Symbol-Timing Estimation in Space–Time Coding Systems Based on Orthogonal Training Sequences

Yik-Chung Wu, S. C. Chan, Member, IEEE, and Erchin Serpedin, Senior Member, IEEE

Abstract—Space–time coding has received considerable interest recently as a simple transmit diversity technique for improving the capacity and data rate of a channel without bandwidth expansion. Most research in space–time coding, however, assumes that the symbol timing at the receiver is perfectly known. In practice, this has to be estimated with high accuracy. In this paper, a new symbol-timing estimator for space–time coding systems is proposed. It improves the conventional algorithm of Naguib et al. such that accurate timing estimates can be obtained even if the oversampling ratio is small. Analytical mean-square error (MSE) expressions are derived for the proposed estimator. Simulation and analytical results show that for a modest oversampling ratio (such as $Q$ equal to four), the MSE of the proposed estimator is significantly smaller than that of the conventional algorithm. The effects of the number of transmit and receive antennas, the oversampling ratio, and the length of training sequence on the MSE are also examined.

Index Terms—Approximated log-likelihood function, space–time coding, symbol-timing recovery, training sequences.

I. INTRODUCTION

SPACE–TIME (ST) processing using ST coding has received considerable interest recently as an efficient means for high-rate data transmission [1]–[10]. Symbol-timing synchronization is an important issue in ST coding systems because perfect symbol-timing information at the receiver is usually assumed. This problem was first studied in [4], where orthogonal training sequences are transmitted at different transmit antennas to simplify the maximization of the oversampled approximated log-likelihood function. The sample having the largest magnitude, the so-called the “optimal sample,” is assumed to be closest to the optimum sampling instants (it will be referred to as the optimum sample selection algorithm in the sequel for convenience). However, it is shown in this paper that the mean square error (MSE) of this algorithm is lower bounded by $1/(12Q^2)$, where $Q$ is the oversampling ratio. As a result, the performance of this timing synchronization method depends highly on the oversampling ratio. In fact, relatively high oversampling ratios might be required for accurate symbol-timing estimation.

In this paper, a new symbol-timing estimator for ST coding systems is proposed. It improves the optimum sample selection algorithm in [4] so that accurate timing estimates can be obtained even if the oversampling ratio is small. The increase in implementation complexity with respect to that of optimum sample selection algorithm is very small. The requirements and the design procedures for the training sequences are discussed. Analytical expressions for MSE of the proposed estimator are derived. Both analytical and simulation results show that, for a modest oversampling ratio (such as $Q = 4$), the MSE of the proposed estimator is significantly smaller than that of the optimum sample selection algorithm. Furthermore, the effects of the number of transmit and receive antennas, the oversampling ratio, and the length of training sequence on the MSE are also examined.

The paper is organized as follows. The system model of the ST coding system is first described in Section II. A brief overview of the optimum sample selection algorithm for symbol-timing synchronization in an ST coding system is given in Section III. Requirements and design of training sequences are discussed in Section IV. The proposed symbol-timing estimator is then presented in Section V. Analytical MSE expressions are derived in Section VI. Simulation results and discussions are then presented in Section VII, and finally conclusions are drawn in Section VIII.

II. SIGNAL MODEL

Both ST block coding and ST trellis coding systems can be described by the same basic communication model [4]. The simplified baseband equivalent model, with $N$ transmit and $M$ receive antennas, is shown in Fig. 1. The information is encoded by an ST trellis or block encoder to give the encoded symbols $d_1(t), d_2(t), \ldots, d_N(t)$. Each encoded data symbol $d_i(t)$ is pulse shaped and then transmitted simultaneously via different antennas. A superposition of independently faded signals from all the transmit antennas plus noise is received at each receive antenna. The received signal at each receive antenna is first filtered by a matched filter. It is then passed through the symbol-timing recovery and the channel estimation units and, finally, the ST decoder.

For a flat fading channel, the received signal at the $j$th receive antenna can be written as

$$r_j(t) = \sqrt{\frac{E}{N}} \sum_{n=1}^{N} h_{ij} \sum_{n} d_i(n) g(t - nT - \epsilon T) + n_j(t),$$

$$j = 1, 2, \ldots, M$$

(1)
where $E_s/N$ is the symbol energy and $h_{ij}$'s are the complex channel coefficients between the $i$th transmit antenna and the $j$th receive antenna and are assumed to be statistically independent for different transmit/receive antennas (this condition is satisfied if the transmit antennas are well separated, e.g., more than $\lambda/2$, where $\lambda$ is the wavelength of the RF carrier). $d_i(n)$ is the information symbol transmitted from the $i$th transmit antenna; $g(t)$ is the transmit filter, which is assumed to be a root raised cosine pulse; $T$ is the symbol duration; $\epsilon \in [-0.5, 0.5]$ is the unknown timing offset; and $n_j(t)$ is the complex-valued circularly distributed Gaussian white noise at the $j$th receive antenna, with power density $N_0$. Throughout this paper, it is assumed that the channel is frequency flat and quasi-static.

Let the received signal be sampled at a rate $Q$ times faster than the symbol rate $1/T$. The sampled and matched filtered signal at the $j$th receive antenna is given by

$$r_j(m) = \sqrt{\frac{E_s}{N}} \sum_{i=1}^{N} h_{ij} \sum_{n} d_i(n) p(mT/Q - nT - \epsilon T) + \eta_j(m) \quad (2)$$

where

$$r_j(m) \triangleq r_j(mT/Q), \quad p(t) \triangleq g(t) \otimes g_r(t), \quad \eta_j(m) \triangleq \begin{cases} 1 & \text{if } m = mT/Q, \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad g_r(t) \text{ denotes the matched filter.}$$

III. Timing Synchronization by Optimum Samples Selection

As proposed in [4], orthogonal training sequences can be periodically transmitted in between data symbols (as shown in Fig. 2) to assist the timing synchronization. The idea is that at the receiver, if the position of the orthogonal training sequences can be correctly located, the signal from any one of the transmit antennas can be extracted (and signals from other antennas are removed) by multiplying the received signal with the orthogonal sequence transmitted from that antenna. Note that the structure of training sequences in this paper is different from that presented in [4]. In this paper, a cyclic prefix and cyclic suffix, each of length $L$, are included in order to remove the intersymbol interference (ISI) from the random data transmitted before and after the orthogonal training sequences. Since $L$ is usually kept as a small number, the increase in length of training is very small, especially when the length of the orthogonal training sequences is large.

Let $c_t = [c_t(0) \quad c_t(1) \quad \cdots \quad c_t(L_t - 1)]$ be the $i$th ($i = 1, \ldots, N$) orthogonal training sequence of length $L_t$ to be transmitted from the $i$th transmit antenna. The sampled signal at the $j$th receive antenna can be obtained by replacing $d_i(n)$ in (2) with $c_t(n)$. Further, let $m = lQ + k(l = 0, 1, \ldots, L_t - 1$ and $k = k_0, k_0 + 1, \ldots, k_0 + Q - 1$, where $k_0 = -\lfloor (1/2 - \epsilon)Q \rfloor$ and $[x]$ denotes the nearest integer less than or equal to $x$) so that each sample is indexed by the $l$th transmit bit and the $k$th phase. In order to maintain the orthogonality between the received training sequences and the local copies, the first phase is taken at $-\lfloor (1/2 - \epsilon)Q \rfloor$ such that all the $Q$ samples for the $l$th transmit bit are taken from $-T/2 \leq t - lT \leq T/2$. Then, the received signal $r_j(lQ + k)$, due to the orthogonal training sequences, can be rewritten as

$$r_j(lQ + k) = \sqrt{\frac{E_s}{N}} \sum_{i=1}^{N} h_{ij} \sum_{n} c_t(n) \times p(kT/Q + (l - n)T - \epsilon T) + \eta_j(lQ + k)$$

for $l = 0, 1, \ldots, L_t - 1$, and $k = 0, 1, \ldots, Q - 1 \quad (3)$
where \( \epsilon' \triangleq \epsilon + k_0/Q \). Note that \( k_0 \) has been dropped from the index of \( \eta_j(Q+k) \) since a fixed time shift does not affect the noise statistics. In practice, it is sufficient to estimate \( \epsilon' \) only as it represents the time difference between the first sample of the training sequence and the next nearest optimum sampling instance. Grouping the samples with the same phase, one can form the vector \( \mathbf{r}_j(k) \) as in (4) and (5), shown at the bottom of the page. Please also refer to the other equation shown at the bottom of the page.\(^2\)

Define the sequence \( \Psi_{ij}(k) \triangleq c_i^H \mathbf{r}_j(k) \), where \( c_i^H \) denotes the transpose conjugate of \( c_i \). Since \( c_i \)'s are orthogonal to each other when the relative delay is zero, it follows that

\[
\Psi_{ij}(k) = \sqrt{\frac{E_s}{N}} h_{ij} \mathbf{p}(k) + \sqrt{\frac{E_s}{N}} h_{ij} c_i^H \mathbf{C}_i \mathbf{p}(k) + c_i^H \eta_j(k) \quad (6)
\]

for \( k = 0, \ldots, Q-1, ||c_i|| \triangleq \sqrt{c_i^H c_i} \) is the norm of \( c_i \), which is a constant. \( \mathbf{C}_i \) is the same as \( \mathbf{C}_1 \) but with the \((L+1)\)th column removed, and \( \mathbf{p}(k) \) is the same as \( \mathbf{p}(k) \) but with the \((L+1)\)th entry removed. The second term in (6) represents the ISI if the training sequences are not orthogonal when the relative delay is not zero. The last term in (6) is the noise term.

From (6), it can be observed that if the second and third terms are very small [a training sequence design procedure that makes the second term zero is discussed in the next section; the third term is small at high signal-to-noise ratios (SNRs)], \( \Psi_{ij}(k) \) has the same shape as \( p(t) \) for \(-T/2 \leq t \leq T/2\), except that it is scaled by a complex channel gain and is corrupted by additive noise. In order to remove the effect of the channel, consider the sequence \( \Lambda_{ij}(k) \triangleq ||\Psi_{ij}(k)||^2 \). Now, the sequence \( \Lambda_{ij}(k) \) should have a similar shape to the function \( |p(t)|^2 \) for \(-T/2 \leq t \leq T/2\). This is illustrated in Fig. 3, where an example sequence of \( \Lambda_{ij}(k) \) is shown (\( Q = 8, L = 32, L = 3 \) and in the absence of noise). Note that a scaled version of \( |p(t)|^2 \) for \(-T/2 \leq t \leq T/2\) is also shown (in dotted line) for comparison. It can be seen that the optimum sampling time is at \( t = 0 \) and the sample with maximum amplitude is the one closer to the optimum sampling instant than the remaining samples.

A simple symbol-timing synchronization algorithm is to choose a value of \( k \) closest to the optimum sampling instants. That is, the optimum sampling phase \( k = \hat{k} \) is selected such that

\[
\mathbf{r}_j(k) \triangleq [r_j(k) \quad r_j(Q+k) \quad r_j(2Q+k) \quad \cdots \quad r_j((L_t-1)Q+k)]^T
\]

\[
= \sqrt{\frac{E_s}{N}} \sum_{i=1}^{N} h_{ij} c_i \mathbf{p}(k) + \eta_j(k)
\]

\( c_i \triangleq \begin{bmatrix}
    c_i(\text{mod}(-L, L_t)) \\
    c_i(\text{mod}(-L + 1, L_t)) \\
    \vdots \\
    c_i(\text{mod}(L + 1, L_t)) \\
\end{bmatrix}
\)

\( \mathbf{p}(k) \triangleq \begin{bmatrix}
    p(kT/Q - LT - \epsilon'T) \\
    p(kT/Q - (L - 1)T - \epsilon'T) \\
    \vdots \\
    p(kT/Q + LT - \epsilon'T) \\
\end{bmatrix}^T 
\)

\( \eta_j(k) \triangleq \begin{bmatrix}
    \eta_j(k) \eta_j(Q+k) \quad \cdots \quad \eta_j((L_t-1)Q+k) \\
\end{bmatrix}^T 
\)
it maximizes $\Lambda_{ij}(k)$. Since the channels for different antennas are independent, the average of $\Lambda_{ij}(k)$ over all $i$ and $j$ is maximized (see (8), where the scaling factor $1/MN$ is not included in order to preserve a simplified notation). As mentioned in [4], this represents the samples of an approximated log-likelihood function for symbol-timing synchronization, when the ISI plus noise term in (6) is assumed to be Gaussian. Therefore, the optimum sampling phase is selected as [4]

$$\hat{k} = \max_{k=0,1,\ldots,q-1} \Lambda_{ML}(k)$$  \hspace{1cm} (7)$$

with

$$\Lambda_{ML}(k) = \sum_{j=1}^{M} \sum_{i=1}^{N} \Lambda_{ij}(k),$$  \hspace{1cm} (8)$$

Under the optimistic assumption that the samples closest to the optimum sampling positions are correctly estimated (at high SNRs), the estimation error, normalized with respect to the symbol duration, is a uniformly distributed random variable in the range $[-1/2Q, 1/2Q]$. Therefore, the MSE is $1/(12Q^2)$. Thus, a relatively high oversampling ratio might be required in order to obtain a small MSE.

IV. DESIGN OF TRAINING SEQUENCES

The performance of the proposed timing estimator is directly influenced by the presence of ISI and noise terms in (6). In order to minimize the contribution of the ISI term in (6), the training sequences need to be designed such that

$$c_i^H \cdot c_{i'} = 0$$  \hspace{1cm} (9)$$

for all combinations of $i$ and $i'$. Combing with the fact that sequences from different antennas have to be orthogonal when the relative delay is zero, the problem of training sequences design resumes to finding $N$ sequences such that

$$c_i^H \cdot c_{i'} = \begin{cases} \|c_i\|^2, & i = i' \\ 0, & i \neq i' \end{cases},$$

where $I$ denotes the identity matrix. This is exactly the problem of designing multiple $(2L + 1)$-perfect sequences [11]–[13], with each of length $L_d$. Here, we just mention the procedures for designing the training sequences, interested readers can refer to the original papers [11]–[13] for details.

1) Construct a sequence $s = [s(0) \ s(1) \ \cdots \ s(L_d - 1)]$ with length $L_d$ such that all of its out-of-phase periodic auto-correlation terms are equal to zero. One example of this kind of sequence is a Chu sequence [14].

2) Construct another sequence $s' = [s'(0) \ s'(1) \ \cdots \ s'(L_d + 2NL - 1)]$ of length $L_d + 2NL$ as in (10), shown at the bottom of the page. Note that $L_d \geq 2NL$ must be satisfied. That is, if the number of transmit antennas $N$ is large, we cannot use training sequences with short length.

3) The orthogonal training sequences are given by

$$c_i = [s'_i(2i - 1)L \ \cdots \ s'_i((2i - 1)L + L_d - 1)].$$  \hspace{1cm} (11)$$

For example, let us consider $L_d = 32$, $L = 3$, $N = 2$. First, we construct a Chu sequence of length 32. Then, we cyclically extend the Chu sequence by copying the first $2 \times 2 \times 3 = 12$ bits and putting them at the back. Then, $c_1 = [s'(3) \ s'(4) \ \cdots \ s'(34)]$ and $c_2 = [s'(9) \ s'(10) \ \cdots \ s'(40)]$.

V. TIMING SYNCHRONIZATION BY ESTIMATION

In an optimum samples selection algorithm, symbol timing is estimated by maximization of the oversampled approximate log-likelihood function. As the number of samples becomes very large (which requires a large oversampling ratio), the estimate could become accurate. However, noting that the approximated log likelihood function is “smooth” (see Fig. 3), we expect that the maximization of the log-likelihood function can be done by interpolation based on a few samples, thus keeping the oversampling ratio at a small number.

More precisely, let us construct a periodic sequence $\tilde{\Lambda}_{ML}(m)$ by periodically extending the approximated log-likelihood sequence $\Lambda_{ML}(k)$ in (8). Further, denote $\tilde{\Lambda}_{ML}(\hat{\epsilon})$ as the continuous and periodic approximated log-likelihood function with its samples given by $\tilde{\Lambda}_{ML}(m)$. According to the sampling theorem, as long as the sampling frequency $Q/T$ is higher than twice the highest frequency of $\tilde{\Lambda}_{ML}(\hat{\epsilon})$, then $\tilde{\Lambda}_{ML}(\hat{\epsilon})$ can be represented by its samples $\tilde{\Lambda}_{ML}(m)$ without loss of information. The relationship between $\tilde{\Lambda}_{ML}(\hat{\epsilon})$ and $\tilde{\Lambda}_{ML}(m)$ is then given by

$$\tilde{\Lambda}_{ML}(\hat{\epsilon}) = \sum_{m=-\infty}^{\infty} \tilde{\Lambda}_{ML}(m) \text{sinc} \left( \frac{\hat{\epsilon}T - mT/Q}{T/Q} \right).$$  \hspace{1cm} (12)$$

Now, expand $\tilde{\Lambda}_{ML}(\hat{\epsilon})$ into a Fourier series

$$\tilde{\Lambda}_{ML}(\hat{\epsilon}) = \sum_{k=-\infty}^{\infty} A_k e^{j2\pi k \hat{\epsilon}}.$$  \hspace{1cm} (13)$$

where

$$A_k = \int_{-1}^{1} \tilde{\Lambda}_{ML}(\hat{\epsilon}) e^{-j2\pi k \hat{\epsilon}} d\hat{\epsilon}.$$  \hspace{1cm} (14)$$

Substituting (12) into (14) yields

$$A_k = \sum_{m=-\infty}^{\infty} \tilde{\Lambda}_{ML}(m) \times \int_{-1}^{1} \text{sinc} \left( \frac{\hat{\epsilon}T - mT/Q}{T/Q} \right) e^{-j2\pi k \hat{\epsilon}} d\hat{\epsilon}$$

$$= \sum_{k=0}^{Q-1} \Lambda_{ML}(k) \times \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} \text{sinc} \left( \frac{\hat{\epsilon}T - mT/Q}{T/Q} \right) e^{-j2\pi \hat{\epsilon}} \hat{\epsilon} d\hat{\epsilon}$$

$$= \sum_{k=0}^{Q-1} \Lambda_{ML}(k) e^{-j2\pi k/TQ} \frac{1}{Q} \sum_{f=-\infty}^{\infty} \text{sinc}(\pi f) f = \hat{\epsilon}/Q.$$  \hspace{1cm} (15)$$

\[s' = [s(0) \ s(1) \ \cdots \ s(L_d - 1) s(0) \ s(1) \ \cdots \ s(2NL - 1)]\]  \hspace{1cm} (10)
where \( \mathcal{F} \{ \} \) denotes the Fourier transform. It is clear that if \( Q \) is even, we have the equation shown at the bottom of the page, and if \( Q \) is odd, we have the other equation shown at the bottom of the page.

From (13), it can be seen that once the coefficients \( A_\ell \) are determined, the timing delay \( \hat{\epsilon} \) can be estimated by maximizing \( \hat{A}_{ML}(\hat{\epsilon}) \) for \( 0 \leq \hat{\epsilon} \leq 1 \). Note that \( \hat{A}_{ML}(k) \) only contains samples of the approximated log-likelihood function at certain delays, while \( \hat{A}_{ML}(\hat{\epsilon}) \) is a continuous function of \( \hat{\epsilon} \). Therefore, maximizing \( \hat{A}_{ML}(\hat{\epsilon}) \) provides a more accurate estimate of the timing delay than maximizing \( \hat{A}_{ML}(k) \). For efficient implementation, the maximization can be performed by discrete Fourier transform (DFT)-based interpolation. More specifically, \( \hat{A}_{ML}(\hat{\epsilon}) \) for \( 0 \leq \hat{\epsilon} \leq 1 \) can be approximated by a \( K \)-point sequence, denoted as \( \hat{A}_{ML}(k') \) for \( 0 \leq k' \leq K - 1 \), by zero padding the high frequency coefficients of \( A_\ell \) and performing a \( K \)-point inverse discrete Fourier transform (IDFT). For a sufficiently large value of \( K \), \( \hat{A}_{ML}(k') \) becomes very close to \( \hat{A}_{ML}(\hat{\epsilon}) \) for \( 0 \leq \hat{\epsilon} \leq 1 \), and the index with the maximum amplitude can be viewed as an improved estimate of the timing parameter \( \hat{\epsilon} \).

To avoid the complexity in performing the \( K \)-point IDFT, an approximation is applied to (13). More precisely, extensive simulations show that \( A_{\pm 1} \) are much greater than \( A_\ell \) for \( |\ell| > 1 \); therefore,

\[
\hat{A}_{ML}(\hat{\epsilon}) \approx A_0 + 2 \Re\{A_1 e^{j 2\pi \hat{\epsilon}}\} \quad \text{for} \quad 0 \leq \hat{\epsilon} \leq 1
\]

(16)

where \( \Re\{x\} \) stands for the real part of \( x \). In order to maximize the approximated log-likelihood function \( \hat{A}_{ML}(\hat{\epsilon}) \), we have

\[
\arg(A_1) = -2\pi \hat{\epsilon}
\]

(17)

where \( \arg(x) \) denotes the phase of \( x \). Equivalently

\[
\hat{\epsilon} = -\frac{1}{2\pi} \arg \left\{ \sum_{k=0}^{Q-1} \hat{A}_{ML}(k)e^{-j2\pi k/Q} \right\}.
\]

(18)

The estimated delay \( \hat{\epsilon} \) is the time between the first sampling phase and the nearest optimum sampling instant. The calculation within the arg-operation is actually the second output of a \( Q \)-point DFT of the sequence (or the Fourier coefficient at symbol rate \( f = 1/T \)). Note that the increase in complexity of the proposed algorithm in (18) with respect to that of optimum samples selection algorithm is only a \( Q \)-point DFT (which can be efficiently implemented using Goertzel’s algorithm) and an arg-operation. From the simulation results to be presented at Section VII, it is found that an oversampling factor \( Q \) of four is sufficient to yield good estimates in practical applications. Therefore, the four-point DFT in (18) can be computed easily without any multiplications since \( \exp(-j2\pi k/4) \in \{\pm 1, \pm j\} \).

This greatly reduces the arithmetic complexity of implementation.

VI. PERFORMANCE ANALYSIS

We derive the MSE expressions of the proposed estimator as a function of \( E_s/N_0 \) in this section. First, express the true delay as

\[
\hat{\epsilon} = -\frac{1}{2\pi} \arg(e^{-j2\pi \epsilon}).
\]

(19)

Taking the difference between (18) and (19), the MSE is given by

\[
E[\hat{\epsilon} - \epsilon]^2 = \left( \frac{1}{2\pi} \right)^2 \mathbf{E} \left[ \left( \frac{\phi - \phi^*}{j(\phi + \phi^*)} \right)^2 \right]
\]

(20)

where

\[
\phi \triangleq e^{j2\pi \epsilon} \sum_{k=0}^{Q-1} \hat{A}_{ML}(k)e^{-j2\pi k/Q}.
\]

(21)

Applying the approximation \( \arg(x) \approx x \) for small \( x \), we have

\[
E[\hat{\epsilon} - \epsilon]^2 \approx \left( \frac{1}{2\pi} \right)^2 \mathbf{E} \left[ \left( \frac{\phi - \phi^*}{j(\phi + \phi^*)} \right)^2 \right] \]

(22)

\[
\approx - \left( \frac{1}{2\pi} \right)^2 \mathbf{E} \left[ \frac{\phi^2 - 2E[\phi^*] + E[(\phi^*)^2]}{\phi^2 + 2E[\phi^*] + E[(\phi^*)^2]} \right] \]

(23)

\[
= - \left( \frac{1}{2\pi} \right)^2 \frac{\Re\{E[\phi^2]\} - \Re\{E[\phi^*]\}}{\Re\{E[\phi^2]\} + \Re\{E[\phi^*]\}} \]

(24)

The second approximation is justified by the fact that the mean of the denominator \( \mathbf{E}[\phi + \phi^*]^2 \) is much larger than the mean of the numerator \( \mathbf{E}[(\phi - \phi^*)^2] \) (which is illustrated in Fig. 4 for \( \epsilon = -0.5, -0.25, 0, 0.25, \) and \( 0.5 \) with \( N = 2, M = 4, \) \( \alpha = 0.3, Q = 4, L_t = 32, \) and \( L = 4 \), and the variance of the numerator and denominator are much smaller than the mean of the denominator (which is true for medium to high SNRs). Some additional explanations regarding this approximation can be found in [18]. From (23) and (24), we have the fact \( \mathbf{E}[\phi^2]^2 \approx (\mathbf{E}[\phi^2])^2 \) was used.

It is proved in Appendix I that

\[
\mathbf{E}[\phi^2] = E_s L_t 2^4 M N e^{-j4\pi \epsilon} L_t^2 \left( \frac{1 + M N}{N^2} \right)_2^{S_S} \Sigma_{S} \]

\[
+ \left( \frac{E_s}{N_0} \right)^{-1} 2L_t N_0 \Sigma_{S}^{S_N} + \left( \frac{E_s}{N_0} \right)^{-2} \Sigma_{N_S}^{N_N} \]

(25)
Fig. 4. Magnitude of $E[(\phi - \phi^*)^2]$ and $E[(\phi + \phi^*)^2]$ as a function of $E_s/N_0$ for $\epsilon = -0.5, -0.25, 0, 0.25,$ and $0.5, (N = 2, M = 4, \alpha = 0.3, Q = 4, L_1 = 32, L = 4)$. Note that all curves for different values of $\epsilon$ overlap.

$$E[\phi^2] = E_s T_M N \left[ L_d^2 \frac{(1 + MN)}{N^2} \right] \Xi_{SS}^2$$

$$+ \left( \frac{E_s}{N_0} \right)^{-1} 2 L_d \Xi_{SN} \Xi_{SS}^2 + \left( \frac{E_s}{N_0} \right)^{-2} \Xi_{NN}^2$$

(26)

where

$$\Xi_{SS} \triangleq \sum_{k=0}^{Q-1} p^2(k'i'/Q - \epsilon'T)e^{-j2\pi k'/Q}$$

(27)

$$\Xi_{SN} \triangleq \sum_{k=0}^{Q-1} \sum_{k' = 0}^{Q-1} p(k'i'/Q - \epsilon'T)(k''T/Q - \epsilon'T)$$

$$\times \varphi((k' - k'')T/Q)e^{-j2\pi k''/Q} e^{-j2\pi k'/Q}$$

(28)

$$\Xi_{NN} \triangleq \sum_{k=0}^{Q-1} \sum_{k' = 0}^{Q-1} \varphi^2((k' - k''T/Q)e^{-j2\pi k'/Q} e^{-j2\pi k''/Q}$$

(29)

$$\Xi_{SN} \triangleq \sum_{k=0}^{Q-1} \sum_{k' = 0}^{Q-1} p(k'i'/Q - \epsilon'T)(k''T/Q - \epsilon'T)$$

$$\times \varphi((k' - k'')T/Q)e^{-j2\pi k''/Q} e^{-j2\pi k'/Q}$$

(30)

$$\Xi_{NN} \triangleq \sum_{k=0}^{Q-1} \sum_{k' = 0}^{Q-1} \varphi^2((k' - k''T/Q)e^{-j2\pi k'/Q} e^{-j2\pi k''/Q}$$

(31)

and

$$\varphi(\tau) \triangleq \int_{-\infty}^{\infty} g_s(t)g_0(t + \tau) dt$$

(32)

is the correlation between noise samples introduced by the matched filter.

Since the timing delay is assumed to be uniformly distributed, the average MSE can be calculated by numerical integration of (24).

VII. SIMULATION RESULTS AND DISCUSSIONS

The performances of the synchronizers based on the optimum sample selection (7) and the proposed algorithm (18) are evaluated in this section. The MSE of the estimates are calculated using both the analytic expressions derived in the last section and Monte Carlo simulations, where each MSE value is obtained by averaging over $10^5$ estimates. The timing offset $\epsilon$ is generated to be uniformly distributed in the interval $[-0.5, 0.5]$. The channel coefficients $h_{ij}$ are generated as complex Gaussian random variables with zero mean and a variance of 0.5 per dimension. The raised cosine pulse with excess bandwidth $\alpha = 0.3$ is considered. The training sequences are generated following the procedures in Section IV with $L = 4$. In all the figures, the MSE of both the proposed algorithm and the optimum sample selection algorithm are plotted against $E_s/N_0$, with the markers showing the simulation results while the solid lines represent the theoretical MSE derived in the last section.

A. Effect of Oversampling Ratio

In (12), it is assumed that the sampling frequency is at least twice the highest frequency of $\hat{\lambda}_{ML}(\hat{\theta})$. Since $\hat{\lambda}_{ML}(\hat{\theta})$ has the same shape as $|\hat{p}(t)|^2$ for $-T/2 \leq t \leq T/2$, where $\hat{p}(t)$ is a raised cosine pulse, it is natural to predict that the sampling frequency $Q/T$ has to be greater than $2 \times 2/T$ (i.e., $Q \geq 4$). This prediction is corroborated by Fig. 5, where the MSE are shown for $Q = 2, 4, 8, 16$ in a two-transmit four-receive antenna system with $L_d = 32$. Several conclusions can be drawn from the figure.

1) Performances of the optimum sample selection algorithm are lower bounded by $1/(12Q^2)$ and are poorer than that of the proposed algorithm, for all values of $Q$.
Fig. 5. MSE performance for different oversampling ratios \(Q(N = 2, M = 4, L_t = 32, \alpha = 0.3)\).

(2) It can be seen that for \(Q = 2\), the MSE of the proposed algorithm is much higher than that corresponding to other oversampling ratios. This confirms the above argument that \(Q\) has to be greater than four in order to represent \(\hat{\Lambda}_{ML}(\hat{\theta})\) without much loss of information. For \(Q = 8\) and 16 the performance improves at high \(E_s/N_o\). This can be explained by the fact that \(\hat{\Lambda}_{ML}(\hat{\theta})\) is a truncated version of \(|P(\hat{\theta})|^2\), so \(\hat{\Lambda}_{ML}(\hat{\theta})\) is no longer bandlimited. Therefore, \(\hat{\Lambda}_{ML}(\hat{\theta})\) would, in general, suffer from aliasing from the neighboring spectra. Increasing \(Q\) thus reduces the aliasing and improves the performance.

3) The analytical MSEs (solid lines in the figure) match very well with the simulation results for \(Q = 4, 8, \) and 16. Note that for \(Q = 2\), the analytic MSE expression does not hold and only the simulation results have been plotted in Fig. 5.

4) Strictly speaking, \(Q\) should be at least equal to 16 in order to represent \(\hat{\Lambda}_{ML}(\hat{\theta})\) using its samples \(\hat{\Lambda}_{ML}(m)\) without loss of information. However, for \(Q = 4\), the MSE of the proposed algorithm reaches the order of \(10^{-5}\) at medium and high \(E_s/N_o\), which is a reasonably good performance in practical applications. Because of this reason, \(Q = 4\) is used to generate the simulation results for the rest of this paper.

B. Effect of Length of Training Sequences

Fig. 6 shows the MSE of a two-transmit four-receive antenna system with different lengths \((L_d)\) of the training sequences. In this figure, it can be seen that increasing the length of training sequences improves the performance at low \(E_s/N_o\). But at high \(E_s/N_o\), the MSEs are the same for all \(L_d\). Again, the performance of the proposed algorithm is much better than that of optimum samples selection algorithm. It is also notable that the analytic MSE expressions match the simulation results very well.

C. Effect of Number of Receive Antennas

Fig. 7 compares the MSE for different numbers of receive antennas when two-transmit antennas and \(L_d = 32\) are used. We can see that increasing the number of receive antennas reduces the MSE at low \(E_s/N_o\) but it does not help at high \(E_s/N_o\). The proposed algorithm exhibits much smaller MSE than the optimum sample selection algorithm. When comparing the theoretical and simulation results of the proposed algorithm, it can be seen that they match pretty well except for the \(M = 1\) case. This is due to the fact that the \(\text{arctan}\) approximation in (22), in general, holds only for AWGN channels\(^3\) but not for fading channels. In the presence of fading, the channel output may assume a large range of values and the approximation does not hold anymore. Of course, a better approximation, such as \(\text{arctan}(x) \approx x - x^3/3 + x^5/5\) may be used, but the analysis would become extremely complicated as higher order moments are involved. Fortunately, as the number of transmit or receive antennas increases, the equivalent averaged channel across all transmit/receive antennas tends to behave like an AWGN channel and the approximation becomes valid again. This can be seen from the cases \(M = 2\) and \(M = 4\); the theoretical and the simulation results are closer when compared with the \(M = 1\) case. For \(M = 8\) and \(M = 16\), the theoretical and the simulation results match exactly.

\(^3\)Note that this approximation has been applied in similar applications [16], [17] in AWGN channels only.
Finally, we assess the MSE when different numbers of transmit antennas are used with $L_x = 64$. The results shown in Fig. 8 illustrate that increasing the number of transmit antennas does not change the MSE performance. The theoretical and the simulation results for the proposed algorithm match very well. Once again, the proposed algorithm performs much better.

**D. Effect of Number of Transmit Antennas**

A new symbol-timing delay estimator for ST coding systems has been proposed. It improves the optimum sample selection algorithm of Naguib et al. [4] such that accurate timing estimates are obtained even if the oversampling ratio is small. The increase in implementation complexity with respect to the optimum sample selection algorithm is very small. The require-
ments and the design procedure for the training sequences are discussed. Analytical expressions for MSE of the proposed estimator are derived. It is shown that the MSE analytical expressions match very well with the simulation results in most of the cases. Simulation results also show that for modest oversampling ratios (such as $Q = 4$), the MSE of the proposed estimator is significantly smaller than that of the optimum sample selection algorithm. Furthermore, the performance of the proposed algorithm improves with the number of receive antennas being employed or the length of training sequences.

**APPENDIX I**

**CALCULATION OF $E[\phi^2]$ AND $E[\phi\phi^*$]

Since we can construct orthogonal sequences such that (9) is satisfied, the ISI term in (6) vanishes. Further, with the fact that $||\mathbf{c}_i||^2 = L_t$, we have

$$
\Lambda_{ML}(k) = \sum_{i=1}^{N} \sum_{j=1}^{M} |\psi_{ij}(k)|^2 = W^2 h_{ij}^2 (kT/Q - \epsilon T) + v(k)
$$

where

$$W \triangleq \sqrt{E_s/NL_t},$$

$$h \triangleq \sum_{i=1}^{N} \sum_{j=1}^{M} |h_{ij}|^2,$$

$$v(k) \triangleq \sum_{i=1}^{N} \sum_{j=1}^{M} \left\{ |\mathbf{c}_i^H \mathbf{\eta}_j(k)|^2 \right\} + 2Wp(kT/Q - \epsilon T) \Re \left[ h_{ij} (\mathbf{c}_i^H \mathbf{\eta}_j(k))^* \right].$$

Then, (21) can be rewritten as

$$\phi = W^2 h_{ij} e^{j2\pi \epsilon' T} \sum_{k=0}^{Q-1} y^2 (kT/Q - \epsilon' T) e^{-j2\pi k/Q} + e^{j2\pi \epsilon' T} \sum_{k=0}^{Q-1} v(k) e^{-j2\pi k/Q}. \quad (37)$$

Before we proceed to the calculation of $E[\phi^2]$ and $E[\phi\phi^*]$, we first calculate the mean and the second moment of $v(k)$. Note the following facts:

$$E[h_{ij}(l_1 Q + k')] = 0 \quad \forall j, l_1, k' \quad (38)$$

$$E[h_{ij} h_{ij'}(l_1 Q + k')] = 0 \quad \forall i, j, j', l_1, k' \quad (39)$$

$$E[h_{ij}(l_1 Q + k') h_{ij'}(l_2 Q + k'')] = 0 \quad \forall j, j', l_1, l_2, k', k'' \quad (40)$$

$$E[h_{ij}(l_1 Q + k') h_{ij'}(l_2 Q + k'')] = N_o \varphi ((l_1 - l_2)Q + k' - k'' T)/Q) \delta_{jj'} \quad (41)$$

$$E[h_{ij} h_{ij'}^*] = \delta_{ii} \delta_{jj'} \quad (42)$$

where $\delta_{ii'} = 1$ if $i = i'$ and zero otherwise. Since the matched filter is a root raised cosine filter, we also have

$$\varphi(0) = 1 \quad (44)$$

$$\varphi(\tau) = \varphi(-\tau) \quad (45)$$

$$\varphi(IT) = 0 \quad \text{for} \ l \neq 0. \quad (46)$$

Let

$$v_{ij}(k) = |\mathbf{c}_i^H \mathbf{\eta}_j(k)|^2 + 2Wp(kT/Q - \epsilon T) \Re [h_{ij} (\mathbf{c}_i^H \mathbf{\eta}_j(k))^*] \quad (47)$$

\[\text{Fig. 8. MSE performance for different numbers of transmit antennas } N = 64, Q = 4, \alpha = 0.3, M = 2.\]
such that \( v(k) = \sum_{i=1}^{N} \sum_{j=1}^{M} v_{ij}(k) \). The mean of \( v_{ij}(k) \) is

\[
\mathbb{E}[v_{ij}(k)] = \sum_{L_1=1}^{L_1-1} \sum_{L_2=1}^{L_2-1} c_i(l_1)c_j(l_2)\mathbb{E}[\eta_j(lQ+k)\eta_j(l'Q+k)]
\]

\[
= \sum_{L_1=1}^{L_1-1} c_i(l_1)\mathbb{E}[\eta_j(lQ+k)^2]
\]

\[
= N_0L_1
\]

(48)

where in the first equality, we applied (39) and in the second equality, we applied (46). Therefore, \( \mathbb{E}[v(k)] = MN_0L_1 \) is a constant and independent of \( k \).

The second moment of \( v_{ij}(k) \) is given by

\[
\mathbb{E}[v_{ij}(k')v_{i'j'}(k'')] = \mathbb{E}\left[ c_i^H(\eta_j(k'))c_j^H(\eta_j(k'')) \right]^2 + 4W_2^2(k'T/Q - \epsilon'T)p(k'T/Q - \epsilon'T)
\]

\[
\times \mathbb{E}\left[ \Re\left[ h_{ij}^* (c_i^H\eta_j(k'))^* \right] \times \Re\left[ h_{i'j'} (c_j^H\eta_j(k''))^* \right] \right].
\]

(49)

Note that (39) makes the cross terms vanish. Considering the first term in (49)

\[
\mathbb{E}\left[ c_i^H(\eta_j(k'))^2 \right] = \mathbb{E}\left[ c_j^H(\eta_j(k''))^2 \right]
\]

\[
= \sum_{L_1=1}^{L_1-1} \sum_{L_2=1}^{L_2-1} c_i^2(l_1)c_j^2(l_2)c_{\eta}(l_3)c_{\eta}(l_4)
\]

\[
\times \mathbb{E}\left[ \eta_j(l_1Q+k')\eta_j(l_2Q+k') \right]
\]

\[
= \sum_{L_1=1}^{L_1-1} c_i^2(l_1)c_j^2(l_2)c_{\eta}(l_3)c_{\eta}(l_4)
\]

\[
\times \varphi((l_1 - l_4)T + (k' - k'')T/Q) \delta_{ij}. \]

(50)

Using the fact that if \( a,b,c,d \) are jointly Gaussian, then

\[
\]

(51)

and applying (38), (40), and (41), we have

\[
\mathbb{E}[\eta_j(l_1Q+k')\eta_j(l_2Q+k')\eta_j(l_3Q+k')\eta_j(l_4Q+k'')]
\]

\[
= N_0^2[\varphi((l_1 - l_4)T)\varphi((l_3 - l_4)T)]
\]

\[
+ N_0^2[\varphi((l_1 - l_4)T) + (k' - k'')T/Q) \times \varphi((l_2 - l_3)T + (k' - k'')T/Q) \delta_{ij}. \]

(52)

Plugging this result back into (50), we obtain

\[
\mathbb{E}\left[ c_i^H(\eta_j(k'))^2 \right] = N_0^2L_1^2 + N_0^2\left\{ \sum_{L_1=1}^{L_1-1} c_i^2(l_1)c_{\eta}(l_4)
\times \varphi((l_1 - l_4)T + (k' - k'')T/Q) \right. \]

\[
+ \sum_{L_1=1}^{L_1-1} c_i^2(l_2)c_{\eta}(l_3)
\times \varphi((l_2 - l_3)T + (k' - k'')T/Q) \left. \delta_{ij}. \right\}
\]

(53)

Consider first \( i \neq j \). We note that the second term in (53) is approximately zero since \( \varphi(\tau) \) is a decaying function of \( \tau \). When \( l_1 = l_4 \) or \( l'_1 - l'_4 \) is small, \( \varphi((l_1 - l_4)T + (k' - k'')T/Q) \approx 0 \) has significant values. But in these cases, \( \sum_{l_1=1}^{L_1-1} \sum_{l_1=1}^{L_1-1} c_i^2(l_1)c_{\eta}(l_4) = 0 \) since the training sequences are designed such that they are orthogonal when the relative delay is small. When \( |l_1 - l_4| \) is large, \( \varphi((l_1 - l_4)T + (k' - k'')T/Q) \approx 0 \). The same argument applies to \( \varphi((l_2 - l_3)T + (k' - k'')T/Q) \). For \( i = j \), the only case that the second term in (53) is nonzero is when \( l_1 = l_4 \) and \( l_2 = l_3 \). Therefore, we have

\[
\mathbb{E}\left[ c_i^H(\eta_j(k'))^2 \right] = N_0^2L_1^2 (1 + \varphi^2((k' - k'')T/Q)\delta_{ij}) \delta_{ij}. \]

(54)

Now consider the second term of (49) (ignoring the nonrandom part at this moment). Expanding it out and applying (42) and (43), we note that it is zero except for the case \( i = i' \) and \( j = j' \), in which case we have

\[
4N_0^2\mathbb{E}\left[ |h_{ij}|^2 \right] \times \mathbb{E}\left[ \Re\left[ h_{ij} (c_i^H\eta_j(k'))^* \right] \times \Re\left[ h_{i'j'} (c_{i'}^H\eta_{j'}(k''))^* \right] \right]
\]

\[
= 4N_0^2\left\{ \sum_{L_1=1}^{L_1-1} \sum_{L_2=1}^{L_2-1} c_i(l_1)c_{i'}(l_2)
\times \varphi((l_1 - l_4)T + (k' - k'')T/Q) \right. \]

\[
+ \sum_{L_1=1}^{L_1-1} c_i(l_1)c_{i'}(l_2)
\times \varphi((l_2 - l_3)T + (k' - k'')T/Q) \left. \times \varphi((l_1 - l_4)T) \right. \times N_0^2L_1^2 \varphi((k' - k'')T/Q) \delta_{ij}. \]

(55)

Plugging (54) and (55) back into (49), we obtain

\[
\mathbb{E}[(v(k'))^2(k'')]
\]

\[
= N_0^2L_1^2 + N_0^2L_1^2 \varphi^2((k' - k'')T/Q)\delta_{ij} \delta_{jj'}
\]

\[
+ 2N_0L_4W_2^2p(k'T/Q - \epsilon'T)p(k''T/Q - \epsilon'T) \times \varphi((k' - k'')T/Q) \delta_{ij}. \]

(56)

Finally

\[
\mathbb{E}[v(k')v(k'')]
\]

\[
= \sum_{j=1}^{N} \sum_{j'=1}^{N} \mathbb{E}[v_{ij}(k')v_{ij}(k'')]
\]

\[
+ \sum_{j=1}^{N} \sum_{j'=1}^{N} \sum_{j^\prime \neq j} \mathbb{E}[\eta_j(lQ+k')\eta_{j'}(lQ+k'')] \delta_{ij} \delta_{ij'}
\]

\[
= MN(N + \varphi^2((k' - k'')T/Q))N_0^2L_1^2
\]

\[
+ 2MN_0L_4W_2^2p(k'T/Q - \epsilon'T)p(k''T/Q - \epsilon'T) \times \varphi((k' - k'')T/Q). \]

(57)
Now, return to the calculation of $\mathbb{E}[\phi^2]$ and $\mathbb{E}[\phi^8]$. From (37), we have

$$
\mathbb{E}[\phi^2] = W^2 \mathbb{E}[h^2] e^{j\pi \varepsilon_0} \left( \sum_{k=0}^{Q-1} \nu^2 (kT/Q - \varepsilon T) e^{-j2\pi k/Q} \right)^2
+ e^{j\pi \varepsilon_0} \mathbb{E} \left[ \left( \sum_{k=0}^{Q-1} \nu(k) e^{-j2\pi k/Q} \right)^2 \right].
$$

(58)

The cross terms vanish since $h$ and $\nu(k)$ are uncorrelated and $\mathbb{E}[\nu(k)]$ is a constant and independent of $k$. Note that $h$ is a central chi-square random variable with $2MN$ degrees of freedom and the variance in each dimension equals 0.5, so $\mathbb{E}[h^2] = MN(1+MN)$. Using (57), it can be easily shown that

$$
\mathbb{E} \left[ \left( \sum_{k=0}^{Q-1} \nu(k) e^{-j2\pi k/Q} \right)^2 \right] = 2MN\nu_0\sigma^2 W^2 \Xi_{SN} + MN\nu_0^2 I^2 \Xi_{NN}
$$

(59)

where

$$
\Xi_{SN} \triangleq \sum_{k'}^{Q} \sum_{k''}^{Q-1} \Phi(kT'/Q - \varepsilon T) \Phi(k''T/Q - \varepsilon T) \times \phi_0(k' - k'')T'/Q e^{-j2\pi k''/Q} e^{-j2\pi k'/Q}
$$

(60)

$$
\Xi_{NN} \triangleq \sum_{k'}^{Q-1} \sum_{k''}^{Q} \phi_0^2 (k' - k'')T/Q e^{-j2\pi k''/Q} e^{-j2\pi k'/Q}.
$$

(61)

Plugging (59) back into (58), the expression for $\mathbb{E}[\phi^2]$ can be obtained and is given by (25). A similar procedure can be applied to obtain the expression for $\mathbb{E}[\phi^8]$.
