7.9$  (winter) and  $7.1$  (spring)  $\times 10^5$  bacteria  $\text{ml}^{-1}$ , increasing to maximum  
260 abundances of  $21.1$  (winter) and  $11.2$  (spring)  $\times 10^5$  bacteria  $\text{ml}^{-1}$  in the dark and  $19$  (winter) and  
261  $14.0$  (spring)  $\times 10^5$  bacteria  $\text{ml}^{-1}$  in the UV treatment at day 1 (Figure 1c, d). This corresponded to  
262 an average bacteria biomass growth (BG) of  $2.2 \pm 1.6 \mu\text{mol C l}^{-1}$  in the dark and  $1.6 \pm 0.1 \mu\text{mol C l}^{-1}$   
263 in the UV treatment. There was no statistical significant difference in BA between the two pre-  
264 treatments (t-test,  $p > 0.05$ ,  $n = 6$ ). Microscopic examination revealed that no heterotrophic  
265 nanoflagellates were present in both types of incubations (data not shown).

266 The initial ETS activity was higher in the dark treatments (Table 1). It increased after day 0  
267 reaching values between  $4.4 \pm 0.2$  and  $6.2 \pm 0.2 \mu\text{mol C l}^{-1} \text{d}^{-1}$  in the dark and  $2.4 \pm 0.1$  to  $4.5 \pm 0.1$   
268  $\mu\text{mol C l}^{-1} \text{d}^{-1}$  in UV treatments after 1 to 2 days. In the winter experiment, the ETS activity  
269 declined after day 2, reaching final average values of  $1.8 \pm 0.1$  (dark) and  $0.2 \pm 0.1 \mu\text{mol C l}^{-1} \text{d}^{-1}$   
270 (UV). In the spring experiment, the ETS activity increased after day 2 in the dark treatment  
271 reaching final respiration rates of  $5.7 \pm 0.6 \mu\text{mol C l}^{-1} \text{d}^{-1}$ , while it decreased in the UV treatments

272 reaching rates of  $3.8 \pm 0.1 \mu\text{mol C l}^{-1} \text{d}^{-1}$  (Table 1: Figure 1 e, f). The impact of the UV pre-  
2 treatment on ETS activity was evaluated by comparing the average ETS measurements of 3  
273 replicate samples for the two treatments and combining both sampling periods (winter and spring),  
274 which showed a statistical significant difference, suggesting that the DOM photoalteration had a  
275 negative impact on ETS activity (t-test,  $p < 0.05$ ,  $n = 8$ ).  
276

277 The initial BCD was higher in the dark treatments during both experiments, with average  $\pm$   
14 SD values of  $3.46 \pm 2.06 \mu\text{mol C l}^{-1} \text{d}^{-1}$  in the dark compared to  $0.66 \pm 0.24 \mu\text{mol C l}^{-1} \text{d}^{-1}$  in the UV  
15 treatments (Table 1). The BCD peaked in both experiments at incubation day 1, decreasing  
16 thereafter to reach average values of  $3.88 \pm 2.06$  (dark) and  $2.04 \pm 1.80 \mu\text{mol C l}^{-1} \text{d}^{-1}$  (UV) after 4  
17 days (Table 1). The integrated BCD ( $\text{BCD}_{\text{int}}$ ) was calculated by integrating the BCD estimates over  
18 the incubation period, resulting in average values of  $12.72 \pm 11.73$  (dark) and  $11.34 \pm 5.50 \mu\text{mol C}$   
19  $\text{l}^{-1}$  (UV) (Table 1). A t-test comparing the average BCD showed a significant negative impact of the  
20 DOM photoalteration (t-test,  $p < 0.05$ ,  $n = 8$ ).

33 Initial BGE was on average  $19 \pm 10 \%$  in the dark and  $10 \pm 8 \%$  in the UV treatments (Table  
34 1). The BGE generally declined after day 1, reaching average values of  $3 \pm 1$  (dark) and  $1 \pm 1 \%$   
35 (UV) after 4 days incubation (Table 1; Figure 1g, h). The BGE was higher during winter, in  
36 agreement with the higher BG during this period. The integrated BGE ( $\text{BGE}_{\text{int}}$ ) showed average  
37 values of  $6 \pm 2$  (dark) and  $5 \pm 2 \%$  (Table 1). There was no significant difference in BGE between  
38 the two pre-treatments (t-test,  $p > 0.05$ ,  $n = 8$ ).

47 The percentage of DAPI-counts detected by the mix of Eub338 probes represented on average  
48  $94 \pm 10 \%$  of the cells (Table 2). In the winter experiment, the initial bacterial community was  
49 dominated by *Bacteroidetes* (48 %), with only minor contributions of SAR11 (13 %) and  
50 *Roseobacter* (6 %) (Table 2). The contribution of *Roseobacter* increased in both treatments reaching  
51 32 and 14 % in the UV-light and dark treatments at day 2. *Gammaproteobacteria* also increased in  
52

296 both pre-treatments but the contribution was 2.3-fold larger in the UV-light than in the dark  
2  
307 treatment, while *Bacteroidetes* decreased from 48 to 13 (dark) and 23% (UV) at day 2 (Table 2).

298 During spring, the bacterial community was initially dominated by *Bacteroidetes* (37 %) and  
7  
299 *Gammaproteobacteria* (32 %), but *Roseobacter* (18 %) also contributed (Table 2). *Bacteroidetes*  
9  
300 increased rapidly in the dark incubation reaching 54 % after 1 day of incubation, while it decreased  
10  
301 in the UV treatment to 21 % (Table 2). The contribution of *Gammaproteobacteria* increased in the  
11  
302 UV-light pre-treatment (48% at day 2) but decreased in the dark incubation (15%), while the  
12  
303 *Roseobacter* was relatively more abundant in dark incubations. Both *Betaproteobacteria* and  
13  
304 SAR86 showed very low relative abundances throughout the experiments (0–5 % of DAPI counts)  
14  
305 (Table 2). The abundance of *Gammaproteobacteria* was positively impacted by the DOM  
15  
306 photoalteration (t-test,  $p < 0.05$ ), while none of the other groups showed statistically significant  
16  
307 difference between the dark and UV treatments.

#### 308 4. Discussion

309 Solar radiation has previously been shown to affect DOM bioavailability, nutrient dynamics  
310 and bacterial community composition (e.g. Abboudi et al., 2008; Obernosterer and Benner, 2004;  
311 Obernosterer et al., 1999; Tranvik and Bertilsson, 2001). Our study demonstrates a negative impact  
312 of photo-altered DOM on the bacterial activity of the Ria de Vigo, while the abundance of  
313 *Gammaproteobacteria* was positively impacted.

##### 314 4.1. Photochemical induced changes on chemical and optical parameters

315 The effect of UV light on the DOM pool is determined by its origin and previous sunlight  
316 exposure (Obernosterer and Benner, 2004). Our UV treatments showed no detectable DOC  
317 (detection limit  $\sim 2 \mu\text{mol C l}^{-1}$ ) photodegradation to inorganic carbon, while slight changes in DOC  
318 bioavailability were found (Table 1). In the UV treatments, a decrease in CDOM absorption and

F(340/440) to DOC ratio was found, suggesting changes in the DOM composition and quality (Table 1). The CDOM absorption at 340 nm decreased 20-50 %, which is comparable with other studies (< 50 %; Blough and Del Vecchio, 2002; Nieto-Cid et al., 2006).

#### 4.2. *Effect of photochemical changes on the bacterial community during incubation studies*

Labile organic and inorganic compounds released from DOM by UV-light have been shown to stimulate bacterial production and respiration (e.g. Moran and Zepp, 1997). The decrease in humic-like fluorescence during the UV pre-treatments suggests that coloured, high molecular weight compounds were transformed into colourless low molecular weight forms or inorganic carbon; the final outcome for the bacterial production and ETS activity was negative. Decreases in bacterial activity after DOM exposure to sunlight has been reported before in other systems (e.g. Tranvik and Kokalj, 1998; Obernosterer et al., 1999) and has been explained by (1) DOC photo-oxidation to CO or CO<sub>2</sub> (Bertilson and Tranvik 2000); (2) production of ROS radicals (Scully et al., 2003); and/or (3) autochthonous DOM getting less bioavailable after UV exposure due to polymerization and condensation reactions (Harvey et al., 1983; Obernosterer et al., 1999). As we found no difference in DOM concentration between dark and UV treatments, photo-oxidation to CO or CO<sub>2</sub> is not a likely cause for the negative effect. ROS species can lower bacterial growth by competing for substrate and causing oxidative stress (Scully et al., 2003; Petasne and Zika, 1997; Lesser, 2006). In this study we did not measure ROS production, so we cannot exclude this as a possible reason for the decrease in bacterial activity. It has repeatedly been shown that photochemical transformations of allochthonous DOM enhance the bacterial production by converting UV-absorbing complex molecules into labile compounds (e.g. Moran and Zepp, 1997). In contrast, when autochthonous DOM is exposed to UV light it becomes less accessible to bacterial degradation (Tranvik and Bertilson, 2001). The net effect of UV radiation on DOM bioavailability depends therefore on the contribution of allochthonous and autochthonous organic matter.

343 Bioavailable DOM in the Ría de Vigo has previously been shown to be primarily of autochthonous  
2  
344 marine phytoplankton origin (Lønborg et al., 2010a). As slightly higher BDOC values were found  
3  
4  
5  
345 in the dark treatments during winter when the contribution of allochthonous DOM was lowest (high  
6  
7  
346 salinity and FDOM/DOC ratio), the most likely reason for the negative effect was that the originally  
8  
9  
10  
347 labile DOM pool became more bio-resistant upon irradiation (Obernosterer et al., 1999). This  
11  
12  
348 suggests that solar-driven DOM transformation decreases the bacterial transfer of energy and  
13  
14  
349 nutrients to the microbial food web in the Ría de Vigo. Though, it should be kept in mind when  
15  
16  
17  
350 extrapolating our findings that we only conducted experiments during the winter and spring periods.  
18  
19

20  
21 The initial BGE was on average  $19 \pm 10$  % in the dark and  $10 \pm 8$  % in the UV treatments,  
22  
23 which is comparable to values previously reported for the Ría de Vigo (range 7–55%; Lønborg et  
24  
25 al. 2011) and the average value found for marine systems (~20%; del Giorgio and Cole 1998).  
26  
27  
28 During the 4 days incubation period we found a steep decrease in the BGE, suggesting that as the  
29  
30 labile DOM got consumed more carbon was used for energy production than for biomass  
31  
32 production (del Giorgio and Cole 1998), leading to low BGE values (< 4 %) at end of the  
33  
34  
35 incubations. The studies that have addressed how photo-altered DOM affects BGE have reported  
36  
37 both positive and negative responses (e.g. Moran et al., 2000; Pullin et al., 2004). In our study, no  
38  
39  
40 significant effect of the UV exposure on BGE was found. This suggests that bacteria in the dark and  
41  
42 UV incubations used the same energy per unit biomass produced and that BP and BR responded in  
43  
44 the same way to photo-altered DOM. In this study, BGE was calculated using respiratory ETS  
45  
46 activity. Most previous studies measuring ETS have measured potential in vitro activity (after ETS  
47  
48 enzymes isolation and addition of a superabundance of electrons donors), showing large variations  
49  
50  
51 in the relation between respiration and ETS activity (R/ETS ratio) (Martínez-García et al., 2009). In  
52  
53  
54 this study we used the in vivo ETS activity (living cells are incubated and natural levels of electron  
55  
56  
57 donors are present) which has a rather constant R/ETS ratio (Martínez-García et al., 2009). This  
58  
59  
60  
61  
62  
63  
64  
65

367 suggests that the use of ETS activity as a measure of respiration cannot explain the lack of response  
2  
368 in BGE. The differences in the response of BGE to photo-altered DOM between studies may  
3  
4  
5  
369 therefore be explained by varying nutrient availability and DOM composition between study areas.  
6  
7

8  
9  
10 As the microbial cultures added to the laboratory incubations had been collected together with  
11 the exposed samples, they had been stored 3.5 days before use. This could have impacted the  
12  
13 composition of the added bacterial community, but as the contribution of the different groups to the  
14  
15 total bacterial abundance was approximately the same as that found by Teira et al. (2009), for the  
16  
17 same sampling period, the storage seems to have had a minor effect. Alteration of DOM by solar  
18  
19 radiation has previously been suggested to cause rapid changes in the bacterial community  
20  
21 composition in marine systems, but few studies have identified which specific bacterial groups are  
22  
23 influenced (Abboudi et al., 2008; Piccini et al., 2009). In this study, we based our bacterial  
24  
25 community analysis on FISH probes which does not allow any detailed phylogenetic identification  
26  
27 of the bacteria, but provides valuable information on the proportions and actual abundance of  
28  
29 different phylogenetic groups. An enrichment of *Gammaproteobacteria* has repeatedly been  
30  
31 observed during incubations and in response to changes in nutrient and organic matter composition  
32  
33 (Hornák et al., 2006; Teira et al., 2008). Consistently with these findings, we observed that  
34  
35 *Gammaproteobacteria* grew well in the dark (spring only) and UV pre-treated water but their  
36  
37 growth was much more pronounced in the UV treatments, suggesting that members of this group  
38  
39 were positively affected by photo-altered DOM. Some members of the *Gammaproteobacteria*  
40  
41 group has frequently shown low percentages of active cells incorporating labile substrates, such as  
42  
43 glucose, amino acids or protein (del Giorgio and Gasol, 2008), suggesting that this broad  
44  
45 phylogenetic group might include a great diversity of specialized bacteria, some of which could be  
46  
47 successful using less bioavailable photo-altered DOM. By contrast, Piccini et al., (2009) found that  
48  
49 *Beta-* and *Alphaproteobacteria* dominated the DOM degradation after UV exposure. This difference  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

391 in community response is probably connected with the higher contribution of autochthonous DOM  
2  
392 and different initial bacterial community composition in our system compared with the coastal  
3  
4  
5  
393 lagoon investigated by Piccini et al., (2009).  
6  
7

394 Our findings suggest that photo-altered DOM has a negative impact on the bacterial  
8  
9  
10  
395 metabolism and favours the growth of *Gammaproteobacteria* in the Ría de Vigo. Caution should be  
11  
12  
396 taken to extrapolate these results, as the experiments were only conducted in winter and spring. We  
13  
14  
397 therefore suggest that future studies will take a more detailed approach towards understanding the  
15  
16  
398 impacts of photo-alteration on specific DOM sources and the subsequent effects on the bacterial  
17  
18  
399 community.

562 Table 1. Concentrations of phosphate (DIP), nitrate (NO<sub>3</sub><sup>-</sup>), nitrite (NO<sub>2</sub><sup>-</sup>), ammonium  
563 (NH<sub>4</sub><sup>+</sup>), dissolved humic-like substances (F(340/440)) and CDOM absorption coefficient at  
564 340 nm (a<sub>CDOM</sub>(340)) at the sampling site (Field) in the Ría de Vigo and after 3.5 days in the  
565 darkness (dark) or exposed to natural sunlight (UV). Initial concentrations of dissolved  
566 organic carbon (DOC) and nitrogen (DON) at the sampling site and in the incubations (day  
567 0), at incubation day 4 (DOC<sub>4</sub> and DON<sub>4</sub>) and the corresponding bioavailable fraction  
568 (BDOC and BDON). The F(340/440) /DOC ratio is shown for the sampling site and after 3.5  
569 days exposure to dark and UV-light. Bacterial production (BP), electron transport system  
570 (ETS) activity, bacterial carbon demand (BCD) and growth efficiency (BGE) are shown for  
571 incubation days 0 (BP<sub>0</sub>, ETS<sub>0</sub>, BCD<sub>0</sub>, BGE<sub>0</sub>) and 4 (BP<sub>4</sub>, ETS<sub>4</sub>, BCD<sub>4</sub>, BGE<sub>4</sub>) and the  
572 integrated BCD (BCD<sub>Int</sub>) and BGE (BGE<sub>Int</sub>) over the incubation time. Values are averages ±  
573 standard deviation; –, not measured.
