**ABSTRACT:** A still unclear question related to sugarcane cropping refers to the low response of the planted cane to nitrogen fertilization. Two experiments were carried out in areas under a Typic Hapludox, located in Pirassununga, São Paulo State, Brazil, and an Arenic Kandudult, located in Jaboticabal, São Paulo State, Brazil, with the objective to evaluate planted cane response to nitrogen fertilization at planting. The experimental design was organized as random blocks and treatments consisted of three N rates (40, 80, and 120 kg ha<sup>-1</sup> N-urea) and a control without N. Nitrogen fertilizers were applied to the bottom of the planting furrow and then incorporated into the soil. During the maximum growth stage, +1 leaf samples were collected from all experimental plots to evaluate the crop nutritional status. In the Pirassununga experiment, N fertilization at planting increased N, K, Mg, and S contents in the leaves and increased the stalk yield, without effect in the technological attributes. Conversely, no stalk yield response was observed at the Jaboticabal experiment, but N fertilization benefited the stalk technological attributes. The N rates increased the sugar yield per hectare in both experiments. The highest margin of agricultural contribution was obtained at the rate of 40 kg ha<sup>-1</sup> N. Key words: *Saccharum* spp., nitrogen, urea

### Produção de colmos e atributos tecnológicos da cana planta relacionados com a adubação nitrogenada

**RESUMO:** Uma questão não esclarecida na cultura da cana-de-açúcar se refere à baixa resposta da cana planta à adubação nitrogenada de plantio. Nesse sentido, foram desenvolvidos dois experimentos em áreas cultivadas sobre um Latossolo Vermelho-Amarelo Distrófico (Pirassununga, SP) e um Latossolo Vermelho Distrófico (Jaboticabal, SP), com objetivo de avaliar a resposta da cana planta a adubação nitrogenada de plantio. O delineamento experimental foi em blocos ao acaso, e os tratamentos foram três doses de N (40, 80 e 120 kg ha<sup>-1</sup> na forma de uréia) mais um tratamento controle sem adição de N. Os fertilizantes nitrogenados foram aplicados no fundo de sulco de plantio e incorporados ao solo. Durante a fase de máximo crescimento da cultura, foram coletadas amostras de folhas +1 em todas as parcelas experimentais para a determinação do estado nutricional. Em Pirassununga, a adubação nitrogenada de plantio aumentou as concentrações de N, K, Mg e S nas folhas diagnósticas e a produção de colmos, sem apresentar efeito nos atributos tecnológicos. Por outro lado, em Jaboticabal não houve resposta em produtividade, mas houve efeito nos atributos tecnológicos. Obtiveram-se incrementos na produção de açúcar por hectare em ambas as áreas em função da fertilização nitrogenada. A maior margem de contribuição agrícola foi obtida com a dose de 40 kg ha<sup>-1</sup> de N. Palavras-chave: *Saccharum* spp., nitrogênio, uréia

#### Introduction

The great importance of nitrogen for sugarcane relates to the fact that the plant is a *Poaceae*, with C4-type carbon metabolism, characterized by high liquid photosynthesis rate, and high nitrogen and solar energy use efficiency, thus being highly effective in producing dry matter. However, a still unclear question related to sugarcane cropping refers to the low response of newly planted cane to nitrogen fertilization. Literature is quite rich in papers that evaluated the effect of rates, sources, and forms of nitrogen application in sugarcane, with

very heterogeneous responses in planted cane and relatively homogeneous responses in ratoon cane (Carnaúba, 1990).

The lack of newly planted cane response to nitrogen fertilization has been attributed to several causes such as: i) biological atmospheric nitrogen fixation; ii) N-fertilizer losses via leaching; iii) root system vigor as compared to ratoon cane; iv) high nitrogen stock in the seed cane (billets); v) weather conditions, such as temperature and precipitation; and vi) improved soil fertility, after renovating sugarcane areas, in association with liming, mechanical tillage, and incorporation of residues from previous

crops (Azeredo et al., 1986; Carnáuba, 1990; Urquiaga et al., 1992; Carneiro et al., 1995; Orlando Filho et al., 1999).

Although a great number of authors did not find N fertilization benefits in planted cane, this practice is recommended and performed in most Brazilian sugar mills, even under conditions of low response expectations. Why is that so? Would it be a lack of confidence in experimental results? Within this context, the objective of this study was to evaluate planted cane response to nitrogen fertilization at planting, by assessing stalk production, dry matter weight, foliar diagnosis, stalk technological attributes, sugar yield per unit area, and margin of agricultural contribution.

### Material and Methods

The experiments were performed in two sugar cane producing areas located in the state of São Paulo, Brazil. The first is in Pirassununga, São Paulo state, Brazil (21°55' S; 47°10' W, altitude is 650 m and the climate is Aw - Tropical Savanna, according to Köppen classification). This area has a slightly rolling slope (< 5%), and the soil is a Typic Hapludox (Soil Survey Staff, 2003) or Latossolo Vermelho-Amarelo Distrófico (Embrapa,

2006). The chemical characterization of the soil is presented in Table 1. For soil preparation, two heavy diskings were performed, before and after subsoiling. The first was done to eliminate the old ratoon, and the second was done to incorporate 2 t ha<sup>-1</sup> of dolomitic lime and 2 t ha<sup>-1</sup> of phosphogypsum. Medium-depth disking was also performed for the final preparation of the soil before the opening of the furrows (planting). The sugar cane was planted from February 21-24, 2005.

The second area is in Jaboticabal, São Paulo state, Brazil (21°19' S, 48°19' W, predominant altitude in the region is 600 m, and the climate is Aw - Tropical savanna). The area presents a slightly rolling slope (< 5%), and the soil is an Arenic Kandistult (Soil Survey Staff, 2003) or Latossolo Vermelho Distrófico (Embrapa, 2006). The chemical characterization of the soil is presented in Table 1. The main operations performed for the renovation of the sugar cane fields before planting were: chemical desiccation of the previous ratoon with the application of 4 L ha<sup>-1</sup> of herbicide (glyphosate); deep plowing for the incorporation of plant residues and 2 t ha<sup>-1</sup> of dolomitic lime; and disking for the final preparation of the soil before the opening of furrows (planting). The sugar cane was planted from April 4-8, 2005.

The chemical determinations were accomplished according to van Raij et al. (2001); S.O.M. = soil organic matter; SB = sum of bases; CEC = cation exchange capacity; BS = base saturation. m (%) = aluminum saturation.

Both experiments consisted of a random block design with four replicates. Treatments were three N rates (40, 80, and 120 kg ha<sup>-1</sup> N in the form of urea) applied to the bottom of the planting furrow and incorporated into the soil, in addition to a control. The experimental plots consisted of 48 rows with 15 m-long (furrows) spaced 1.5 m apart. At planting, all plots received the application of 120 kg ha<sup>-1</sup> K<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub> in the bottom of the furrow, using potassium chloride and triple superphosphate as sources, respectively.

Two seed cane billets per meter were used at sugarcane planting thus providing a distribution of 17 to 20 buds per meter of furrow. The sugarcane seedlings deposited on the bottom of the furrow were cut into billets containing 2 to 3 buds, after which the furrows were machined-covered. The experiment was planted with sugarcane cv SP81- 3250.

As part of the evaluation of the availability of N to the crop during the planted cane season, 30 seedpieces were collected at random during planting, which were divided into three subsamples (n<sup>o</sup>. of seedlings necessary for the planting of 15 m of a row) and, in these, fresh matter, dry matter and nutrients content were determined (Malavolta et al., 1997) (Table 2).

The nutritional state of the plants was evaluated at the stage of maximum development of the crop, on January 12 and 17, 2006 in the experiments in Pirassununga and Jaboticabal, respectively. Evaluation followed the recommendation of van Raij and Cantarella (1997), in which five leaves in the +1 position (F+1) were collected at random in each plot, which then constituted a random sample. From each leaf (F+1) only the middle third was collected, approximately 0.2 m, excluding the center nervure. The F+1 is the first leaf from the top of the plant that visibly presents the point of separation between limbus and sheath of the leaf, denominated as the dewlap, also being denominated as the TVD ("Top Visible Dewlap"). These samples were dried in a forced air circulation oven at 65°C until reaching a constant weight, then being ground in a Wiley type mill and ana-

lyzed in regard to their macronutrients content (Malavolta et al., 1997).

In order to evaluate the final planted cane productivity as a function of N fertilization at planting, the cane was harvested on 06/07/2006 in Pirassununga and on 07/11/2006 in Jaboticabal. Dry matter yield of the above-ground part was estimated by harvesting all sugarcane plants from a 3 m row in all plots; cane samples were separated into dry leaves, tips, and stalks. Determinations were made directly in the field with those samples for natural plant material mass. All materials were chopped in a forage chopper, producing subsamples that were placed in plastic bags which were then closed, identified, and taken for moisture determination. Samples were dried in a lab oven at 65°C for 72 h in order to obtain dry matter. The results were extrapolated to kg ha<sup>-1</sup>, considering a row spacing of 1.5 m.

Root sampling was carried out after harvesting the above-ground part of the sugarcane plants, by using a probe (55 mm internal diameter) and at the 0 to 60 cm of depth. The sampling method and calculation procedures for transforming the mass per unit area (kg ha<sup>-1</sup>) were adopted according to Otto et al. (2009). In those samples, the roots were separated from the soil by dry sifting (sieve mesh - 2 mm). The roots separated from the soil were washed in running water, dried in a ventilated oven at 65°C, and dry matter values were obtained.

Stalk productivity (tons of sugarcane stalks per hectare - TSS) for all planted cane plots (four blocks) was evaluated by cutting the cane mechanically and weighing the chopped cane in a truck equipped with instruments in 16 rows per plot (four sequences of four consecutive rows - 240 m). The other rows were harvested mechanically without weighing. In this harvest, samples consisting of ten stalks per plot were separated and harvested in sequence on the row, in order to evaluate technological parameters: Brix, Purity, Fiber, Juice Pol, Cane Pol, Reducing Sugars (RS), and Total Recoverable Sugars (TRS), according to Fernandes (2003).

The margin of agricultural contribution (MAC) was calculated from TRS price data at the closure of the 2006/2007 cropping season, HLT costs (harvesting, loading, and transporting), and cost per ton of urea, provided by the farming departments of each sugar mill. The model employed to calculate MAC was processed according to Fernandes (2003). The margin of contribution represents the difference between gross income obtained with the products and variable costs of the production system. Contribution margin can be analyzed from the grower's standpoint: the grower delivers cane for grinding (agricultural system) or for agricultural mills that produce their own raw materials (agroindustrial system). In this research, we chose to use margin of agricultural system contribution (MAC), which can be determined more easily and does not require expected income data from sugar and alcohol sales. Therefore, MAC represents the difference between income with raw materials (TSS) delivered to a processing plant and variable costs such as harvesting, loading, and transporting (HLT), management practices (urea application), and leasehold (not considered in the calculation).

Throughout the entire period of the experiment, the meteorological parameters (solar radiation, wind speed, relative humidity, temperature and rainfall) were measured by means of automatic meteorological stations installed near the two experimental areas. The reference evapotranspiration (ET<sub>0</sub>) was calculated by the Penman-Monteith method, in accordance with Allen et al. (1998). For the calculation of crop evapotranspiration (ET<sub>c</sub>), the crop coefficient (K<sub>c</sub>) for each stage of crop development was considered, in accordance with Doorenbos and Kassan (1994). However, the K<sub>c</sub> of 1.05 for the period of maximum growth was replaced by the K<sub>c</sub> of 1.25, in accordance with modifications for sugar cane proposed by Allen et al. (1998), which were confirmed by Inman-Bamber and McGlinchey (2003). With this information, in addition to the rainfall measured at the experimental areas, the climatologically water balance was calculated using electronic spreadsheets (Rolim et al., 1998), in accordance with Thornthwaite and Mather (1955), thus obtaining the real evapotranspiration (ET<sub>r</sub>) (Figure 1).

Results were submitted to analysis of variance, using F test at the 90% confidence level. The effects of N rates were compared by polynomial regression analysis.

## Results and Discussion

### Nutritional Status of the Planted Cane

The majority of nutrient contents were in the range of sufficiency suggested for the sugar cane crop planted in the São Paulo State, Brazil (van Raij and Cantarella, 1997), an exception being made for the content of S in both experiments and the contents of Ca in samples from Jaboticabal (which were below the lower limit of sufficiency), and the contents of K at SA (which were above the upper limit of sufficiency). Nevertheless, the results mentioned for Ca and S are at the threshold of the ranges

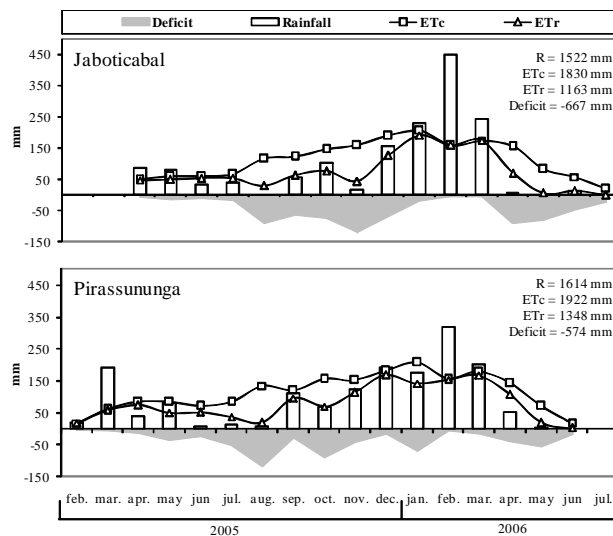

Figure 1 – Climatologically water balance of the experimental areas of Jaboticabal and Pirassununga. ET<sub>c</sub>: crop evapotranspiration; ET<sub>r</sub>: real evapotranspiration; R: rainfall

of sufficiency and were not owing to the availability of the nutrients in the soil, because the contents of S and Ca (Tables 1) ranged from average to high (van Raij et al., 1997). Therefore, these results are probably due to the effect of dilution arising from growth of the crop (Jarrell and Beverly, 1981) which occurred at the time of collection of the leaves for diagnosis.

In the experiment carried out in Pirassununga, there was a reduction in the N contents in the F+1 in the treatments with application of N (Table 3), but as there was an increase in the dry matter production (Table 4), the dilution effect may have occurred. On the other hand, in the experiment carried out in Jaboticabal, an increase in the N contents was observed in the treatments with the application of N fertilizer. However, there was no effect of the N on the dry matter production of the crop (Table 4), which generated an effect of N concentration in the plants, which may characterize luxury consumption by the crop.

The K contents increased in a linear fashion with N fertilization in the two experiments. At SA the contents of K in the F+1 leaves were above the upper limit of the range of sufficiency suggested for the São Paulo State, Brazil (Table 3). Nevertheless, as the K content in the soil was elevated at the beginning of the experiment (Table 1), there may have been luxury consumption of K by the plants, which was confirmed by the K extractions obtained at harvest of the plant cane (Franco et al., 2008). Together with this, the greater availability of K in the soil may have influenced uptake of the nutrient due to the greater spatial variation of K distribution in the soil (Souza et al., 2006).

In both experiments, there was no effect of the doses of N on the contents of P and Ca of the diagnostic leaves (Table 3). Regarding the Mg contents, there was no effect of the N rates on the experiment located in

Table 3 – Adequate content of nutrients in the diagnostic leaf for the sugar cane crop of São Paulo State, Brazil, and nutrient content on leaf of planted cane.

#van Raij and Cantarella, (1997); <sup>NS</sup>non-significant; \*\*\*, \*\* and \*significant at 1%, 5%, and 10% probability, respectively. LR and QR: Linear Regression and Quadratic Regression, respectively.

Jaboticabal. In Pirassununga there was a linear increase in the Mg content of the leaves. This fact may be explained by the participation of Mg in the chlorophyll molecule and also as an enzyme activator (Epstein and Bloom, 2006). In this case, there is a synergism between Mg and N, keeping in mind that nitrogen fertilization increased the biomass production of the plants of this area (Pirassununga).

There was a linear increase in the leaf S content with the N rates in Jaboticabal's experiment (Table 3), although without response in Pirassununga. Sulfur is found in plants mainly as cysteine, methionine, proteins, co-enzymes, thiamine, biotine and coenzyme A, and its deficiency may interfere in the synthesis of regulatory proteins, essential for maintenance of cellular activity (Epstein and Bloom, 2006). There is synergism between N and S, with the deficiency of S being able to limit response of the plant to nitrogen fertilization. This may have occurred in Jaboticabal, since the plants of that experiment presented the greatest contents of N in the leaves, such that the contents of S, if not below the range

considered as adequate, are near the lower limit of 1.5 g kg<sup>-1</sup> S (van Raij and Cantarella, 1997). Nevertheless, S participates in many organic compounds (all the plant proteins contain S in the same way that all of them have N), and there is a ratio between the content of N and S in the leaves, generally between 10 and 15, which indicates adequate nutrition (Prates et al., 2006). A strongly stoichiometry is established between these two elements: on average, there are approximately 34 atoms of N for each atom of S and, for most crops, the ratio between these nutrients in the plant dry matter is in the order of 15/1 (Malavolta, 1980). Taking into account the N/S ratios in the two experiments (14, 14, 13 and 13 for the treatments 0, 40, 80 and 120 kg ha<sup>-1</sup> N, respectively, in the experiment at Pirassununga; and 15, 14, 13 e 12 for these same treatments at Jaboticabal), one concludes that the N and S contents of the diagnostic leaves were satisfactory.

#### Dry Matter and Stalk Yield

<sup>NS</sup>non-significant; \*\*\*, \*\* and \*significant at 1%, 5%, and 10% probability, respectively. TSS: tons of sugarcane stalks per hectare; LR and QR: Linear Regression and Quadratic Regression, respectively.

stalks per hectare - TSS) was observed in the Jaboticabal experiment for treatments receiving N at planting (Table 4). In addition, dry matter for the stalks, above-ground part (stalks, dry leaves, and tip), and total (above-ground part plus roots) showed a quadratic response ( $p < 0.05$ ), in which the treatment involving the application of 80 kg ha<sup>-1</sup> N stood out.

No effect of N fertilization on the production parameters evaluated was observed in Jaboticabal (Table 4). However, in the root dry matter yield evaluation, the 40 kg ha<sup>-1</sup> N rate increased this variable, yielding more than 1,000 kg ha<sup>-1</sup> above the control (Table 4). Trivelin et al. (2002) observed a linear response in the root system dry matter productivity of planted cane (cv SP80-1842) as a function of N rates at planting. This fact may provide greater productivity in the 1<sup>st</sup> ratoon (residual effect), because roots and rhizomes constitute storage organs in sugarcane. Vitti et al. (2007) verified a pronounced residual effect of nitrogen fertilization applied to the 3<sup>rd</sup> ratoon on stalk productivity of the subsequent ratoon.

Nitrogen fertilization in planted cane is still an open question in the sugarcane industry. However, positive effects of nitrogen nutrition on planted cane productivity have been found. Trivelin et al. (2002) observed a stalk productivity increase in cv SP80-1842 as a response to nitrogen fertilization at planting (rates of 30, 60, and

90 kg ha<sup>-1</sup> N). Korndörfer et al. (2002) obtained positive response to the addition of 60 kg ha<sup>-1</sup> N in seven sugarcane cultivars, with a mean increase of 10 TSS. Orlando Filho et al. (1999) observed a 35% reduction in planted cane stalk productivity without N application as in comparison to when the nutrient was applied. Korndörfer et al. (1997) stated that planted cane productivity increased linearly with N rates (30, 60, and 120 kg ha<sup>-1</sup>), and that for each 10 kg ha<sup>-1</sup> N applied there was a mean increase of 3.5 TSS. In an experiment with 18-month-old planted cane, Paes et al. (1997) observed that the application of N rates provided a linear TSS productivity increase in cultivars RB739359 and NA56-79, while cv CB45-3 did not respond to nitrogen fertilization. According to Paes et al. (1997), these results highlight a differential behavior between cultivars, thus demonstrating that there are variety-related differences with respect to nitrogen use effectiveness on stalk productivity. In addition, Espironelo et al. (1977), and Espironello et al. (1987), also observed that planted cane responded to N fertilization.

The results obtained in Jaboticabal corroborate those of Azeredo et al. (1986), and Bittencourt et al. (1986), who reported a lack of planted cane response to nitrogen fertilization. Nevertheless, Azeredo et al. (1986) indicated response in 20% of the experiments (two out of a total of nine assays), at a 120 kg ha<sup>-1</sup> N rate, yielding

twice as much as the control. Although not having obtained planted cane response to nitrogen fertilization, Bittencourt et al. (1986) suggested that in soils without very high available N contents, the addition of 60 kg ha<sup>-1</sup> N at planting should be considered the maximum amount. These authors reported a comprehensive review of the literature in their studies, demonstrating the low response of planted cane to nitrogen fertilization at planting: Azeredo et al. (1986) reported that nitrogen fertilization in planted cane provided productivity increases in just 19% of the 135 experiments cited; Bittencourt et al. (1986) observed planted cane response to N fertilization in 50% of the studies reviewed.

The different responses in the experiments were not caused by the rainfall regime, since monthly and total rainfall was similar in both locations (Figure 1). On the other hand, due to high experimental error, sometimes associated with fertilization assays, studies that show a little response in yield caused by nitrogen fertilization do not achieve statistical significance, leading many technicians to consider that planted cane can dismiss the application of the nutrient. However, a different scenario emerges when data from groups of assays are evaluated together (Cantarella et al., 2007). Penatti and Cantarella (data not published), cited by Cantarella et al. (2007), pooled together 74 field experiments and observed that the majority of those studies did not show a significant response to nitrogen fertilization individually, but when analyzed conjointly, they showed a clear tendency of response, with an economic rate of 75 kg ha<sup>-1</sup> N.

In that study, planted cane response to added N-fertilizer could be also associated with soil type. Azeredo et al. (1994) obtained a highly significant TSS increase by adding 180 kg ha<sup>-1</sup> N to an Inceptisol (a 68 TSS increase), while only a tendency of response was seen in Oxisols. These results led Azeredo et al. (1994) to conclude that planted cane response to N fertilization in the soils studied was associated with the soil capacity to provide the nutrient due to organic nitrogen mineralization. Within the same line of thought, Orlando Filho (1993) emphasized that there are three conditions in which planted cane may respond to nitrogen fertilization: eutrophic soils (high fertility); soils where sugarcane is cultivated for the first time, and soils under reduced tillage. Consequently, based on the attributes of the soils of our experiments, since conventional soil tillage was used in the experiments and the soils have been cultivated with sugarcane for several years, planted cane would respond to fertilizer-N additions in Pirassununga (epitrophic soil), while no response would be obtained in Jaboticabal (dystrophic soil). Vinasse was applied in the Jaboticabal experiment (150 m<sup>3</sup> ha<sup>-1</sup> year<sup>-1</sup>) during about ten years until 24 months before beginning this assay, and this practice may explain the lack of sugarcane yield response (TSS) to nitrogen fertilization, probably due to increase of organic-N soil due to the vinasse.

The interpretation of fertilizer-N response results in planted cane presents, in general, a series of difficulties,

due to the complex behavior of this nutrient in the soil, and also there is not an effective and economically viable analytical method to establish soil N availability to plants. Several factors have been listed to explain poor responses to N in planted cane, including the mineralization of soil organic matter and crop residues from the sugarcane itself, favored by soil turning during sugarcane field renovation (Cantarella et al., 2007). Zambello Júnior and Orlando Filho (1981) observed that soil tillage operations increase soil aeration during a season of increased temperature and moisture, causing increased soil microbial activity, which quickly breaks down crop residues (especially roots), decreasing the C/N ratio, thus providing greater N availability to planted cane planted between February and March in the South-Central region of Brazil.

Organic N mineralization over the planted cane cycle is probably the most important source of N for the crop (Salcedo et al., 1985). The fact that ratoon cane responds more frequently to nitrogen fertilization (Carnaúba, 1990) could be explained by the reduction in mineral N content in the soil profile at the end of the planted cane cycle (Salcedo and Sampaio, 1984), together with a potential decrease in organic N mineralization over the cycle. Microbial activity in the ratoon cane would become more difficult because of decreased soil aeration caused by soil compaction, as well as by low temperature and moisture conditions (typical in the Central-Western region of Brazil) (Zambello Júnior and Orlando Filho, 1981). The breakdown of this organic matter (crop residues and roots) with high C/N ratio and a period of great N requirement by the crop would cause any addition of N to the process to be accompanied by rapid response, in terms of growth, from the ratoon. In fact, Salcedo et al. (1985) studied C and N mineralization in a soil cultivated with sugarcane and verified that the amounts of soil N that were mineralized over the planted cane cycle were sufficient to meet the crop's demand for nitrogen.

The survey conducted to quantify the stock of nutrients in crop residues at SA (Franco et al., 2007) showed that a large quantity of N (about 200 kg ha<sup>-1</sup>) was incorporated into the soil in the renovation of the sugarcane plantation. After sugarcane trash had remained in the field for 18 months, Ng Kee Kwong et al. (1987) observed that 73 to 83% of the N contained in the residue remained in the soil organic matter, that is, there was an average release of 25% during that period. Nitrogen recovery by sugarcane from crop residues incorporated into the soil varies from 2.4% to 15%. (Ng Kee Kwong et al., 1987; Chapman et al., 1992; Gava et al., 2005). Based on these values around 30 kg ha<sup>-1</sup> N present in crop residues at SA would be absorbed by the crop, explaining, in part, the lack of planted cane response to nitrogen fertilization at planting. In addition, during the soil fallow period between the last ratoon harvest and the new planting, mineral N accumulates in the soil profile in quantities that vary with the intensity of rains, soil type, and

other factors (Salcedo and Sampaio, 1984). These quantities, however, represent a small amount of the N absorbed by the crop.

Other researchers have attributed the low planted cane response to nitrogen fertilization at planting to biological atmospheric nitrogen fixation (BNF) performed by diazotroph organisms capable of forming associations (or associative symbiosis) by colonizing roots and internal plant tissues, that is, by establishing endophytic associations (Cantarella, 2007). Döbereiner et al. (1972) observed an abundant population of free-living N-fixing bacteria in sugarcane plantations, whose numbers markedly increased near tussocks. The energy provided by sugarcane billets at planting allows the development of N-fixing microorganisms in the rhizosphere, providing an extra supply of the nutrient. When added to the soil, this supply seems to allow adequate planted cane development (Carnaúba, 1990). Urquiaga et al. (1992) estimated the contribution from nitrogen biological fixation in sugarcane to be in the order of 40 to 60% of the plant's total N, or about 30 to 160 kg ha<sup>-1</sup> year; the quantity of fixed N varied with sugarcane cultivar. Based on <sup>15</sup>N/N balance, Boddey et al. (1991) observed that some sugarcane cultivars can obtain high amounts of N from their association with diazotroph organisms, at values equivalent to 60 to 80% of the plant's N total (about 200 kg ha<sup>-1</sup> year). Because no response from planted cane to N has been observed in most experiments, the presence of fixing microorganisms in the sugarcane rhizosphere is an indication that fixation must play an important role in N self-sufficiency (Carnaúba, 1990). However, the subject of BNF in sugarcane raises controversy, since there is no evidence, under field conditions, that biological N<sub>2</sub> fixation can guarantee that N will be supplied to medium- or high-productivity crops (Cantarella, 2007). According to Cantarella (2007), studies conducted in South Africa and Australia demonstrated that biological N<sub>2</sub> fixation is not a significant source of this nutrient for sugarcane, although N<sub>2</sub> fixing bacteria have been isolated from the field. Also, the use of inoculants is still not possible, since the N<sub>2</sub> fixing population in sugarcane is diversified and a species that could be pointed out as the main responsible for fixation has not been identified so far (Boddey et al., 2003).

The majority of these organisms have other forms of promoting vegetative growth, such as the production of plant hormones, resistance to stress, production of siderophores, and antibiosis, among others (Reis et al., 2006). According to Reis et al. (2006), some questions relating to BNF in grasses remain unanswered: Is there enough C supply to support a high bacterial population? Or the bacteria can become a sink for the plants? Fixation products are directly transferred to the plant or this occurs only after cell death and mineralization? Numbers found in non-legume plants are around 10,000,000 cells per gram of green matter; in the case of rhizobium, this number reaches 100,000,000,000 bacteroids per gram of green matter. Would these numbers be enough? Many aspects still remain to be studied in order to make this

association more effective. Therefore, biological N<sub>2</sub> fixation in sugarcane is a much more complex and doubtful question, so far without practical results, as to fertilizing planted cane with nitrogen. It is presently at least illogical to attribute the lack of response of planted cane to nitrogen fertilization exclusively to BNF, in view of the available knowledge on the subject. Possibly, part of planted cane total N really comes from BNF, but that amount does not actually meet the crop nitrogen requirements, especially in high productivity sugarcane plantations.

Altogether, nutritional reserves in the planting billet constitute an important source of N for planted cane. Carneiro et al. (1995) attempted to demonstrate that the N content in planting billets (seed cane) can contribute towards sugarcane nitrogen nutrition and, together with other factors that make N available for the crop, would justify, in part, the lack of response from planted cane to nitrogen fertilization. However, the N amounts present in the seed cane in the experiments (Table 2) were low (about 10 kg ha<sup>-1</sup>). According to Carneiro et al. (1995), about 50% of the N from seed cane is translocated to new plant parts (roots and above-ground part). Based on this result, the N contribution from planting billets to the total N quantity of the entire plant was only 5 kg ha<sup>-1</sup>, thus not justifying the lack of response from planted cane to nitrogen fertilization at SA.

Based on the various literature data, it can be stated that the lack of response from planted cane at SA and the poor response in Pirassununga to N fertilization were mostly due to the mineralization of the native organic matter freshly incorporated into the soil during the crop renovation, together with the type of soil tillage adopted (conventional management) and the long newly planted cane cycle (about 16 months).

#### Technological Parameters of the Planted Cane

The technological parameters analyzed at sugarcane harvest were not modified by nitrogen fertilization at SL (Table 5), except for the moisture. Similar results were obtained by Orlando Filho and Zambello Júnior (1980); Azeredo et al. (1986); Espironelo et al. (1987); Korndörfer et al. (1997); Orlando Filho et al. (1999); Trivelin et al. (2002); Korndörfer et al. (2002). On the other hand, the addition of N to planted cane at planting improved stalk technological quality in Jaboticabal, and all technological parameters analyzed were increased at the 40 and 80 kg ha<sup>-1</sup> N rates, except for RS (Table 5), but with a tendency for the values to be smaller at the 40 and 80 kg ha<sup>-1</sup> N rates. Reducing sugars (RS), a term employed to designate sugars (glucose and fructose) that have the property of reducing copper oxide from the cupric to the cuprous condition, are color precursors in the industrial process, that is, they take part in reactions that increase sugar color, depreciating product quality (Fernandes, 2003); as sucrose contents increase in the stalks (maturation process), reduction of those sugars occurs in the sugarcane plants. Orlando Filho and Zambello Júnior (1980) observed that cane Pol

was linearly and inversely correlated with reducing sugars percentages. Increased qualitative attributes due to N addition were only observed by Paes et al. (1997), who verified a linear response in cane Pol in cv RB73 9359 as a function of N rates (0, 50, and 100 kg ha<sup>-1</sup>), similarly to what occurred at SA.

Nitrogen fertilization is normally associated with greater vegetative growth, which invariably determines plants with higher moisture contents, but with decreased sucrose accumulation (Korndörfer and Martins, 1992). In fact, Fritz (1974 cited by Korndörfer and Martins, 1992) studied the effect of increasing N rates and observed a reduction in sucrose content due to an increase in stalk moisture, since sucrose contents determined in dry matter did not change. In the same line of thought, Innes (1960 cited by Korndörfer and Martins, 1992) stated that for each percentage increase unit in TSS due to N, there is a 0.01% decrease in stalk sugar content. In both experiments (without statistical significance in the experiment located in Jaboticabal) the moisture of the stalks was lower at the 80 kg ha<sup>-1</sup> N rate (Table 5). Trivelin et al. (2002) did not observe any effect of nitrogen fertilization at planting on stalk moisture. However, Trivelin et al. (1996) verified over the entire ratoon growth and maturation period in sugarcane cv SP70-1143 that moisture in the above-ground part of plants conducted without nitrogen fertilization was smaller than in plants fertilized with 100 kg ha<sup>-1</sup> N. According to Silva

and Casagrande (1983), N facilitates Ca absorption, an essential element in the salt composition of the cytoplasm and in the cell wall makeup in the form of calcium pectate, resulting in greater cell structuring and facilitating water absorption, which could negatively affect the product's technological quality (Silva, 1983).

Other authors also verified the deleterious effects of nitrogen fertilization, especially with the application of high rates (> 120 kg ha<sup>-1</sup> N) on sucrose accumulation by sugarcane, similar to what occurred in Jaboticabal with the application of 120 kg ha<sup>-1</sup> N, where Brix, Juice Pol, cane Pol, and TRS were lower in relation to the other treatments. Silveira and Crocomo (1981) observed a decreased sucrose content in sugarcane plants grown in the presence of a high N content. Espironelo et al. (1977) verified that sugar contents in stalk samples were not significantly influenced by N rates and modes of application; however, smallest values were obtained at rates of 120 and 180 kg ha<sup>-1</sup> N. Espironelo et al. (1987) obtained a negative linear effect for sucrose content as a function of N rates (0, 70, 140, and 210 kg ha<sup>-1</sup>). Orlando Filho and Zambello Júnior (1980) observed that cane Pol percentage only decreases with the application of 480 kg ha<sup>-1</sup> N.

The decrease in fiber contents at SA at the 40 and 80 kg ha<sup>-1</sup> N rates is a direct result of higher Brix contents in the stalks. Under the technological aspect, sugarcane stalks consist of juice and solids that are insoluble in

Sugar = TSS × TRS; Gross Income = Sugar × TRS in the closure of the 2006/2007 cropping season (0.3544 at SL and 0.3476 at SA); HLT: harvesting, loading, and transporting costs; HLT = R\$ 14.69 (SA) and R\$ 17.27 (SL); Urea cost at SL in February/2005 = R\$ 1,050.00 or R\$ 2.33/ kg N; Urea cost at SA in March/2005 = R\$ 1,010.00 or R\$ 2.24/ kg N; Total Cost = HLT + Urea; MAC: Margin of agricultural contribution. US\$ 1.00 = R\$ 2.05 (April 2007 – closure of the 2006/2007 cropping season).

water, referred to as cane fiber (Fernandes, 2003). The juice contains water (cane moisture) and total soluble solids, which correspond to sugars and non-sugars, referred to as Brix. Therefore, there is a direct antagonistic relationship between Brix and Fiber contents. Korndörfer et al. (1997) observed a fiber content reduction in four sugarcane cultivars (planted cane) with N application, which is interesting from the sugar and alcohol industry point of view, since grinding those stalks with smaller fiber content will increase yield.

Nitrogen fertilization of planted cane in the experiments of this study resulted in higher sugar production per hectare, but in a distinct manner. The increased TSS in Pirassununga generated higher sugar production per hectare, while at SA the increase was due to increased cane Pol. There is consensus in the literature as to the effects of adding N on sugar production per area, i.e., stalk sugar content decreases with nitrogen fertilization, but the amount of sugar produced per hectare is higher as a result of higher TSS productivity (Espironelo et al., 1987; Korndörfer et al., 1997; Paes et al., 1997; Korndörfer et al., 2002; Trivelin et al., 2002).

The margin of contribution was calculated in order to attest benefits of N fertilization at planting. The data employed to calculate MAC in both experiments are presented in Table 6. The 40 kg ha<sup>-1</sup> N rate resulted in the highest MAC in Pirassununga. The use of higher N rates would result in financial disadvantages. The same result was obtained at SA, i.e., the application of 40 kg ha<sup>-1</sup> N in the form of urea applied at planted cane planting (buried at bottom of the furrow) generated the highest financial return, with a positive difference of US\$ 7.00 ha<sup>-1</sup> relative to the 80 kg ha<sup>-1</sup> N rate.

The application of 40 kg ha<sup>-1</sup> N in Jaboticabal generated a return of US\$ 223.00 ha<sup>-1</sup>, while the same management practice in Pirassununga provided a smaller return,

in the order of US\$ 106.00 ha<sup>-1</sup>. These results were due to the higher HLT cost in Pirassununga when compared to Jaboticabal, and also because nitrogen fertilization in Pirassununga increased TSS, thus generating a higher HLT cost per ha. In addition, harvesting seasons were different in each experiment, causing Jaboticabal's plants to accumulate more sugar in relation to SL plants.

As a conclusion, N fertilization in 18-month-old new cane, planted between February and April is an indispensable practice. The N rate to be applied in sugarcane plantation areas of the State of São Paulo (cultivated for several years with sugarcane, under conventional soil tillage when sugarcane is planted) should be similar to the rate at which the best MAC was obtained in this study (40 kg ha<sup>-1</sup> N applied in the form of urea in the planting furrow). Other authors have also recommended similar amounts of N (varying from 40 to 60 kg ha<sup>-1</sup>) for planted cane (Bittencourt et al., 1986; Morelli et al., 1997).
