

Malformations of cortical development

Current concepts and advanced neuroimaging review

Celi Santos Andrade¹, Claudia da Costa Leite²

ABSTRACT

Malformations of cortical development (MCD) result from disruptions in the complex process of the human brain cortex formation and are highly associated to severe epilepsy, neurodevelopmental delay and motor dysfunction. Nowadays, magnetic resonance imaging (MRI) is the cornerstone of the work-up of patients with epilepsy and modern advanced imaging techniques have improved not only our ability to detect and characterize cortical malformations, but also in identifying associated functional abnormalities that are far beyond the structural visualized lesions. Herein, we address the most currently used classifications of MCD and make a concise review of the embryological process of cortical development. Our main goal is to summarize recent advances and new trends in diagnostic imaging techniques concerning MCD. Thereafter, follows a brief discussion of specific disorders and their radiological features.

Key words: malformations of cortical development, epilepsy, magnetic resonance imaging, diagnostic imaging.

Malformações do desenvolvimento cortical: conceitos atuais e revisão de neuroimagem avançada

RESUMO

As malformações do desenvolvimento cortical (MDC) resultam de distúrbios no complexo processo do desenvolvimento do córtex cerebral humano e estão comumente associadas a epilepsia severa e disfunções neuropsicomotoras. Atualmente, as imagens por ressonância magnética (RM) são a pedra angular no manejo de pacientes com epilepsia e modernas técnicas avançadas de imagem melhoraram não só a nossa capacidade de detectar e caracterizar as malformações corticais, mas também levaram ao reconhecimento de anomalias funcionais associadas que estão muito além das lesões estruturais visibilizadas. Abordaremos as classificações mais utilizadas de MDC e revisaremos a embriologia do desenvolvimento cortical. Nosso principal objetivo é destacar os avanços recentes e as novas tendências em técnicas de diagnóstico por imagens relacionadas às MDC. Em seguida, faremos uma breve discussão sobre alguns transtornos específicos e suas características radiológicas.

Palavras-chave: malformações do desenvolvimento cortical, epilepsia, imagem por ressonância magnética, diagnóstico por imagem.

Accepted 12 August 2010

Malformations of cortical development (MCD) are highly epileptogenic lesions and some cases also present in childhood with early encephalopathy, neurodevelopmental delay, motor deficits and learning difficulties¹⁻⁵. Neuroimaging is an extreme-

ly important tool in the evaluation of patients with refractory epilepsy and constant advances in diagnostic imaging techniques have improved our ability in identifying focal lesions. Besides that, modern imaging studies have recently shown met-

Chief of the Neuroradiology Group and of the Magnetic Resonance Section, Clinics Hospital of University of São Paulo, School of Medicine, São Paulo SP, Brazil.

abolic and functional abnormalities beyond the visible structural lesions, shedding light to the pathophysiological basis of human epileptogenesis.

The aim of this review is to address the current concepts of MCD and recent advances in modern imaging techniques concerning the diagnosis and understanding of these epileptogenic disorders. Before that, we will make a concise revision of the normal human brain cortex formation. For each subtype of MCD, we will state its histopathological, clinical and imaging characteristics with a pertinent differential diagnosis. Because of its medical and radiological significance, the following MCD will be addressed in this article: focal cortical dysplasia, hemimegalencephaly, heterotopia, lissencephaly, polymicrogyria, and schizencephaly.

Classification of MCD and normal cortical development

The study and classification of MCD are complicated by the fact that two malformations are virtually never completely identical and often combinations of different subtypes of malformations occur together in the same patient. Indeed, MCD have a wide spectrum of histomorphological alterations, heterogeneous clinical presentations and highly variable neuroradiological manifestations, that makes this group of diseases even more intriguing and somewhat challenging.

The most currently adopted categorization is the classification scheme of Barkovich et al.^{2,6,7}, which is based on three embryological processes of brain development: neuronal and glial proliferation, and differentiation, and eventual apoptosis; neuronal migration; and cortical organization. These embryological steps should not be viewed as separate sequential processes, but as a complex mechanism that ultimately results in brain formation. The classification is based on the earliest stage at which the abnormality occurs, together with pathological, genetic and imaging aspects^{2,3}.

The description of radial glia dates from the 19th century and has strongly influenced the history of neuroscience⁸. The normal human brain cortical development is a so extraordinary and complex biological process, with so many molecular requirements, signaling cascades and precise expression patterns of key genes^{9,12}, that one may wonder how is it possible not to have more commonly malformations and misdevelopments.

Neurons originate from stem cells of the subependymal layer of the wall of the ventricles (the so-called germinal matrix). The germinal matrix cells with neuronal differentiation (neuroblasts), when mature, begin a process of migration. The migration of neurons in the periventricular region to the deep nuclei and to the surface of the cerebral cortex is driven by radial fibers in the eighth

week of gestation. The cerebellar nuclei and cortex are also formed in this period. The migration occurs in an orderly manner, so that the cells that will form the first layer of the cortex are the first to migrate and thereafter cells that will form the layers 6, 5, 4, 3 and 2. Cortical neurons migrate for varying distances until they reach the cortex in their final position, forming the hexalaminar cytoarchitecture of the adult neocortex^{9,10}. After being organized in several layers, the neurons separate from the radial fibers and initiate the formation and growth of dendrites and synapses. The radial fibers are separated from the neurons after the migration and originate glial cells⁸. Most of the process of neuronal migration occurs around the 16th week of gestation; however, this process will only end in about the fifth month of life. The cortical connections are formed very early, and continue to develop in an intricate mechanism that leads to the development of gray matter and white matter.

Brain sulcation and gyration are directly related to neuronal migration and are responsible for the increased cortical surface, without increasing its volume.

Disturbances in several molecular pathways¹¹⁻¹⁵ that regulate these complex mechanisms may have a genetic basis^{3,10}, although exogenous insults, such as cytomegalovirus infection, can also cause some types of MCD; the nature and timing of the insult in relation to the development process are the factors that determine the type of MCD.

Modern neuroimaging techniques

The diagnosis of any MCD ideally requires high resolution multiplanar magnetic resonance imaging (MRI)^{6,16}. This is by all means the method of choice for evaluation of the MCD because it demonstrates excellent contrast between white matter and gray matter, gives exact topographic characterization of the development of cortical gyri and sulci, and allows more accurate analysis of the formation of white matter and stages of myelination. Computed tomography (CT) scans can fail to make the diagnosis in more than 30% of affected patients², but it is crucial to remember that this may be the only method available in some cases. Thus, it is important to recognize that CT changes, although subtle, are similar to those found in MRI studies.

New advanced MRI techniques have gradually improved image quality and reinforced our ability to identify, delineate and characterize brain lesions. According to some authors, the gain in spatial resolution with increasing magnetic field strength - moving from 1.5 T to 3.0 T, 7.0 T and greater - and subsequent increase in signal to noise ratio, can potentially bring more anatomical details in complex brain malformations¹⁶. Advances in multichannel coil technology, with phased array sur-

face coils, have increased resolution and contrast of the acquired images¹⁶, with maximum gains in the cortical surface, which is especially useful in the detection of mild cortical dysplasias.

Some recent MR advanced sequences may also improve image quality and might be helpful in characterization of MCD. The introduction of volumetric T1-weighted sequences with high spatial resolution (SPGR - spoiled gradient recalled echo, MPRAGE - magnetization prepared rapid gradient echo) that allow high quality multiplanar reconstructions favors a more accurate diagnosis. Volumetric FLAIR at 3 Tesla can be very sensitive for characterizing subjacent white matter involvement¹⁶. Susceptibility weighted imaging (SWI), due to its increased contrast and resolution, has a potential role in delineating cortical lesions¹⁷.

Computer-assisted methods, such as voxel-based morphometry (VBM)¹⁸, surface reconstructions and segmentation techniques^{19,20} may aid in detection of subtle lesions, but these automatic approaches still need to surpass intrinsic inaccuracies and remain to be proven helpful to the unassisted human eye in prospective studies^{16,18}. Nevertheless, clinical information is still absolutely important in guiding the intensive and time-consuming visual search that is required in the evaluation of millimetric volume acquisitions with multiplanar reformats.

Improvements in fetal MRI with rapid pulse sequences, parallel imaging, more sophisticated coils and motion correction tools are also optimizing the early *in utero* detection of MCD^{16,21,22}. The prenatal appearance of MCD is similar to that seen in the child and fetal MRI may detect malformations not visualized in sonography²². Besides that, the lack of myelination at this age may potentially make subtle cortical dysplasias easier to identify.

Although conventional MRI with high spatial resolution readily identify the malformed cortex in most cases, recent investigations have begun to look into the associated abnormalities in the white matter and cerebral connectivity by diffusion tensor imaging (DTI) and tractography²³. Some studies have shown a reduction in the volume of white matter in the affected cerebral hemispheres containing the MCD and more widespread alterations in diffusivity and anisotropy, that could be of potential clinical importance if surgery is considered, and also in the investigation of cryptogenic epilepsy^{16,24}.

Magnetoencephalography (MEG) may detect interictal epileptiform activity in up to one-third of electroencephalogram (EEG)-negative patients, by measuring very weak magnetic fields induced by neuronal discharges^{16,25}. MEG seems to be useful in identifying cortical lesions and also mapping normally functioning eloquent cortex, thus improving overall surgical outcome²⁶.

In the last decade, functional neuroimaging studies

have also led to a better understanding of the pathophysiology of symptomatic epilepsy. Available techniques include single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). SPECT scans showing changes in regional cerebral blood flow (rCBF) can predict the localization of an epileptogenic focus associated with an underlying abnormality, which may be particularly useful in the absence of obvious structural abnormality on MRI²⁷. PET shows hypometabolism in the interictal phase, which can aid to lateralize the epileptogenic focus¹⁶. Studies using PET and fMRI demonstrated functional cortex located in MCD, confirming findings of invasive EEG and warning of the extreme care required when surgical resection is contemplated²⁷. Despite widespread use of these diagnostic techniques in the presurgical evaluation, there are few studies specifically concerning MCD.

Leite and colleagues, in a study of multivoxel proton magnetic resonance spectroscopy (MRS) showed reduced levels of N-acetylaspartate/creatinine (NAA/Cr) in both the MCD and on the normal appearing contralateral side in patients with unilateral lesions, warning the fact that the metabolic abnormalities in MCD extend far beyond focal lesions evident on structural tests^{28,29}. Others authors have also demonstrated metabolic abnormalities in MCD, such as reduced NAA and increased choline (Cho), as well as in the macroscopically normal perilesional zone, usually decreased NAA and Cr³⁰⁻³².

Currently, our group is developing experiments with phosphorus MRS that can potentially bring more information on the phospholipid metabolism and brain energetic status in patients with MCD. Preliminary results have shown elevation of phosphocreatine (PCr) levels, which may correlate to hypometabolism in the interictal phase, and alterations in phosphomonoesters (PME) and phosphodiesteres (PDE), which indicate a breakdown in the membrane synthesis. We also could note abnormalities in the contralateral normal appearing cerebral tissue³³.

The idea that in MCD the visible lesion represents only the "tip of the iceberg" has been widely debated. The presence of perilesional or contralateral metabolic abnormalities might be of clinical interest, particularly in patients in whom a surgical procedure is being considered. This could explain why surgical resection does not bring good results for the control of epilepsy in some patients with focal MCD³⁴.

Focal cortical dysplasia

The great interest in focal cortical dysplasias (FCD) relies in the severity of clinical symptoms and the high frequency that this disorder is managed surgically. In 2004,

Palmini et al. published a panel consensus on the terminology and classification of cortical dysplasias³⁵.

FCD is an important cause of unfamiliar, non-syndromic, intractable epilepsy, with early onset in childhood. There are no features on physical examination suggestive of the diagnosis, although some reports of associated findings, such as linear epidermal nevus³⁶. FCD is a major cause of focal motor epilepsy or continuous partial epilepsy that can be life threatening, so that surgical treatment is a therapeutic modality considered in many of these patients^{2,37,38}.

Researchers have identified a variety of cytologic and histomorphologic abnormalities: giant pyramidal neurons, disorganized dysplastic neurons, “balloon” cells (large round cells with eosinophilic cytoplasm resembling a balloon), disordered lamination and clustering of neurons^{1,2,36,37,39-42}. Evidences from *in vitro* studies show that cytomegalic neurons are primary epileptogenic cells, whereas “balloon” cells are electrophysiologically inactive^{38,43}.

FCD are probably not a single entity. Indeed, the histological appearance is not uniform, ranging from molecular phenotypes, cytological components, organizational disturbances, genetic disorders, mechanisms of activation and appearance on MRI^{15,17,40}.

FCD are characterized on MRI (Fig 1) as focal cortical thickening with abnormal signal intensity, blurring of the gray-white matter interface, sometimes with signal intensity abnormalities in the underlying white matter mostly hyperintense signal in T2 and FLAIR (fluid-attenuated inversion recovery) and hypointense signal in T1, with the aspect of a wedge-shaped tail extending radially to the ventricle (“transmantle” dysplasia)^{5,16,36,37,39,44}. Other characteristic imaging findings are focal white matter atrophy, a deep sulcus and broadening of the gyri adjacent to the FCD.

These changes are not always present together, nor are pathognomonic in isolation. FCD is usually found in frontal or temporal lobes, although it can occur in any location. Electroencephalogram (EEG) may show particular ictal changes in individuals. Detailed pre-surgical evaluation is mandatory, since FCD can occur in areas of eloquent cortex and the epileptogenic zone may be more extensive than the lesion visualized on MRI^{6,25,26,36}.

This lesion can occasionally be quite subtle, and analysis of MR images together with clinical data, EEG and possibly nuclear medicine tests such as SPECT is essential for a correct assessment of the case and valorization of more subtle findings⁶. Sometimes superficial neuronal or neuroglial tumors like dysembryoplastic neuroepithelial tumor (DNET) and ganglioglioma can be a relevant consideration in the differential diagnosis, especially in less typical cases.

Hemimegalencephaly

Hemimegalencephaly or unilateral megalencephaly is related to the unilateral hamartomatous excessive growth of all or part of one cerebral hemisphere, with defects in neuronal proliferation, migration and cortical organization.

Affected patients typically have macrocephaly at birth, and can present early in childhood with refractory epilepsy, neurological development delay and hemiparesis⁴⁵. Across this spectrum, milder cases may present with discrete seizures, completely controlled. The brain may be affected in isolation, or there may be hypertrophy of part or all of the ipsilateral body.

Some syndromes may be associated: neurofibromatosis type I, tuberous sclerosis, epidermal nevus syndrome, Proteus syndrome, ipsilateral hypomelanosis of Ito, Klippel-Trenaunay-Weber syndrome, focal alopecia, and dysembryoplastic neuroepithelial tumor^{1,2,14,44}.

Fig 1. Focal cortical dysplasia. MRI performed at 3 Tesla exhibit an area of mild cortical thickening, with blurring of the white-gray matter interface in the left frontal lobe in the T1 FFE (fast field echo) axial image (arrow in A), that is also visualized in the FLAIR axial image, along with hyperintense signal in the underlying white matter (arrow in B).

Fig 2. Hemimegalencephaly. Axial T2 FSE (fast spin echo) [A] shows an enlarged right cerebral hemisphere. 3D SPGR (spoiled gradient recalled echo) coronal reformat [B] also exhibits ipsilateral cortical thickening, with shallow sulci resembling pachygyria. Ventricular asymmetry is very conspicuous.

Anatomic or functional hemispherectomy may be indicated for clinically intractable epilepsy, if contralateral hemisphere is normal. The transfer of functions to the contralateral hemisphere is greater in younger children, due to brain plasticity.

Microscopically, laminar cortical organization is completely changed, with the presence of giant neurons in the cortex and in the underlying white matter. Histopathological studies usually demonstrate findings similar to those observed in cortical dysplasias^{14,40}, with the presence of “balloon” cells in some cases¹.

MRI may show moderate to severe increase of the cerebral hemisphere, with increased volume of white matter, which may show in some cases abnormal signal. There is generally cortical thickening, with shallow sulci resembling agyria/pachygyria (Fig 2). The distinction of the interface between white matter and gray matter is usually blurred^{2,5}. The lateral ventricle on the affected side is usually irregularly shaped and enlarged, in proportion to the increased cerebral hemisphere. However, in a few cases, the ipsilateral ventricle may be small².

The main clue to the diagnosis of unilateral megalencephaly is the increase of the lateral ventricle on the affected side, contrary to what occurs in expansile or infiltrative lesions with mass effect, which compress and shift the ventricular system. In hemimegalencephaly, there is usually an association with other MCD, such as lissencephaly and polymicrogyria⁵.

Heterotopia

Heterotopia, one of the most commonly MCD revealed on MRI, occurs when neurons originating in the periventricular region fail to migrate, leaving tracks or nodules of neurons in heterotopic location, adjacent to the ependymal line or in subcortical topography. Based on MR images, there are three types of heterotopia: peri-

ventricular nodular heterotopia, focal subcortical heterotopia, and band heterotopia.

The typical patient with periventricular nodular heterotopia (Fig 3) is most commonly female, during or after the second decade of life that presents with epilepsy, refractory or not to drug treatment. Usually there is no cognitive impairment and there are rare associations with disturbances outside the central nervous system, such as vasculopathy, patent ductus arteriosus or coagulopathy³⁶.

Most cases of familial periventricular nodular heterotopia affect predominantly women and are caused by mutations in *FLNA*. However, mutations in this gene can also cause sporadic periventricular heterotopia in women as well as familial and sporadic cases in men. Other genes also appear to be involved, such as *DCX*, *ARFGEF2* and a locus on chromosome 5p^{36,46}.

Periventricular nodular heterotopia can be associated with mesial temporal sclerosis (dual pathology). In these cases, surgical resection of the affected hippocampus invariably brings no benefits and should be avoided³⁶.

Patients with periventricular nodular heterotopia associated with other MCD compared to those with isolated periventricular heterotopia, have more severe clinical course, with more frequent seizures, failure to drug treatment and increased risk of mental retardation. The extent and distribution of subependymal nodules contraindicate surgery in most cases. Only a few patients were treated surgically, with varying results³⁶.

The nodules of heterotopic gray matter can also occur in subcortical white matter (focal subcortical heterotopia) with distortion of the ventricle, unilaterally or bilaterally (Fig 4). There are reduction in the volume of white matter and thinning of overlying cortex. In these cases, more extensive clinical and cognitive deficits may ensue.

In band heterotopia (Fig 5), layers of gray matter are found in subcortical white matter, and are separated from

Fig 3. Periventricular nodular heterotopia. Volumetric T1 FFE (fast field echo) sequence performed at a 3 Tesla scanner with axial reconstruction in thin sections (1 mm thick) shows subependymal heterotopic gray matter adjacent to the right lateral ventricle (arrow).

Fig 4. Subcortical heterotopia. T1 SPGR (spoiled gradient recalled echo) in the axial plane demonstrates multiple nodules isointense to gray matter in subcortical location in the left cerebral hemisphere. There can be also seen reduction in the volume of white matter, and thinning of the overlying cortex.

the cortex by a thin layer of white matter. The thickness of the bands varies among patients and also along the fronto-occipital axis in the same individual. The thickness of the band is also related to the severity of the clinical picture, being more severe when there are thicker bands of gray matter^{36,45}.

Histological specimens show heterotopic neurons with normal morphology in isolation or in clusters, but lacking appropriate synaptic connections. The pathophysiological basis is not completely understood and it seems that the gray matter nodules are intrinsically epileptogenic³⁶.

Imaging diagnosis is usually obvious, showing periventricular or subcortical tissue isointense to gray matter on all sequences evaluated, that does not enhance after intravenous injection of paramagnetic contrast agent. In cases of band heterotopia, there is a characteristic configuration of “double cortex”. The thickness of the bands varies, with blurring of the interface between the white matter and gray matter. Differential diagnosis includes subependymal nodules that occur in tuberous sclerosis, but these may enhance after contrast injection and may be calcified. The identification of the signal intensity similar to the gray matter on all MR sequences is the key to the correct diagnosis of gray matter heterotopia.

Lissencephaly

Lissencephaly is a rare cause of severe epilepsy, mental retardation and early death. However, MRI has shown that many patients survive into adulthood.

In lissencephaly, migration of all neurons is severely affected and the brain surface is smooth, with cortical

Fig 5. Subcortical band heterotopia. T2 weighted thin section in the coronal plane demonstrates a band of gray matter (arrowheads) in the frontal and temporal lobes, separated from the cortex by a thin layer of white substance, resembling a “double cortex”. Figure kindly given by Dr. Fábio Eduardo Fernandes da Silva.

disruption and reduced white matter volume. The term agyria defines the complete absence of cerebral gyri on the cerebral surface and is synonymous of complete lissencephaly. Pachygyria represents a few large and thick gyri, with shallow sulci, and corresponds to incomplete lissencephaly^{2,5}.

Studies in relatives with subcortical band heterotopia and others with lissencephaly have led to the discovery

Fig 6. Lissencephaly. MR imaging (T2 FSE, axial plane) shows a smooth brain surface with no sulci on the anterior region (agyria), and a few shallow sulci posteriorly, with thick and broad gyri (pachygyria).

of new genes, *DCX* on chromosome X and *LIS1* on chromosome 17. Mutations in any of these genes can lead to any of these disorders or combinations of them, in men or women. Other genes also seem involved in the generation of this phenotype, such as *YWHAE*, *ARX*, *TUBA1A* and *RELN*^{2,3,5,36,41}.

Lissencephaly may occur in isolation or as part of other syndromes. “Cobblestone” cortical malformations are mainly related to muscular dystrophy syndromes, clinically heterogeneous, but usually manifesting with hypotonia at birth, generalized muscle weakness and joint contractures in varying degrees. The diagnosis may be obtained by muscle biopsy, allied to characteristic imaging findings in the central nervous system. The three main disturbances in this group are Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy^{5,41,44}.

The Walker-Warburg syndrome shows characteristic imaging findings: hydrocephalus with marked ventriculomegaly, hypogenesis of corpus callosum, hypoplasia, and dysmorphism of brain stem and cerebellum, microphthalmia, and severe hypomyelination. Occipital cephaloceles are present in half of the cases^{2,5}. The cortex is thick, with few shallow sulci and irregularity of gray-white matter junction, reflecting the extent of bundles of cortical neurons to the underlying white matter, hence the characteristic imaging appearance of the “cobblestone” cortex.

The Fukuyama congenital muscular dystrophy is a genetic condition, seen primarily in Japanese descendants with mutations in the *FCMD* gene on chromosome 9q31-33². These patients have two main types of cortical anomalies:

polymicrogyria in the frontal lobes, and “cobblestone” cortex with shallow sulci predominantly in the posterior temporal, and occipital lobes. There are also cerebellar dysplasias with subcortical cysts, and delayed myelination of encephalic white matter⁵.

Muscle-eye-brain disease also features “cobblestone” cortex with irregular gray-white matter interface, cortical thickening (most pronounced anteriorly in the frontal lobes than posteriorly), with a reduction in number and depth of the sulci. There is severe hypomyelination, and the brain stem and cerebellum are dysmorphic. The pons is small, with an anterior slit, and there may also be fusion of the colliculi and presence of cerebellar cysts. The ocular globes are small, with subretinal fluid collections^{2,5}.

There is no single effective drug treatment in patients with lissencephaly, and the epilepsy caused is usually refractory. Surgery in these patients is usually ineffective, but sometimes callosotomy may be considered.

Microscopically, there is disorganization of the lissencephalic cortex, and blurring of the interface with the white matter. If there is association with band heterotopia, layers of subcortical gray matter are composed of neurons similar to those found in cortical gray matter².

In MRI, the cortical surface is smooth, the gyri may be scarce and flat (pachygyria) or absent (agyria) (Fig 6). Incomplete opercularization with shallow and verticalized sylvian fissures give an aspect of brain in “eight” or also called “snowman” or “hourglass” brain in the axial plane⁴⁴. In Walker-Warburg syndrome, the appearance of lissencephaly is typical, with the characteristic image of the “cobblestone” cortex.

Classic lissencephaly usually presents no great diagnostic challenge; however, pachygyria may sometimes be more subtle, close to the standard brain configuration usually found.

Polymicrogyria

Polymicrogyria is the presence of too many small abnormal gyri that produce an irregular cortical surface. Polymicrogyria is not invariably associated with epilepsy, and may present as neurological development delay, oromotor apraxia or congenital hemiparesis^{36,47,48}.

Several patterns of inheritance have been described. A mutation in *MECP2* has been found in a man with perisylvian syndrome and severe neonatal encephalopathy. A recent study involving hybrid genetic and MRI identified *PAX6* as a gene in which mutations can cause unilateral polymicrogyria³⁶.

It has been reported clinical association with congenital arthrogryposis^{2,5,47} and with some specific syndromes, such as Delleman syndrome, Fukuyama congenital muscular dystrophy, Neu-Laxova syndrome, hypomelanosis of Ito, Aicardi syndrome, and diGeorge syndrome².

Fig 7. Perisylvian polymicrogyria. Imaging at 3 Tesla displays an operculum dysplastic and incomplete, with polymicrogyric cortex surrounding the sylvian fissure, which is vertically oriented and extends posteriorly to the parietal lobe, well demonstrated in the sagittal reformat of a volumetric T1-FFE (fast field echo) sequence.

Several particular patterns of polymicrogyria have been described; the main one is bilateral perisylvian polymicrogyria, clinically characterized by a combination of pseudobulbar palsy, spastic tetraparesis, learning difficulties and epilepsy. Some specific combinations of periventricular nodular heterotopia with overlying polymicrogyria have also been described^{3,46,48,49}.

Moreover, the fact that there is necrotic tissue within the malformed cortex, that most changes occur in the middle cerebral artery territory, and the existence of polymicrogyria adjacent to the borders of schizencephaly and porencephaly, suggest that hypoxic-ischemic insults may, at least in some cases, be related to the genesis of polymicrogyria⁵. There may also be a relation to congenital infections such as those caused by cytomegalovirus.

Some experimental models suggest that the epileptogenic area extends far beyond the obviously visualized abnormality. Resection of an isolated area rarely is beneficial in refractory epilepsy³⁶.

At least two major histological types are recognized: the four-layered cortex with simplified organization (most common), and the unlayered type, yet there are several histological intermediate subtypes and these two main types can coexist in adjacent areas^{36,46}.

MRI shows excessive cortical gyration with an aspect of cortical thickening and shallow sulci, and irregularity of the gray-white matter interface. This entity may be focal, multifocal or diffuse; unilateral or bilateral, symmetric or asymmetric. In cases of perisylvian syndrome (Fig 7), there is polymicrogyria surrounding opercular portions with enlarged and vertically oriented sylvian fissures, extending to the parietal lobes, well demonstrated in the sagittal plane^{2,47}.

Fig 8. Schizencephaly. T1-weighted image in the coronal plane performed at 3 Tesla demonstrates an indentation (“nipple”) in the left lateral ventricle, and a transcortical cleft extending from the ependymal to the pial surface (arrow). The cleft is lined by polymicrogyria, which can be also seen in the right frontal lobe (arrow-head). The septum pellucidum is absent.

Polymicrogyria may, in some contexts, simulate pachygyria, since excessive cortical gyration, when very small, simulates a thickened cortex with smooth surface, but these entities may be more easily distinguished in volumetric MRI sequences with high resolution images.

Schizencephaly

Schizencephaly is defined by the presence of a transcortical cleft, extending from the ventricular surface to the pial surface, lined with gray matter, and often with polymicrogyria along its edges.

There may be a variety of associated abnormalities involving the septum pellucidum, optic nerves, the corpus callosum or the hippocampi⁵. Septo-optic dysplasia (deMorsier syndrome) might be considered in a patient with schizencephaly, optic nerve hypoplasia and absence of septum pellucidum^{5,44}. As in polymicrogyria, vascular, infectious and genetic causes have been considered in the genesis of this malformation^{2,46}, and perhaps the severity of the insult differentiates these two entities, being more severe in the case of schizencephaly.

There may be a wide spectrum of clinical presentations. Patients with bilateral clefts usually have microcephaly and severe developmental delay, with spastic quadriplegia, while patients with unilateral clefts may have much less severe clinical phenotypes². Surgical treatment has been reported in cases of medically intractable epilepsy, but it is rarely considered.

Usually the cleft is lined by dysplastic gray matter, and there may be adjacent areas of polymicrogyria, pachygyria and heterotopic gray matter nodules⁴⁶.

MRI shows a transcortical cleft which may be apposed

together (closed lips, type I) or clearly unapposed (open lips, type II), communicating the ventricle with the periencephalic subarachnoid space, lined by gray matter⁵. The lesions may be unilateral or bilateral (in this case, usually symmetrical in location but not in size). In a closed lips schizencephaly, the presence of an indentation in the ependymal surface may be the most significant clue to the correct diagnosis, the so-called nipple (Fig 8).

The greatest differential here is between open lips schizencephaly and porencephaly. Both are lesions with signal intensities similar to cerebrospinal fluid, but the tissue that lines the cavity is the key to the correct diagnosis - if it shows signal intensity characteristics similar to gray matter, the hypothesis of schizencephaly can be safely considered.

In summary, recognition of the main patterns of MCD in MR images is the mainstay in the work-up of these patients, and advanced neuroimaging techniques may aid in the correct diagnosis, leading to a more accurate classification of these complex and highly epileptogenic entities.
