

## THE MACROBENTHIC FAUNA IN THE DUTCH SECTOR OF THE NORTH SEA IN 2004 AND A COMPARISON WITH PREVIOUS DATA

R. DAAN AND M. MULDER

This report presents data of the monitoring program of macrozoobenthos in the Dutch Continental Shelf (DCS) of the North Sea, a cooperation between the National Institute for Coastal and Marine Management/RIKZ (Rijkswaterstaat), the North Sea Directorate (Rijkswaterstaat) and the Department of Marine Ecology (NIOZ)

## 1. SUMMARY

In this report the results are presented of a macrobenthos survey on the Dutch Continental Shelf (DCS), carried out in 2004. The survey forms part of the 'Biological monitoring program of marine waters' (MON\*BIOLOGIE, generally referred to as 'BIOMON') which was initiated by the National Institute for Coastal and Marine Management (RIKZ). The purpose of the program is to obtain insight into the year-to-year variations of the macrobenthic assemblages and to detect trend-like changes, that possibly indicate anthropogenic influences on the marine environment (*e.g.* eutrophication, pollution, beam-trawl fishery).

Within the framework of this project fieldwork is carried out every year in spring. In 2004 the 100 BIOMON stations were sampled in the period between March 5 and April 6. On the basis of the results collected in 2004 and previous years an analysis is made of the trends and fluctuations of some selected species and of basic community attributes over the period 1986-2004. The community attributes studied were the diversity, abundance and biomass of the total macrofauna. Temporal variation or trends were investigated separately for each of the four subareas in the DCS *i.e.* the Coastal, Offshore areas, Dogger Bank and Oyster Ground. The conclusions of this study can be summarized as follows:

1. At the Dogger Bank the sand star *Acrocnida brachiata*, the bivalve *Mysella bidentata* the amphipod *Bathyporeia elegans* and the gastropod *Euspira nitida* showed increasing abundance after a decreasing trend in the preceding years. Nevertheless the total fauna abundance was relatively low due to low densities of a few normally abundant polychaete species. New to the Dogger Bank is the occurrence of the polychaete *Euclymene droebachiensis*.
2. In the Oyster Ground the decrease in average silt concentrations that was observed in the two preceding years continued in 2004. Between 1999 and 2004 the silt concentrations decreased at 33 of the 42 stations in this area. The decrease was particularly dramatic in the Frisian Front area. In the other subareas silt contents did not change and the median grain sizes were stable too.
3. In the Oyster Ground there is no indication that the decrease of the silt concentrations has affected the abundance of one or more of the most common species. Typical silt species like the brittlestar *Amphiura filiformis* and the crustacean *Callianassa subterranea* both increased. The polychaetes *Prionospio steenstrupi* and *Chone infundibuliformis* were found for the first time in the Oyster Ground. *P. steenstrupi* has previously been found only once in the offshore area; *C. infundibuliformis* was known from the Klaverbank and from a station north of the Dogger Bank.

4. The dip in fauna densities, observed in 2003 in the western part of the southern offshore area, has appeared to be just an incidental feature. The mean number of species per sample was in 2004 back at the usual level of the years before 2003. The density of the gastropod *Euspira nitida* had strongly increased. On the other hand some common polychaete species (*Magelona mirabilis*, *M. johnstoni*, *Chaetozone setosa*, *Lanice conchilega*, *Spiophanes bombyx* and *Aricidea minuta*) continued the decreasing trend observed in previous years. The crustacean *Leptognathia* spec., in 2003 found in the Oyster Ground, was found for the first time in the offshore area. New to the offshore area were also the polychaete *Thelepus cincinnatus* and the anthozoan *Peachia cylindrica*. Both were formerly known from the Klaverbank only.
5. In the coastal area biomass values were at the same high level as found in 2003. This was mainly caused by the abundance of the razor clam *Ensis americanus*. Although the numbers of *E. americanus* had decreased compared to 2003, biomass remained the same since growth of the surviving animals compensated the loss of biomass by mortality. The data suggest that growth of *E. americanus* is density dependent. A species new to the coastal area, and probably to the Dutch sector, is the polychaete *Malacoceros vulgaris*. The species was known from the German Bight. Another species that was not found before within BIOMON in the coastal area is the polychaete *Nereis diversicolor*. In fact this is an estuarine species and well known from the Wadden Sea.

## 2. SAMENVATTING

In dit rapport worden de resultaten gepresenteerd van een macrobenthos bemonstering die in 2004 werd uitgevoerd op het Nederlands Continentale Plat (NCP). De bemonstering vond plaats in het kader van het ‘Biologische Monitoring Programma Zoute Wateren’ (MON\*BIOLOGIE, gewoonlijk aangeduid als ‘BIOMON’), dat geïnitieerd is door het Rijksinstituut voor Kust en Zee. Met het project wordt beoogd inzicht te krijgen in de jaarlijkse fluctuaties van de macrobenthos gemeenschappen en vast te stellen of er op de langere termijn trendmatige veranderingen optreden. Dergelijke veranderingen zouden onder meer kunnen plaats vinden als gevolg van anthropogene activiteiten (bijv. eutrofiëring, verontreiniging, boomkorvisserij).

In het kader van dit project wordt jaarlijks veldonderzoek uitgevoerd in het voorjaar. In 2004 zijn de 100 BIOMON stations tussen 5 maart en 6 april bemonsterd. Aan de hand van de gegevens die in 2003 en voorgaande jaren zijn verzameld is een overzicht verkregen van de trends en fluctuaties bij een aantal geselecteerde soorten en een aantal kenmerken van de benthische gemeenschap als geheel over de periode 1986 - 2004. De parameters die de bodemgemeenschap kenmerken zijn hier de diversiteit, de dichtheid en de biomassa van de totale fauna. Temporele variatie en trends zijn voor vier subgebieden van het NCP, de Kustzone, het Offshore gebied, de Doggersbank en de Oestergronden, afzonderlijk onderzocht. De conclusies van deze studie kunnen als volgt worden samengevat:

1. Op de Doggersbank vertoonden de slangster *Acrocnida brachiata*, het tweetandschelpje *Mysella bidentata*, de amphipode *Bathyporeia elegans* en de gastropode *Euspira nitida* een toename, na een periode van afname in de voorgaande jaren. Toch was de totale faunadichtheid relatief laag, als gevolg van de geringe dichthesen van enkele gewoonlijk talrijke polychaetensoorten. Nieuw voor de Doggersbank is de vondst van de polychaet *Euclymene droebachiensis*.
2. In de Oestergronden zette de afname in slibgehalten van het sediment, zoals waargenomen in de voorgaande twee jaren, zich voort. Tussen 1999 en 2004 zijn de slibgehalten op 33 van de 42 stations in de Oestergronden gedaald. De afname was met name evident in het Friese Front gebied. In de andere subgebieden was er geen verandering in slib en ook de mediane korrelgrootte was constant.
3. In de Oestergronden bestaat er geen aanwijzing dat de afname van slibconcentraties gevlogen heeft gehad voor de dichthesen van een of meer van de meest algemene soorten. Karakteristieke slibsoorten als de slangster *Amphiura filiformis* en het kreeftje *Callianassa subterranea* namen de laatste jaren juist toe. Soorten die nog niet

eerder in de Oestergronden werden aangetroffen zijn *Prionospio steenstrupi* en *Chone infundibuliformis*, beide polychaeten. *P. steenstrupi* is voorheen slechts één keer aangetroffen in het offshoregebied. *C. infundibuliformis* was al bekend van de Klaverbank.

4. De bijzonder lage faunadichtheid die in 2003 in het westelijke deel van het zuidelijke offshoregebied werden gevonden bleek van tijdelijke aard te zijn. In 2004 was het aantal soorten per monster weer terug op het niveau van voor 2003. De gastropode *Euspira nitida* bleek in het gehele offshoregebied sterk te zijn toegenomen. Aan de andere kant had de afnemende trend die zich de afgelopen jaren had voorgedaan bij de polychaeten *Magelona mirabilis*, *M. johnstoni*, *Chaetozone setosa*, *Lanice cochilega*, *Spiophanes bombyx* en *Aricidea minuta* zich voortgezet. Nieuw voor het offshoregebied was de kreeftachtige *Leptognathia*, die eerder alleen een keer (in 2003) gevonden was in de Oestergronden. Ook nieuw waren de polychaet *Thelepus cincinnatus* en de anemoon *Peachia cylindrica*. Beide waren tot nog toe alleen bekend van de Klaverbank.
5. In de kustzone was de gemiddelde totale biomassa nog op praktisch hetzelfde hoge niveau als in 2003. Het hoge biomassagetal kwam met name voor rekening van de amerikaanse zwaardschede *Ensis americanus*. Hoewel de aantallen *E. americanus* in een jaar tijd wel waren afgenummerd bleef de biomassa op peil, doordat mortaliteit gecompenseerd werd door groei van de overlevende dieren. De data wijzen erop dat groei van *E. americanus* dichtheidsafhankelijk is. Een soort die nieuw is voor de kustzone, en waarschijnlijk voor het NCP, is de polychaet *Malacoceros vulgaris*. Deze soort was wel bekend van de Duitse Bocht. Binnen het BIOMON-programma was ook de polychaet *Nereis diversicolor* nog niet eerder in de kustzone aangetroffen. Dit is echter een estuariene soort, die algemeen bekend is van de Waddenzee.

### 3. INTRODUCTION

In 1989 the **BIO**logical **MON**itoring program of marine waters (project MON\* BIOLOGIE) was started with the goal to study the temporal variation of the marine ecosystems on the Dutch Continental Shelf (DCS) including the Wadden Sea and the Delta area. It is an initiative of the National Institute for Coastal and Marine Management (RIKZ) of Rijkswaterstaat in association with several Dutch institutes (Yland, 1995). The biological monitoring program comprises besides the macrobenthos also plankton, fish, seagrass, hard substrate populations, seabirds and mammals.

This report presents the data collected during the macrobenthos survey carried out in spring 2004. Further the results of the 2004 survey are compared with the BIOMON data collected in previous years (1991-2003) and those obtained during the ICES North Sea Benthos Survey (ICES-NSBS, 1986) and the MILZON-BENTHOS program (1988-1993). In 1990 a pilot study of the BIOMON project was carried out at 7 locations on the DCS and the results are also included in the data base.

The aim of the BIOMON program is to obtain insight in the spatial and temporal variation in the composition of the macrobenthos and to detect possible trendlike changes on the DCS as a whole or in parts of it. During the first years (1991-1994) there were 25 stations located along 5 transects perpendicular to the Dutch coast. At these stations 5 replicate boxcore samples were collected each year. Although in this way a rather detailed picture was obtained of the fauna composition at each of these stations, it was argued that (changes in) the macrobenthos composition of the DCS as a whole could better be studied by spreading the sampling effort over a larger number of stations. Therefore, from 1995 onwards the sampling strategy changed and each year 100 stations were visited, that were selected according to a stratified random sampling design in each of the 4 subareas of the DCS, i.e. Dogger Bank, Oyster Ground, Offshore area and Coastal area (Fig. 1). The number of stations within each subarea was proportional to its surface area. At each station only one sample was taken. The 100 stations that were selected include the 25 original BIOMON stations. The selection procedure is described in more detail by Essink (1995) and Holtmann *et al.* (1996).

The analysis of the results obtained in previous years (Daan & Mulder, 2004) has shown that there were generally no clear trends at the community level (faunal density, biomass, biodiversity parameters) in the 4 subareas. However, the southern part of the offshore area appeared to be extremely poor in fauna in 2003. Particularly the number of species per sample was very low that year. The new data may show whether this was just an incidental dip or a trendwise development.

At the species level there were some trendlike developments at the Dogger Bank and in the coastal area. At the Dogger Bank the sand star *Acrocnida brachiata*, the bivalve *Mysella bidentata* and the amphipod *Bathyporeia elegans* showed decreasing abundance between 2000 and 2003, whereas the polychaete *Aricidea minuta* had completely disappeared. In the coastal area the amphipod *Urothoe poseidonis* showed a continuous increase from 1998 onwards. Further, there was a strong increase of the razor clam *Ensis americanus*, particularly in terms of biomass.

In the Oyster Ground there was a recovery of the brittle star *Amphiura filiformis* after a dip of this species in the second half of the nineties, particularly in the Frisian Front area. Further no trendlike changes could be observed at the species level. This may seem remarkable, since there was a strong decrease in silt contents of the sediment in recent years. Apparently this decrease had no direct consequence with respect to the abundance of individual species.

The new data will show to what extent the trends observed in previous years continued in 2004.

#### 4. MATERIAL AND METHODS

To ensure that any changes that are observed are not due to methodological differences, the procedures for sampling and processing the fauna samples are standardized (Essink, 1991) and have remained unaltered since the beginning of the monitoring project in 1991.

##### 4.1. SAMPLING

In 2004 the BIOMON stations were sampled in the period March 5 to April 6. Most stations have a water depth >5 m and were visited with the RV Arca (North Sea Directorate, RWS). However, two stations in the Coastal subarea with a water depth less than 10 m, *viz.* COA 13 & 14 were sampled with the RV. Delta.

Fig. 1 shows the positions of the stations . The exact geographical positions of the 100 stations, together with the DONAR codes and selected abiotic characteristics (depth/sediment) of the stations are summarized in Table 1a/b. More general information about the cruise carried out with the vessel and the weather conditions during the survey in 2004 can be found in the cruise report of Rijkswaterstaat (Anonymous, 2004).

#### 4.2. SAMPLE TREATMENTS

At each station two boxcore samples ( $0.078 \text{ m}^2$ , minimal depth 15 cm) were taken. One of the samples was used for sediment analysis and the other sample was washed through a sieve with round holes (1 mm) to collect the macrobenthic fauna. For sediment analysis 2 subsamples (3.4 cm Ø, depth 10 cm) were pooled and immediately stored at -20°C. The residue of the macrobenthos samples was preserved in a borax-buffered solution of 4-6 % formaldehyde in seawater and stored at room temperature.

In the laboratory the macrobenthos samples were stained with rose-bengal and washed over a set of nested sieves with 0.7 mm as the smallest mesh size, to facilitate sorting. The macrofauna was identified to species level, except for some notoriously difficult taxa such as anthozoans, phoronids, priapulids and nemerteans, and subsequently counted. Juvenile macrobenthic animals which because of their size could not be identified to species level were recorded on higher taxonomic levels, usually the genus level. Sizes (to nearest 0.5 mm) were recorded for most molluscs and echinoderms.

#### 4.3. ASHFREE DRY WEIGHT

The ash-free dry weight (AFDW) of the different taxa was determined in one of the following ways:

- *Molluscs and echinoids:*

By means of length-AFDW relationships of the form  $W=a*L^b$  ( $W=\text{AFDW}$  in g and  $L=\text{length}$  in mm).

- *Polychaetes, larger crustaceans, ophiuroids and remaining taxa:*

Indirectly, by converting the (blotted) wet weight into AFDW by means of conversion factors provided by Rumohr *et al.* (1987) and Ricciardi & Bourget (1998). Wet weights were measured with a Mettler PJ300 balance to the nearest mg.

Small amphipods and cumaceans were assigned an average individual AFDW of 0.2-0.5 mg. The same value is used by Holtmann & Groenewold (1992; 1994) in their analysis of macrobenthos from the MILZON-BENTHOS project in the southern North Sea between 1991 and 1993. This estimated individual weight is based on previous determinations of the AFDW of the taxa in question (Duineveld; Holtmann, unpubl.).

#### 4.4. STATISTICS

In addition to the density (ind./m<sup>2</sup>) and biomass (g AFDW/m<sup>2</sup>), the diversity of each macrobenthos sample was calculated. In the literature a suit of biodiversity indices have been used to identify possible changes of the benthic fauna (Hill, 1973; Peterson, 1977; Pearson & Rosenberg, 1978; Harper & Hawksworth, 1994). In this report, we used three indices each representing a different aspect of the faunal diversity. The species richness ( $H_{\text{ill}_0}$ ) stands for the number of species per boxcore sample and is the simplest index. The other two indices, the Shannon-Wiener index ( $H'$ ) (Shannon & Weaver, 1949) and the Simpson index ( $D$ ) for dominance (Simpson, 1949), are based on the proportional abundances of the individual species in the samples. The Simpson index is sensitive to the abundance only of the commonest species and can therefore be regarded as a measure of dominance (Hill, 1973). A high value for Simpsons index means low diversity, whereas a high value for the  $H_{\text{ill}_0}$  or Shannon-Wiener index indicates high diversity.

#### 4.5. SEDIMENT ANALYSIS

At each station shown in Fig. 1, two subsamples were taken from an intact boxcore sample and subsequently pooled for laboratory analysis of the sediment composition (*e.g.* grain size, content of calcium carbonate). The grain size was analyzed with a Malvern Particle Sizer by the laboratory of the National Institute for Coastal and Marine Management (RIKZ, Middelburg). Two parameters were derived from the grain size data: the median grain size ( $\mu\text{m}$ ) and the percentage (by weight) of mud. We here define mud as the total fraction mineral particles  $< 63 \mu\text{m}$ . However, for comparison with previous years we also calculated the fraction  $16\text{-}63 \mu\text{m}$ .

Sediment types were classified on the basis of the median grain size as follows:

Characterization of the sediment type according to the median grain size (after Gullentops <i>et al.</i> , 1977).	
< 175 $\mu\text{m}$	Very fine sand
175 - 250 $\mu\text{m}$	Fine sand
250 - 300 $\mu\text{m}$	Medium-fine sand
300 - 350 $\mu\text{m}$	Medium-coarse sand
> 350 $\mu\text{m}$	Coarse sand

## 5. RESULTS AND DISCUSSION

### 5.1 SEDIMENT COMPOSITION

The median grain size and silt content of the sediment at the stations sampled are listed in Table 1. Spatial and temporal patterns are illustrated in Fig. 2, 3 and 4.

The spatial pattern in median grain size was quite similar to that in preceding years. As a result the mean median grain size in the four subareas appeared to be very stable (Fig. 4). A comparison between the values measured at the individual stations in 2004 (Fig. 2) and those found in 2003 shows that at only four stations the size class had changed. In fact, in none of these four stations there was a really big change, but the median grain size was about the critical level that separates two size classes, so that the measured value is sometimes just below this level, sometimes just above. The differences in median grainsize measured in 2004 and that measured in 2003 was at 88 stations less than 20 µm.

A relatively large median grain size was found at station OYS 8. Although in previous years the values varied already within a relatively broad range of 142 to 202 µm, the value of 232 µm found in 2004 seems to be substantially higher. Station OYS 8 is situated in the southern part of the Frisian Front area, close to the offshore area and therefore at a rather steep depth gradient leading from fine sand south of the station to very fine sand north of it. This might explain why there are relatively large local variations in median grain size.

The distribution of silt in the sediment roughly showed the same spatial pattern as in the preceding years, *i.e.* high silt concentrations in the Oyster Ground and low concentrations in the other subareas (Fig. 3). However, it was noticed already in 2003 that there has been a steady and significant decrease of silt concentrations in the sediment of the Oyster Ground. This decrease appeared to have continued in 2004. From 1999 onwards the mean silt content at the 42 stations in the Oyster Ground changed as follows

1999	2000	2001	2002	2003	2004
13.0 %	11.2 %	11.9 %	8.7 %	8.1 %	7.5 %

Fig. 5 shows that a decrease of silt concentrations took place at 33 of the 42 stations in the area. The strongest decrease was observed at stations where in the nineties the highest concentrations occurred. Particularly in the Frisian Front area, at the southern edge of the Oyster Ground, the change was dramatic. But also in the central part of the Oyster Ground there was a substantial decrease. Increased resuspension by elevated turbulence of near bottom water could be a possible cause for the loss of silt from (the

upper 10 cm of) the sediment. Wind conditions might have changed, resulting in a more frequent occurrence of stormy weather and increased resuspension. We therefore consulted the wind data collected by the Royal Netherlands Meteorological Institute (KNMI, de Bilt) at platform K13, near the southwestern edge of the Oyster Ground (Fig.6). The strongest decline in the silt concentrations was between March 2001 and March 2002. The figure shows that the two months before March 2002 were the most stormy period within the four years over which the measurements are plotted. However, it seems questionable whether this period was extreme enough to explain the strong decrease.

## 5.2. DISTRIBUTION OF THE MACROBENTHIC FAUNA IN 2004

### 5.2.1 Diversity, density and biomass

A total number of 199 species/taxa were identified in the 100 boxcore samples in 2004, including 1 that was identified to genus level only and 12 that were identified to higher taxa (family level or higher). The total number of taxa is within the range of previous years (181 – 231). The distribution of the species over the stations (presence/absence) and the scientific names are given in Appendix-1. The basic data on macrobenthic abundance, biomass and diversity are listed in Appendix-2.

The mean number of species per sample ( $Hill_0$ ) was, like in previous years the highest on the Dogger Bank and in the Oyster Ground and the lowest in the coastal and offshore area (Table 2, Fig. 7,10). There is an overall pattern of high species richness in the north and low species richness in the south. In the Oyster Ground a tendency for a slight increase in species richness can be observed from 1996 onwards. In the other subareas no clear long term trend can be observed in species richness.

As usual, the Shannon Wiener diversity was the highest at the Dogger Bank (Fig. 11). Numbers of individuals were more or less equally distributed among the species found, so Simpson's dominance was low here (Fig.12). Lower Shannon-Wiener diversity was found in the Oyster Ground and the offshore area respectively. In the Oyster Ground, the Shannon Wiener diversity tended to be lower in the period 2001 – 2004 than in the second half of the nineties. In contrast, Simpson's dominance was higher between 2001 and 2004. The cause of these changes is probably the recovery of populations of the brittle star *Amphiura filiformis*. This species occurred in low densities particularly in the second half of the nineties but returned as a highly dominant species in recent years. The opposite holds for the offshore area, where a slight increase could be observed in Shannon Wiener diversity and a decrease of Simpson's dominance. This can be explained by the fact that a few polychaete species (*Lanice conchilega*, *Chaetozone setosa* and *Spiophanes bombyx*),

which were particularly abundant in the mid-nineties and dominated the fauna by number, occurred in lower densities after 2000. As a result the numbers of individuals became more evenly distributed among the different species.

Compared to previous years, relatively low faunal densities were found at the Dogger Bank in 2004 (Table 2, Fig. 8, 13). The average density was about 20% lower than the lowest density found between 1995 and 2003. In contrast, relatively high macrofauna densities occurred in the Oyster Ground. Since 1999 there seems to be a gradual increase, particularly due to the recovery of *Amphiura filiformis*. In the offshore area there was no substantial change compared to previous years. However in the coastal area the average total fauna density was very low in 2004, even 20% lower than the lowest value found between 1995 and 2003. A main cause of the low overall fauna densities in the coastal area were the low abundance of the polychaetes *Spiophanes bombyx* and the *Magelona mirabilis/M. johnstoni* group. But also the populations of the mollusc *Spisula subtruncata* were at a low abundance level. In neither of the four subareas a substantial change could be observed in the contribution of the different taxonomic groups to the total fauna abundance.

After very low biomass values at the Dogger Bank in 2002, a clear sign of recovery could be observed in 2003 (Fig. 14). This recovery seemed to continue in 2004. Unless low overall faunal densities, the average biomass further increased. It was noticed already that the 'recovery' of biomass at the Dogger Bank in 2003 was largely caused by the return of (only a few) large specimens of the sea urchin *Echinocardium cordatum* in the samples (Daan & Mulder, 2004). A few even larger specimens were present in the samples in 2004. Based on their size these animals must have been at least four years old (Duineveld & Jenness, 1984). This means that these animals must have been living at the Dogger Bank already in 2002. Apparently this generation was absent in the samples in 2002, just by incident.

In the Oyster Ground, there has been a slight but continuous increase in biomass from 1997 onwards (Fig. 14). This trend seems to have continued in 2004, partly due to the increase of the brittle star *Amphiura filiformis*. Note that the peak biomass value in 2002 was explained completely, by the incidental occurrence of one very large specimen of the otter-shell (*Lutraria lutraria*) in one Oyster Ground sample.

In the offshore area biomass values seem to be stable since 1995. However, in the coastal area there has been a strong increase in biomass between 2002 and 2003 (Daan & Mulder, 2004). The increase was caused by the biomass increase of the bivalve *Ensis americanus*. This species had a very successful spatfall in 2001 and in spring 2002 large numbers of juvenile specimens were found at several stations. In 2003 the densities were still high, but now the juveniles of 2002 had grown up to a size of 5 to 10 cm, which

explains the strong biomass increase. In 2004 the biomass was still at the high level of 2003. Although the numbers of *E. americanus* in the samples had substantially decreased, the total biomass of the species remained the same, since growth of the surviving animals compensated the loss of biomass by mortality.

### 5.2.2. TEMPORAL VARIATION IN DENSITY AND BIOMASS OF INDIVIDUAL SPECIES

Figs. 15-18 illustrate the temporal variation in density or biomass of a number of individual species in the 4 subareas during the period 1986-2004.

#### Dogger Bank (Fig. 15a-c)

For three species that had shown a decreasing trend in the preceding years this trend came to an end in 2004. The sand star *Acrocnida brachiata*, the bivalve *Mysella bidentata* and the amphipod *Bathyporeia elegans* all occurred in increased abundance in 2004. Also the gastropod *Euspira nitida*, which was found in relatively low abundance in the preceding years, seemed to have considerably increased in the past season. In contrast, the polychaete species *Magelona mirabilis/M.johnstoni*, *Chaetozone setosa* and *Spiophanes bombyx* and the amphipod *Urothoe poseidonis* were found to be rather scarce in 2004. The polychaete *Aricidea minuta*, absent since 1999, was still absent in 2004.

A species new to the Dogger Bank is the polychaete *Euclymene droebachiensis*. In 2004 5 specimens were found at station DOG 7, at the border line with the British sector. We could find only one record of this species from the Dutch sector: van Moorsel (2003) found the species in 2002 at a few stations on the Klaverbank. Further the species is known from the deeper parts of the Central North Sea, north of the Dogger Bak and the Dutch sector. Here de Wilde & Duineveld (1988) found *E. droebachiensis* at 6 stations during the Synoptic Mapping of 1986. At the stations where the species occurred, the number of specimens found was generally more than one.

#### Oyster Ground (Fig. 16a-c)

In the Oyster Ground the brittle star *Amphiura filiformis* continued its recovery from the dip in population densities in the second half of the nineties. At two stations densities were found exceeding 3000 individuals per m<sup>2</sup>. Recovery of *A. filiformis* included the Frisan Front area, where a strong decrease had been observed since 1993. The crustacean *Callianassa subterranea* also shows a gradual numerical increase in recent years. The species has shown a more or less similar long-term trend as found in *A. filiformis*, i.e. a decreasing trend from 1993 onwards and an increasing trend from 2000.

Recently, experiments by Amaro (in prep.) have shown differential impact of *A. filiformis* and *C. subterranea* on the silt-retaining properties of sediments. The results of these experiments showed that high densities of the deposit feeding *C. subterranea* lowered the resistance of sediments to erosion and promoted resuspension of silt into the water column. In contrast, high densities of the filter feeding *A. filiformis* promoted the silt-retaining properties of sediment, whereas at low densities resuspension increased. This finding is interesting since the decreased silt concentrations could possibly be related to changes in the populations of both species. Such a relation, however, seems ambiguous. Indeed, on the one hand the decrease in silt concentrations corresponds with the increase in *C. subterranea* densities. On the other hand, it did not correspond with a decrease in *A. filiformis* densities. In other words, there is no unequivocal relationship.

The bivalve *Nucula nitidosa* shows, from the mid-nineties on a gradual increase. Densities in 2004 were substantially (about 3 to 5 times) higher than in the first half of the nineties. The decreasing trend in the tube-building polychaete *Chaetopterus variopedatus* continued in 2004. The low silt concentrations do not satisfactorily explain this trend, since the decrease started in 2001, when the silt concentrations were still at a high level.

There were two polychaete species that had not been observed in the Oyster Ground before. One specimen of *Prionospio steenstrupi* was present in the sample of OYS 25 in the central Oyster Ground. The species was found only once before, at station OFF 9, west of Petten, in 2000 (Daan & Mulder, 2001). The other species was *Chone infundibuliformis*, present at station OYS 40, at the border with the German sector. On the DCS this species was only known from the Klaverbank (van Moorsel, 1991, 2003). Further the species has been recorded at two stations just north of the Dogger Bank and the Dutch sector during the Synoptic Mapping (de Wilde & Duineveld, 1988).

#### Offshore area (Fig. 17a-c)

In the offshore area there was a strong increase in the average abundance of the gastropod *Euspira nitida*. This increase was partly caused by the very high abundance of *E. nitida* at three stations (OFF 11, 12 and 13) in the northwestern part of the offshore area. At each of these stations the density was well beyond 200 individuals per m<sup>2</sup>, which is higher than found anywhere before in the offshore area. However, also at the other stations the average density had doubled compared to the preceding year.

There were some polychaete species in the offshore area that had shown a decreasing trend in recent years. These species, *Magelona mirabilis/M. johnstoni*, *Chaetozone setosa*, *Lanice conchilega* and *Spiophanes bombyx*, all continued this trend in 2004. Further, also *Aricidea minuta* occurred in lower abundance than in previous years.

Station OFF 33 was in 2004 not as rich (25 species) as it used to be in preceding years (>30 species). However, among the offshore stations it was still one of the richest stations and accommodated such particular mollusc species as *Alvania lactea*, *Tornus subcarinatus*, *Striarca lactea* and Polyplacophorans.

The area immediately south of OFF 33 has shown to be extremely poor in fauna in 2003 and the question was raised, whether the low numbers of species at the 10 stations in this area in 2003 marked the onset of a trendwise decrease. However, the data collected in 2004 show that the species richness at these stations had recovered to values well beyond 10 species per sample, i.e. the usual level of the years before 2003. In other words, there does not seem to be a trendwise decrease in the southwestern offshore area, but only an incidental dip of low duration..

A species not found before in the offshore area is the crustacean *Leptognathia spec.*. In 2003 we found this species for the first time, in the Oyster Ground. We couldn't find any other record from the North Sea. Three other species are new within the BIOMON programme. Two of them were present in the sample of station OFF 27, west of Zeeland. The polychaete *Thelepus cincinnatus* has been found in the Dutch sector only at the Klaverbank (van Moorsel, 2003). Further this species was observed during the Synoptic Mapping at one station northwest of the Dogger Bank (de Wilde & Duineveld, 1988). The other species was the anthozoan *Peachia cylindrica*, a burrowing anemone capable of existing in relatively unstable sands, probably due to its large size and ability to bury itself deeply in the substratum (Manuel, 1981). For the North Sea we could find only two records of this species, both from the Klaverbank (van Moorsel, 1991. 2003). Finally, the polychaete *Eteone flava* was found at station OFF 22, west of Noordwijk. For this species however, there are a number of records from other research programmes at stations in both the offshore area and the Oyster Ground (Mulder, 1986; Mulder et al., 1987; Holtmann & Groenewold, 1992, 1994; Daan et al., 1990).

#### Coastal area (Fig. 18a-c)

In the coastal area the bivalve *Spisula subtruncata* was found at only a few stations and only in low numbers. The *Spisula* banks that were found on the stations COA 3, 4, 6 and 9 in 2000 have gradually disappeared after 4 years, which has resulted in a very low average density in 2004, but there does not seem to be a long-term decreasing trend.

The american razor clam *Ensis americanus* still occurred in high densities in 2004. Indeed, there was a slight numerical decrease compared to 2002 and 2003, but the average density was still higher than ever before 2002 and biomass had not decreased. The major part of the *E. americanus* populations existed of the year class that settled as larval recruits in 2001 and were found as juveniles for the first time in 2002 (Daan & Mulder,

2004). The growth of this year class can be followed at 5 coastal stations where the species was particularly abundant (Fig. 19a/b). The initial densities and size of the juveniles found in 2002 differed substantially between the stations. The highest numbers were observed at station COA 2 near Ameland, but the animals were the smallest here. This might be explained by suboptimal feeding conditions or late settlement. However, it might also indicate that the high densities induced intraspecific competition already among juveniles and, thus, food limited conditions under which growth was not optimal. The largest juveniles occurred in 2002 at COA 8 and 11, near Terschelling and Noordwijk respectively. Animals of intermediate size occurred at COA 3 and 15, near IJmuiden and Voorne-Putten. After 2002 the growth rates were obviously different between stations. Near Ameland and Terschelling the densities remained relatively high, but growth was slow. Near Ameland the animals had grown up to an average of 75 to 80 mm in 2004 and near Terschelling to 90 to 95 mm. At the other three stations the densities were relatively low, but the average size had increased to an average of 110 to 115 mm. These results indicate that enhanced intraspecific competition for space and/or food might have substantially suppressed growth rates in the case of high population densities. This would mean that growth of *E. americanus* in the coastal area is density dependent.

A species new to the BIOMON programme is the polychaete *Malacoceros vulgaris*. We could not find any other record from the Dutch sector. The species is not new to the North Sea. Its occurrence has been mentioned from the area around Helgoland (Harms, 1993). Another species that was not found before during BIOMON is the polychaete *Nereis diversicolor*. However, this species was already reported from the coastal area by Kluijver & Nieuwenhuizen (1998) and there is one unpublished record from a NIOZ course in 2000. In fact *N. diversicolor* is an estuarine species and it is very well known from the Wadden Sea (e.g. Tydeman, 2000; Dekker & Waasdorp, 2004).

## 6. Acknowledgements

The monitoring program is initiated by the National Institute for Coastal and Marine Management (RIKZ), with J. de Vlas and F. Quené as project leaders, and is carried out in cooperation with the North Sea Directorate (DNZ) and the department of Marine Ecology of the NIOZ. We want to thank the captain and crew on board of the RV Arca and RV Delta for their assistance during the fieldwork, W. Schreurs and G. den Hartog (RIKZ Middelburg) for the analysis of the sediment samples, J. de Vlas for critically reading the original manuscript, M. van Arkel for his contribution in the organization and H. Hobbelink for the cover design.
