Abstract. Observations along the southwestern Atlantic WOCE A17 line made during the Dutch GEOTRACES-NL programme (2010–2011) were compared with historical data from 1994 to quantify the changes in the anthropogenic component of the total pool of dissolved inorganic carbon (C_{ant}). Application of the extended multilinear regression (eMLR) method shows that the C_{ant} from 1994 to 2011 has largely remained confined to the upper 1000 dbar. The greatest changes occur in the upper 200 dbar in the Subantarctic Zone (SAZ), where a maximum increase of 37 µmol kg⁻¹ is found. South Atlantic Central Water (SACW) experienced the highest rate of increase in C_{ant}, at 0.99 ± 0.14 µmol kg⁻¹ yr⁻¹, resulting in a maximum rate of decrease in pH of 0.0016 yr⁻¹. The highest rates of acidification relative to C_{ant}, however, were found in Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW). The low buffering capacity of SAMW and AAIW combined with their relatively high rates of C_{ant} increase of 0.53 ± 0.11 and 0.36 ± 0.06 µmol kg⁻¹ yr⁻¹, respectively, has lead to rapid acidification in the SAZ, and will continue to do so whilst simultaneously reducing the chemical buffering capacity of this significant CO₂ sink.

Introduction

The Atlantic Ocean contains the largest store of anthropogenic carbon (C_{ant}) of all the world’s oceans, accounting for approximately 38% of the total C_{ant} inventory (Sabine et al., 2004). Within the Atlantic, the North Atlantic has been found to be responsible for the majority of the uptake of C_{ant}, due to the formation of North Atlantic Deep Water (NADW; Lee et al., 2003; Sabine et al., 2004). However, a recent Atlantic Basin inventory analysis indicates that in the past decade the South Atlantic has been more effective at sequestering C_{ant} (Wanninkhof et al., 2010) than the North Atlantic. These authors calculated a rate of increase in the North Atlantic inventory of 1.9 Pg C decade⁻¹, whereas the South Atlantic inventory grew at a rate of 3.0 Pg C decade⁻¹.

Calculations by Ríos et al. (2012) indicate that the southwestern Atlantic Ocean dominates the South Atlantic sink of C_{ant}, with a storage rate of 0.25 ± 0.035 Pg C decade⁻¹. Quantifying the exact rate of increase in anthropogenic carbon in ocean waters is inherently problematic due to the highly variable nature of dissolved inorganic carbon (DIC) within the ocean and the relatively small fraction of total DIC that the anthropogenic component represents (~3%; Ríos et al., 2010). In the past decade, a number of methods for calculating the increase in C_{ant} (ΔC_{ant}) between reoccupation of ocean transects have been developed (TrOCA, φC_{T}, eMLR). Despite the differing approaches and assumptions, there is overall coherence in the determinations of the anthropogenic
component of inorganic carbon in the Atlantic Ocean (Lee et al., 2003; Vázquez-Rodríguez et al., 2009a; Peng and Wanninkhof, 2010; Wanninkhof et al., 2010). The southwestern Atlantic has been occupied several times over the past 20 years, and several techniques to determine \( C_{\text{ant}} \) have been applied to the WOCE ’94 A17 transect by Ríos et al. (2010). These methods included \( \Delta C^* \) (Gruber et al., 1996), TrOCA (Tracer combining Oxygen, inorganic Carbon and total Alkalinity; Touratier et al., 2007), \( \delta C_{\text{T}}^* \) (Vázquez-Rodríguez et al., 2009a), and TTD (transit time distributions; Waugh et al., 2006) and showed general conformity in the distribution of \( C_{\text{ant}} \). The presence of the western boundary current in the South Atlantic Ocean means that the \( C_{\text{ant}} \) signal penetrates deeper and is larger in the western half of the basin compared to the eastern half (Wanninkhof et al., 2010; Ríos et al., 2010; Vázquez-Rodríguez et al., 2009a). Similarly, Murata et al. (2008) show that the \( C_{\text{ant}} \) signal in Subantarctic Mode Water (SAMW) can be \( \sim 7 \mu \text{mol kg}^{-1} \) higher west of 15° W compared to the east. Mode and intermediate water formation constitute a major pathway of \( C_{\text{ant}} \) into the South Atlantic Ocean interior (McNeil et al., 2001; Sabine et al., 2004). The SAMW is formed in the Subantarctic Zone (SAZ), between the Subtropical Front (STF) and Subantarctic Front (SAF), where a calculated anthropogenic \( \text{CO}_2 \) uptake of 0.07–0.08 Pg C yr\(^{-1} \) occurs (Sabine et al., 1999; McNeil et al., 2001). A total \( \text{CO}_2 \) sink of 1.1 Pg C yr\(^{-1} \) was calculated by McNeil et al. (2007) for the SAZ, making it the largest \( \text{CO}_2 \) sink in the Southern Ocean and a significant sink for anthropogenic atmospheric \( \text{CO}_2 \).

The increase in DIC that results from the uptake of anthropogenic \( \text{CO}_2 \) from the atmosphere leads to increasing proton, bicarbonate ion and carbon dioxide concentrations (\( \text{H}^+ \), \( [\text{HCO}_3^-] \), \( [\text{CO}_2] \)) and decreasing carbonate concentrations (\( [\text{CO}_3^{2-}] \)), a process referred to as ocean acidification. Sabine et al. (2004) state that approximately 50% of the total amount of \( C_{\text{ant}} \) in the world’s oceans resides in the upper 400 m. The associated decrease in pH has been calculated as 0.1 pH units in the surface ocean relative to pre-industrial times (Orr et al., 2005) and is ongoing. In the North Atlantic Ocean, observations have found acidification rates of 0.0016 ± 0.0001 and 0.0012 ± 0.0002 yr\(^{-1} \) for Subantarctic Intermediate Water (SAIW) and Subpolar Mode Water (SPMW), respectively (Vázquez-Rodríguez et al., 2012). Data from the European Time Series in the Canary Islands (ESTOC) station show significantly higher rates of pH decrease in surface waters of 0.0017 ± 0.0004 yr\(^{-1} \) for the time period 1995 to 2004, with notable influence from regional climatic forcing (Santana-Casiano et al., 2007). Acidification rates that deviate from the rate that is expected from \( C_{\text{ant}} \) increases alone have been observed in upper Labrador Sea Water (uLSW), SAIW, and eastern North Atlantic Central Water (eNACW; Vázquez-Rodríguez et al., 2012). These variations have been attributed to a combination of climatic and biological effects. The greater sensitivity of some water masses to acidification has been well documented by González-Dávila et al. (2011) through the application of the buffering factors described by Egleston et al. (2010). González-Dávila et al. (2011) highlighted waters originating at high latitudes as particularly sensitive to increases in the concentration of dissolved \( \text{CO}_2 \) (\( [\text{CO}_2] \)), in particular Antarctic Intermediate Water (AAIW) and upper Circumpolar Deep Water (uCDW) due to low ratios of total alkalinity (\( A_T \)) to DIC.

A number of the biological consequences of ocean acidification are related to the changes in carbonate, and thus calcium carbonate (\( \text{CaCO}_3 \)), ion concentration. Carbonate ions are used by marine calcifying organisms to form both varieties of calcium carbonate: aragonite (e.g. by pteropods) and calcite (e.g. by coccolithophores and foraminifera). Aragonite is the less metastable form of \( \text{CaCO}_3 \) resulting in a saturation horizon (\( \Omega_{\text{AR}} = 1 \)) approximately 2 km shallower than that of calcite in the South Atlantic Ocean, below which depth the \( \text{CaCO}_3 \) present will be in dissolved form. A number of experiments have observed shell dissolution in pteropods incubated at elevated partial pressure of \( \text{CO}_2 \) (\( p\text{CO}_2 \)) (Orr et al., 2005; Lischka et al., 2011) associated with a lowering of the aragonite saturation state. Recently similar results have been observed in situ in the Southern Ocean (Bednarek et al., 2012), indicating that species are already being affected by \( C_{\text{ant}} \) accumulation. Organisms that use aragonite are thus much more vulnerable to decreases in \( [\text{CO}_3^{2-}] \) driven from the surface increase in \( [\text{CO}_2] \).

This study examines the increase in \( C_{\text{ant}} \) in the southwestern Atlantic Ocean between two occupations of the WOCE A17 line, which took place in 1994 and 2010/2011. We calculate the changes in \( C_{\text{ant}} \) (\( \Delta C_{\text{ant}} \)) in the different water masses and subsequently examine the pH changes driven by the invasion of anthropogenic carbon between WOCE ’94 A17 and GEOTRACES-NL (2010/2011). These results are furthermore put into context with regard to the differing buffering capacities of individual water masses.

### 2 Data

The two data sets used in this study are the results from the \( \text{CO}_2 \) survey data from the WOCE ’94 A17 section (public data at http://cdiac.ornl.gov/oceans/woce_a17c.html) and the Dutch West Atlantic GEOTRACES programme, completed in 2011 (GEOTRACES-NL, 2010/2011; public data available at http://www.bodc.ac.uk/geotraces/data/idp2014/). The respective stations from the two campaigns are shown in Fig. 1. The GEOTRACES-NL (2010/2011) section was carried out in two parts. The shown stations north of the Equator were occupied in July 2010 by the Dutch RV Pelagia (expedition 64PE321: from Hamilton, Bermuda, to Fortaleza, Brazil), and the Southern Hemisphere was sampled during March 2011 by the British RRS James Cook (JC057: from Punta Arenas, Chile, to Las Palmas, Gran Canaria).
From DIC, \( A_T \) and DIC data from both the WOCE '94 A17 and GEOTRACES-NL (2010/2011) data sets, with the resulting pH reported on the total pH scale.

2.2.2 Ancillary parameters

Dissolved oxygen samples were collected from a minimum of three depths throughout the water column for CTD sensor calibration. Inorganic nutrients (PO\(_4^3\), Si(OH)\(_4\), NO\(_3\)) were analysed following the methods of Grasshoff et al. (1983). In every run, a control and a naturally sterilized reference nutrient sample (RMNS, Kanbo, Japan) were measured for validation. Precision was estimated to be ±0.01, 0.2 and 0.2 \( \mu \text{mol L}^{-1} \) for PO\(_4^3\), Si(OH)\(_4\) and NO\(_3\), respectively. Values of salinity are reported on the practical salinity scale.

2.2.3 pH calculations

From DIC, \( A_T \) and supplementary data (salinity, temperature, pressure, Si(OH)\(_4\), PO\(_4^3\)), pH, and \( p\text{CO}_2 \) were also calculated in situ for both data sets using CO2_SYS (Lewis and Wallace, 1998) adapted for MATLAB (van Heuven, 2011a), applying the acid dissociation constants of Mehrbach et al. (1973), refitted by Dickson and Millero (1987), and the KSO\(_4\) constant of Dickson (1990). Identical calculations were carried out on \( A_T \) and DIC data from both the WOCE '94 A17 and GEOTRACES-NL (2010/2011) data sets, with the resulting pH reported on the total pH scale.
2.3 Consistency between data sets

In a later section, we employ the extended multi-linear regression (eMLR) method (Wallace, 1995; Friis et al., 2005) to infer $\Delta C_{\text{ant}}$ between the two cruises. The eMLR method considers various biogeochemical properties (in this case salinity, DIC, NO$_3$, Si(OH)$_4$ and apparent oxygen utilization (AOU) = [O$_2$]$_{\text{sat}}$−[O$_2$]$_{\text{obs}}$) and is particularly sensitive to large-scale (“secular”) changes in the distributions of these properties, as well as to analytical biases in their measurement. In order to assess the magnitude and distributions of these changes, we gridded the values of salinity, DIC, NO$_3$, Si(OH)$_4$ and AOU of each data set, and the gridded WOCE data set was subtracted from the GEOTRACES grid. Grid spacing was every 2° of latitude, with 80 layers in the vertical direction, with increased density towards the surface. In the lower Circumpolar Deep Water (ICDW; conceivably the most stable water mass in the section), the differences average $-0.01 \pm 0.015$ (salinity), $-4.2 \pm 12.1$ (DIC), $-1.92 \pm 0.78$ (NO$_3$), $-5.05 \pm 3.3$ (Si(OH)$_4$) and $-3.13 \pm 3.9$ µmol kg$^{-1}$ (AOU).

By limiting the comparison to just ICDW, the number of data points available is limited; as such, we further performed a more robust crossover analysis of the GEOTRACES 2010/2011 data set with data from the CARINA database (CARINA Group, 2009; Tanhua, 2010). This was done for all the tracers used at depths deeper than 3000m. We find an offset of $+1 \pm 0.8$ % for NO$_3$, $-1 \pm 0.5$ % for dissolved oxygen, $-0.004 \pm 0.001$ for salinity, $-1 \pm 0.3$ % for Si(OH)$_4$, $+1.17 \pm 2.8$ µmol kg$^{-1}$ for DIC, and $+5.3 \pm 4.4$ µmol kg$^{-1}$ for $A_T$. These values are all within the threshold values of the CARINA synthesis (Key et al., 2010); thus no corrections were applied to our data.

3 Methods

3.1 eMLR and $C_{\text{ant}}$ calculations

There are two general carbon data-based approaches for studying the increasing oceanic $C_{\text{ant}}$. The first approach uses back-calculation techniques to obtain an estimate of pre-industrial DIC concentration against which to compare current measurements. Methods from the second approach aim to determine the part of change in DIC between two specific time periods that is attributable to anthropogenic invasion. One example of each approach is employed in this study: eMLR (Friis et al., 2005) and $\phi C_T$ (Vázquez-Rodríguez et al., 2009a, b). Various comparison and evaluations of these methods and other methods are available in the literature (Levine et al., 2008; Yool et al., 2010; van Heuven et al., 2011b; Sabine and Tanhua, 2010).

3.1.1 $\Delta C_{\text{ant}}$ from eMLR

The multi-linear regression approach to estimating anthropogenic CO$_2$ invasion was introduced by Wallace (1995). It involves using a number of biogeochemical properties that are known to be related to DIC to fit a model of the observed DIC. As the relationships between DIC and these properties are expected not to change over time, the same statistical relationships can be applied to a second data set of later date. Differences between the thus “predicted” DIC and the observed DIC are attributed to the invasion of anthropogenic CO$_2$. In the extended version (eMLR) developed by Friis et al. (2005), which is applied here, the DIC from two data sets is fitted to the same selection of properties from both data sets, and the difference between parameter coefficients is assumed to be predictive of the difference in $C_{\text{ant}}$ between the two cruises:

$$\Delta C_{\text{ant}} = C_{\text{MLR}_2} - C_{\text{MLR}_1},$$

$$= (a_2 - a_1) + (b_2 - b_1)\text{SiO}_{2,12} + (c_2 - c_1)\text{NO}_{3,2} + (d_2 - d_1)\text{AOU}_{12} + (e_2 - e_1)S_{12} + (f_2 - f_1)T_{12} + (g_2 - g_1)P_{12}. \tag{2}$$

Following Eq. (2), we apply the back-calculation technique as the DIC data from the more recent GEOTRACES-NL (2010/2011) cruise demonstrate a greater precision. The properties used to predict DIC in the WOCE ’94 data set result in an $R^2$ value of 0.97 and a root-mean-square error (RMSE) of 10.7 µmol kg$^{-1}$. For the GEOTRACES-NL (2010/2011) data set a $R^2$ of 0.98 was obtained and an RMSE of 9.9 µmol kg$^{-1}$ (Fig. 2).

The eMLR regressions were applied along isopycnal intervals, as the preferred method of water movement from the surface into the ocean interior is along surfaces of constant density. It thus follows that waters occupying the same density band share a common formation history and can be described by a single equation. Isopycnal bands were chosen based on temperature–salinity plots of the water masses and the amount of data occupying each interval. The coefficients and accompanying statistics from each isopycnal interval are displayed in Table 1a and b for the 1994 and 2010/2011 regressions, respectively. The residuals of each fit are shown in Fig. 2, with the 2011 data set showing an average of 2.1 µmol kg$^{-1}$ in the more stable deeper waters (> 2000 dbar). In comparison, the WOCE ’94 A17 data set shows a deep-water (> 2000 dbar) column average residual of 3.17 µmol kg$^{-1}$, which we attribute to less precise measurements in the earlier data set. Pressure was included in the regression to avoid skewing (over depth) of the residuals of the MLR by the relatively large amount of samples located towards the surface, as mentioned by Hauck et al. (2010).
Table 1a. Calculated coefficients for the performed multi linear regressions for each density interval using the (a) GEOTRACES-NL (2010/2011) data set and (b) WOCE ’94 A17 data set. Differences between the coefficients were calculated following Eq. (2).

3.1.2 $C_{ant}$ from $\phi C_T^\circ$

The $\phi C_T^\circ$ method is a back-calculation approach that uses stoichiometric ratios from biogeochemical processes to account for the addition of DIC in the water column resulting from organic matter remineralization and calcium carbonate dissolution since the time of water formation (Vázquez-Rodríguez, 2008; Vázquez-Rodríguez et al. 2009a). It is based on the general principle of “preformed DIC” (or $C_T^\circ$) of Brewer (1978) and $\Delta C^*$ of Gruber et al. (1996). The main advantage of this method is that it considers the non-steady state of $A_T$ and $pCO_2$ in the subsurface reference layer.

3.2 Buffer factors

The Revelle factor was originally described by Revelle and Suess (1957) and quantified the attenuated response of increasing DIC impacted by increasing $pCO_2$, or vice versa. This work has been built upon by Egleston et al. (2010), who outlined six expressions that define how $[CO_2]$, $[H^+]$, and $\Omega_{Ar}$ or $\Omega_{Ca}$ are impacted by changes in DIC or $A_T$.

The following three expressions for the buffer factors relating to DIC were applied to the GEOTRACES-NL (2010/2011) and WOCE ’94 A17 southwestern Atlantic sections (Eqs. 3–4 and 6–7 are taken from Egleston et al., 2010; however, Eqs. 5 and 8 are taken from Álvarez et al., 2014, who identified and corrected a typo in the definitions of Egleston et al., 2010).
Heuven, 2011a) using the same input conditions as previously used for the calculations were obtained from CO2SYS (ω and ρ).

4 Hydrography of the South Atlantic Ocean

The distributions of potential temperature, salinity, AOU, silicate, and DIC of the GEOTrace-NL (2010/2011) section are shown in Fig. 3. The large water masses have been described elsewhere (Mémerly et al., 2000; Ríos et al., 2010; Wanninkhof et al., 2010); thus the treatment is relatively concise here. Located deeper than 4500 dbar throughout the section is Antarctic Bottom Water (AABW), characteristic in its high DIC and AOU. Values for DIC in this water mass range from 2243 to 2267 µmol kg⁻¹, and AOU values occupy a narrow band between 111 and 128 µmol kg⁻¹. The DIC maximum (2267 µmol kg⁻¹) and potential temperature minimum (−0.16°C) are both found in this water mass, which also shows the deep-water (> 1000 dbar) A_T maximum (2369 µmol kg⁻¹). These characteristics are all representative of the old age of the water mass and are caused by the large amount of organic matter remineralization which has taken place within it. The AABW can most easily be distinguished from the overlying lower Circumpolar Deep Water (CDW) by the high silicate concentrations, which reach values greater than 120 umol kg⁻¹ in AABW. Silicate con-
centrations in the deep waters (> 4000 dbar) demonstrate a strong covariance with $A_T$ ($R^2 = 0.95$), which has been previously noted and stems from the simultaneous dissolution of opaline and calcium carbonate shells from the hard tissue of organisms (Pérez et al., 2002).

The CDW has a core at approximately 3500 dbar at 50° S, above which it merges into uCDW, with its respective core identified by an oxygen minimum at approximately 1500 m (Mémer et al., 2000). Both branches of CDW display properties similar to that of AABW, as they represent a mixture of AABW and Weddell Sea Deep Water (Wong et al., 1999; Orsi et al., 1999). The uCDW and lCDW share isopycnals with upper North Atlantic Deep Water (uNADW) and lower North Atlantic Deep Water (lNADW), respectively, in the northern half of the section (Fig. 3a). The uCDW and uNADW occupy the density band between $\sigma_T > 27.4$ and $\sigma_T < 41.47$, with the front between the two water masses found at approximately 26° N (Mémer et al., 2000). The NADW has been more recently ventilated than CDW and is thus distinguished by lower AOU values of $\sim 60$ µmol kg$^{-1}$ and DIC values lower than 2200 µmol kg$^{-1}$. The deeper lNADW can be separated from uNADW through higher silicate values, which rise to 40 µmol kg$^{-1}$, whereas uNADW has maximum silicate concentrations of 20 µmol kg$^{-1}$ (Fig. 3d). The $A_T$ values are also lower ($\sim 20$ µmol kg$^{-1}$) in uNADW compared to lNADW.

The AAIW enters the section at 200 dbar just south of 48° S, identifiable as a tongue of water with very low salinity and $A_T$ (34.05 and 2275 µmol kg$^{-1}$, respectively, Fig. 3b). The AAIW lies above uCDW and below SAMW (Peterson and Whitworth, 1989). This water mass is carried northward at intermediate depths between $\sigma_T > 27.1$ and $\sigma_T < 27.4$ (Ríos et al., 2012) from south of the SAF. In the southwestern Atlantic Ocean, AAIW extends further north than in other oceans, due to the western boundary current along the coast of South America (Talley, 1996). The AAIW is a relatively young water mass and has AOU values comparable to NADW ($\sim 50$–100 µmol kg$^{-1}$); however, it can be distinguished from uNADW, in its northward reaches, by its elevated silicate concentrations. Situated above the AAIW, the SAMW is often considered a component of the AAIW (Cartney, 1977), where deep winter mixing forms this high-oxygen water mass.

We locate the STF at $\sim 41°$ S, where there is a steep gradient in salinity in the surface 200 dbar. North of the STF, in the surface, and extending northward to a density of $\sigma_T < 26.5$ kg m$^{-3}$, is South Atlantic Central Water (SACW; Ríos et al., 2012), heavily depleted in silicate and with elevated salinity and $A_T$. Against this background, the two Amazon plumes are very distinct at 5 and 15° N, with salinity values of 34.11 and 32.3 and $A_T$ values of 2265 and 2157 µmol kg$^{-1}$, respectively. The maximum values of both salinity and $A_T$ correspond to SACW in the subtropics (17° S), reaching absolute maxima of 37.5 and 2456 µmol kg$^{-1}$, respectively, at 50 dbar depth. The subtropical part of the SACW that features high salinity and $A_T$ is often referred to as the Salinity Maximum Water (SMW). In this study we make no distinction between SMW and SACW.

5 Results and discussion

5.1 Anthropogenic carbon in the southwestern Atlantic Ocean

The distribution of C$_{ant}$ in 2011, calculated using the $\phi C_T$° method (Vázquez-Rodríguez, 2009a), and the calculated increase in C$_{ant}$ (ΔC$_{ant}$) from 1994 to 2011, obtained from an eMLR analysis, are shown in Fig. 4a and b, respectively. Both distributions show good consistency with previous studies (Ríos et al., 2010, 2012; Wanninkhof et al., 2010) and are not dissimilar from each other, with areas of high C$_{ant}$ also demonstrating the highest ΔC$_{ant}$ from 1994 to 2010/2011. The total C$_{ant}$ (Fig. 4a) values show an increase in the surface waters compared to that of Ríos et al. (2010), calculated from the WOCE ’94 A17 data set, which is consistent with the calculated ΔC$_{ant}$ presented here (Fig. 4b). The general pattern is that, from 1994 to 2011, the most evident increase in C$_{ant}$ occurred in the upper 1000 dbar, particularly in the southern half of the section, with the ΔC$_{ant}$ increasing towards the surface. The atmosphere is the main source of C$_{ant}$ to the ocean; thus it follows that the waters most recently in contact with the atmosphere will show the greatest ΔC$_{ant}$. Within the surface waters (< 100 dbar) of the section the ΔC$_{ant}$ gradually decreases northwards in a linear relationship with latitude ($R^2 = -0.74$) to a concentration of 0 µmol kg$^{-1}$ just north of the Equator ($\sim 5°$ N). Despite containing large quantities of C$_{ant}$ (Fig. 4a), low ΔC$_{ant}$ values (< 5 µmol kg$^{-1}$) have been previously noted in the tropical Atlantic region, to a depth of 200 dbar, similar to that observed here (Schneider et al., 2012). The same authors (Schneider et al., 2012) have suggested that greater precipitation in the Intertropical Convergence Zone can cause errors in the surface C$_{ant}$ determinations in the tropical Atlantic, due to the related increase in Revelle factor. In the section presented here the Amazon outflow can also be seen in salinity values; thus a variation in freshwater input may also contribute to errors in the method.

The largest increase (up to 37 µmol kg$^{-1}$) in surface waters was found in the SAZ, just south of 45° S, in agreement with the findings of Wanninkhof et al. (2010). The steepest vertical gradient of ΔC$_{ant}$ is found in the same region, at $\sim 47°$ S just north of the SAF, where over a depth range of 0–600 dbar the ΔC$_{ant}$ decreases from 37 to 0 µmol kg$^{-1}$.

Further north, the deepest penetration of positive ΔC$_{ant}$ val-
ues in the southern half of the section is found at 1200 dbar in the SubTropical Zone (STZ), between 25 and 40° S. The $\Delta C_{\text{ant}}$ zero-contour shoals southward of 35° S to ~600 dbar at 50° S, coinciding with the lower limits of AAIW, as has been noted in other ocean basins (Sabine et al., 2004). In the northern half of the section, the deepest limit of $\Delta C_{\text{ant}}$ penetration in AAIW reaches a depth of ~700 dbar at 15° S, and north of the Equator the AAIW signal becomes distorted as it mixes with NADW. The NADW shows near-zero concentrations of $\Delta C_{\text{ant}}$ throughout its extent, with the exception of the uNADW in the equatorial region, which shows $\Delta C_{\text{ant}}$ values up to 5 µmol kg$^{-1}$. In lNADW and the other deep and bottom waters (AABW, lCDW), $\Delta C_{\text{ant}}$ shows no change or a tendency towards negative values.

To estimate the rate of increase in $C_{\text{ant}}$ in each water mass, we identified their respective cores (Fig. 3b) using the water mass descriptions given in Mémery et al. (2000) and Ríos et al. (2012) and averaged their values.
we corrected our $\Delta C_{\text{ant}}$ value for the additional DIC increase caused solely by atmospheric increases over the last 6 years. The resulting calculated $C_{\text{ant}}$ increase rate was $0.92 \pm 0.14 \mu$mol kg$^{-1}$ yr$^{-1}$, making our result consistent with the previous estimate. As such, we attribute the difference in calculated $\Delta C_{\text{ant}}$ increase rates in SACW to the increase in DIC driven by higher atmospheric $p$CO$_2$ concentrations in 2010/2011.

Despite the similarities in formation history between SAMW and AAIW, the latter shows a much lower $C_{\text{ant}}$ increase rate of $0.37 \pm 0.06 \mu$mol kg$^{-1}$ yr$^{-1}$. The discrepancy between the $C_{\text{ant}}$ increase rates in these two water masses is in line with the differences in air–sea CO$_2$ flux in the region (McNeil et al., 2007). In the SAZ a combination of biological production and temperature variability leads to a large seasonal signal of $p$CO$_2$. The SAMW is formed in the SAZ, where there is high biological production in spring and summer and wintertime cooling of surface waters. The wintertime cooling effect on the solubility of CO$_2$ is sufficient to counteract the increase in DIC from mixing, resulting in a strong year-round CO$_2$ sink. South of the SAF, where AAIW is formed, similar processes operate; however, the biological production is lower, and convective wintertime mixing brings up high-DIC waters, thus reducing the CO$_2$ sink (McNeil et al., 2007). It has also been shown that the formation rate of AAIW in the Indian Ocean is less than that of SAMW, which facilitates more efficient sequestration of $C_{\text{ant}}$ by the latter (Hartin et al., 2011).

Modest increase rates of $0.33 \pm 0.07$ and $0.20 \pm 0.03 \mu$mol kg$^{-1}$ yr$^{-1}$ were calculated for $\nu$CDW and $\nu$NADW, respectively. Both these water masses have been fairly recently ventilated, allowing modest increases in $\Delta C_{\text{ant}}$. The increase rate for $\nu$NADW is in line with values found by Perez et al. (2010). Due to the very low $\Delta C_{\text{ant}}$ values found in NADW and CDW, their respective increase rates are not significant and are not discussed further. In contrast to our calculated $\Delta C_{\text{ant}}$, a number of studies have found increasing concentrations of $C_{\text{ant}}$ in AABW (Murata et al., 2008; Vázquez-Rodríguez et al., 2009a; Brown et al., 2010). However, it has been noted previously that it is absent in eMLR analyses (Wanninkhof et al., 2010). The distributions of $C_{\text{ant}}$ in AABW presented in Vázquez-Rodríguez et al. (2009a) also indicate that $C_{\text{ant}}$ concentrations have not yet spread further north than 50°S, potentially explaining its absence in our analysis.

### 5.2 Associated changes in pH

Assuming no changes in $A_T$ between the WOCE ’94 A17 and GEOTRACES-NL (2010/2011) occupations, we use the $\Delta C_{\text{ant}}$ calculated by eMLR and the measured $A_T$ during GEOTRACES-NL (2010/2011) to calculate the anthropogenically driven change in pH from 1994 to 2011 ($\Delta$ pH$^{1994-2011}$). From the application of the $\phi C_T^0$ method of anthropogenic carbon determination (Sect. 2.3.2) to the

![Figure 4. Distribution of $C_{\text{ant}}$ ($\mu$mol kg$^{-1}$) calculated using the $\phi C_T^0$ method with the GEOTRACES-NL (2010/2011) data set (top); distribution of $\Delta C_{\text{ant}}^{1994-2011}$ ($\mu$mol kg$^{-1}$), calculated using the eMLR approach (middle); and the distribution of the $\Delta$ pH$^{1994-2011}$ associated with $\Delta C_{\text{ant}}$ (bottom). The aragonite saturation horizon (Ω2Ar) is marked for pre-industrial times (solid line), 1994 (dashed line) and 2011 (dotted line).](image-url)
WOCE ’94 A17 data set, we obtain the total $C_{\text{ant}}$ signal from pre-industrial times to 1994 (Fig. 4a). The $C_{\text{ant}}$ value allows the calculation of the decline in pH, which has been caused by increasing $C_{\text{ant}}$ during this time period (from pre-industrial times to 1994: $\Delta pH^{1994}$). The average surface (< 250 dbar) $\Delta pH^{1994}$ across the section was $-0.08$, which is just under the predicted general surface ocean decrease of 0.1 (Orr et al., 2005). The ocean interior experienced relatively small $\Delta pH^{1994}$; however, the change was accompanied by a significant shoaling of the aragonite saturation horizon, most notably in the southern half of the section (Fig. 4c). From pre-industrial times to 1994, south of the SAF, at ~ 49°S, the aragonite saturation horizon rose by ~ 250 m, whereas further north, at 25°S, it rose just 200 m. The change was almost imperceptible north of the Equator. From 1994 to 2011, $\Delta pH^{1994−2011}$, there is a further decline of 0.03 units, marking the total surface $\Delta pH^{2011−1994}$ of 0.11 units since pre-industrial times. Thus, of the total decrease since pre-industrial times to the present day, 27% occurred within the past 17 years. However, we can detect no notable change to the aragonite saturation horizon over the past 17 years (Fig. 4c). Historically, the uptake of $C_{\text{ant}}$ by the surface ocean was relatively gradual, which allowed it to be well distributed throughout the water column. In contrast, the effects of the more recent, steeply increasing anthropogenic acidification have not yet significantly penetrated into the deeper ocean.

The distribution of $\Delta pH^{1994−2011}$ across the section broadly follows the $C_{\text{ant}}$ increases (compare Fig. 4b, c), as expected under the assumption of constant $A_T$. By assuming a constant decrease over the 17 years, the yearly acidification rates are calculated from $\Delta pH^{1994−2011}$ and identified for each water mass core, as done for the yearly $C_{\text{ant}}$ increases (Table 2). The highest rates of acidification were found in the surface waters, where we also observe the greatest rates of $C_{\text{ant}}$ increase, with SACW showing a rate of pH decrease of 0.0016 yr$^{-1}$. The latter value is in line with that calculated for the same water mass on the eastern side of the North Atlantic Ocean at the ESTOC site (0.0017 yr$^{-1}$) for the period 1995 to 2004 (Santana-Casiano et al., 2007; González-Dávila et al., 2011). The SAMW demonstrates the next greatest rate of decline of 0.0014 yr$^{-1}$, followed by AAIW and $u$CDW both showing acidification rates of 0.001 yr$^{-1}$, which are comparable with values from other recently ventilated water masses in the North Atlantic: acidification rates of 0.0019 and 0.0012 yr$^{-1}$ have been reported for SAIW and SPMW, respectively (Vázquez-Rodríguez et al., 2012). The lowest non-zero acidification rate of 0.0005 yr$^{-1}$ is found in $u$NADW.

### 5.3 Buffering capacity

The continuing uptake of atmospheric CO$_2$ gradually depletes the naturally available carbonate ion in the surface ocean, thereby decreasing the capacity to “buffer” further CO$_2$ uptake and leading to the gradual acidification of the seawater. The extent to which the pH is affected by the increase in DIC is dependent upon several properties, including temperature, pressure and $A_T$, which together determine the buffering capacity of the water. As DIC increases, assuming no other changes take place, the buffering capacity of the water is reduced as [CO$_2^-$] decreases and [CO$_2$] increases. The $A_T$ is not altered by the flux of atmospheric CO$_2$ into the ocean. However, $A_T$ is affected by biological processes, notably the dissolution and formation of calcium carbonate, with dissolution dominating in deep waters and formation playing a more important role in the surface. Table 2 quantifies the extent to which the calculated $\Delta C_{\text{ant}}$ has impacted pH in the water masses of the southwestern Atlantic Ocean. Examination of this table clearly shows that the rate of acidification per µmol kg$^{-1}$ of DIC is not equal between water masses. The SAMW, a relatively fresh, low-alkalinity water mass, has an acidification rate of $-0.0014$ yr$^{-1}$, which is 88% of that of SACW, a warmer, more saline water mass. However, the $C_{\text{ant}}$ increase rate of SAMW is only 54% that of SACW. The AAIW shows the same rate of acidification as $u$CDW; however, the increase in $C_{\text{ant}}$ in $u$CDW is 10% lower than that of AAIW. These differences can be attributed to the varying buffering capacities of the water masses.

The distributions of the Revelle factor and the sensitivities of $[\text{H}^+]/[\text{DIC}]$, $[\text{CO}_2]/[\text{DIC}]$ and $\Omega_{\text{CaCO}_3}$ ($\omega$DIC) to changes in DIC for the southwestern Atlantic are shown in Fig. 5 and given per water mass in Table 3. The highest buffer factors, which indicate the greatest sensitivities to increasing DIC (denoted by low values in Fig. 5b, c, and high values in d) were generally found in the deep waters. That is to say that, for a given increase in DIC, these waters will show large resultant changes in $[\text{H}^+],[\text{CO}_2]$ and $[\text{CO}_2^{-}]$, or aragonite and calcite saturation ($\Omega_{\text{Ar}}, \Omega_{\text{Ca}}$). Both $u$CDW and $l$CDW show very similar behaviour – as expected from their similar history – however, interestingly, there is a notable difference between the buffering capacities of the two limbs of NADW. The difference is most noticeable in $\omega$DIC, likely caused by the slightly higher $A_T$ / DIC ratio in $l$NADW. A lower $\beta$DIC in $u$NADW denotes a greater sensitivity to acidification in response to increasing DIC concentrations. More rapid acidification in $u$NADW compared to $l$NADW has been observed by Vázquez-Rodríguez et al. (2012) and attributed to mixing with Labrador Sea Water (LSW), which exhibits a strong decreasing pH trend with time. The lower pH of LSW and its contribution to $u$NADW could account for the reduced buffering capacity calculated in this water mass in the southwestern Atlantic Ocean.

The lowest Revelle factor and highest $\beta$DIC values are found in SACW, closely followed by SAMW, which despite containing large concentrations of $C_{\text{ant}}$, both have relatively low concentrations of DIC compared to the other water masses. The SACW and SAMW also have higher concentrations of $A_T$ giving them greater buffering capacity. The three water masses with the greatest response in pH relative to $\Delta C_{\text{ant}}$ were AAIW, $u$CDW and $l$CDW, with $\beta$DIC...
Table 3. The average water mass values of salinity and potential temperature, with accompanying average buffering capacity values ($\gamma$DIC, $\beta$DIC, $\omega$DIC and Revelle factor) calculated using the GEOTRACES-NL (2010/2011) data set. Water masses are determined using the same criteria as given in Table 2.

Figure 5. Distribution of the Revelle factor across the section (top left) and the three buffering factors relating to DIC: $\beta$DIC (top right), $\gamma$DIC (bottom left) and $\omega$DIC (bottom right). The latter three are all given in mmol kg$^{-1}$.

values of 0.148, 0.141 and 0.143 mmol kg$^{-1}$, respectively. These water masses show the highest DIC / $A_T$ ratios along the section as they all originate in the Southern Ocean (SO), where upwelling brings deep waters rich in [CO$_2$(aq)] and low in [CO$_3^{2-}$] to the surface. In addition, these waters have slightly lower salinities and thus lower borate concentrations, which further diminish their buffering capacity, also reflected in the high Revelle factors (Fig. 5a). For the same DIC value, the buffering capacity of AAIW is substantially lower than that of uCDW stemming from the low $A_T$ of AAIW, which is also reflected in the high $\omega$DIC values. With the current calculated rate of increase in $C_{ant}$, aragonite will become undersaturated in AAIW around the year 2100, when DIC concentrations reach 2208 µmol kg$^{-1}$. This could happen even sooner, as wintertime, storm-driven upwelling entrainment of deep waters into the surface in the SO is predicted to cause seasonal aragonite undersaturation in the region as soon as 2030, when atmospheric CO$_2$ levels reach ~ 450 ppm (McNeil and Matear, 2008).

5.4 Continued $C_{ant}$ increase

The buffering capacity of each water mass will be reduced by increasing the DIC concentrations. To investigate how the buffering capacities of the different water masses in this section have changed over time, and how they will continue to change, the DIC buffer factors of each water mass were calculated and plotted against DIC concentration (Fig. 6). Due to the large relative error of the calculated $\Delta C_{ant}$ increases in the deeper waters, these were not included. The high rate of uptake of $C_{ant}$ by SACW means that this water mass has seen the largest decrease in buffering capacity since pre-industrial times. The $\beta$DIC value has decreased from 0.281 to 0.247 mmol kg$^{-1}$ and $\Omega_{Ar}$ has decreased from 4.1 to 3.3. In contrast, uCDW has shown relatively little change due to the low values of $C_{ant}$. However, extrapolating our calculated $C_{ant}$ rates of increase, we predict a 33 µmol kg$^{-1}$ increase in this water mass over the next century, which will result in a significant reduction in buffering and a pH decrease of
—0.102. The buffering capacities of SAMW and AAIW follow a similar pattern to each other; however, SAMW contains a greater proportion of subtropical water than AAIW, and thus it maintains a slightly higher buffering capacity than AAIW. Both AAIW and υCDW will see a similar increase in C\textsubscript{ant} over the next century (37 and 33 µmol kg\textsuperscript{-1}, respectively); however, the decline in Ω\textsubscript{Ar} will be 1.6 times greater in AAIW, due to higher ωDIC values. The SAMW will see approximately 54% of the increase in C\textsubscript{ant} that SACW will experience; however, it will undergo 84% of the associated pH decline. These extrapolated predictions highlight the vulnerability of SAMW and AAIW to increasing C\textsubscript{ant}, as also noted by Gonzalez-Davila et al. (2011).

The observed pattern of ΔC\textsubscript{ant} in the southwestern Atlantic clearly identifies the SAZ as the most effective entry point of C\textsubscript{ant} into the ocean. In addition, the buffering factors of Egleston et al. (2010) explicitly show that by, the end of this century, the two dominant water masses in this area (SAMW and AAIW) will be the most sensitive to further C\textsubscript{ant} increases. Whilst it is clear that this will accelerate the rate of acidification in these water masses, it is unclear how it will affect the CO\textsubscript{2} uptake in the SAZ. Assuming no changes to primary production, the increased sensitivity of SAMW to DIC changes will lead to much greater seasonal variability in the carbonate system of this water mass between the productive and non-productive period. The biological uptake of DIC in the SAZ in austral spring and summer would lead to a more dramatic decrease in surface water ρCO\textsubscript{2}, allowing a greater air–sea ρCO\textsubscript{2} flux. Conversely, the acidification and decline in Ω\textsubscript{Ar} may be detrimental to calcifying organisms in the area, as observed in the Southern Ocean (Bednarsek et al., 2012), thus limiting export via the biological pump.

The water masses SAMW and AAIW both risk further reduction in their buffering capacities by long-term variability to their physical properties. On decadal timescales a freshening of AAIW has been observed in the Pacific and Indian sectors of the Southern Ocean (Wong et al., 1999). Decadal variability has also been noted in temperature, salinity and biogeochemical parameters of SAMW (Bindoff et al., 2007; Álvarez et al., 2011), which could further diminish or enhance the buffering capacity of this water mass and thus the C\textsubscript{ant}-driven acidification. Variations on decadal timescales have been related to the Southern Annular Mode, the dominant climate forcing over the region (Lovenduski et al., 2007; Álvarez et al., 2011). Similarly in the North Atlantic, the North Atlantic Oscillation exerts a degree of control over the carbonate system variables and C\textsubscript{ant} uptake (Santana-Casiano et al., 2007; Pérez et al., 2010). Such external controls will cause irregular C\textsubscript{ant} uptake over time, as was observed by Brown et al. (2010), making it difficult to accurately predict future C\textsubscript{ant} uptake and associated changes in the buffering capacity.

6 Conclusions

The continuing uptake of C\textsubscript{ant} in the southwestern Atlantic has been assessed through application of eMLR to two data sets collected in 1994 and 2011. The distribution of ΔC\textsubscript{ant} is comparable with previous studies of C\textsubscript{ant} accumulation in the region (Ríos et al., 2010). The largest increases are found in the SAZ, just north of the SAF, a previously identified substantial CO\textsubscript{2} sink (Metzl et al., 1999). The SACW (0.99 ± 0.14 µmol kg\textsuperscript{-1} yr\textsuperscript{-1}), SAMW (0.53 ± 0.11 µmol kg\textsuperscript{-1} yr\textsuperscript{-1}) and AAIW (0.36 ± 0.06 µmol kg\textsuperscript{-1} yr\textsuperscript{-1}) are responsible for the greatest C\textsubscript{ant} uptake, consistent with earlier studies showing them to be an effective pathway of C\textsubscript{ant} into the ocean interior (Álvarez et al., 2009). The lower extent of AAIW marks the greatest depth of penetration of C\textsubscript{ant} into the ocean in the past 17 years, indicating that future uptake will, similarly, be largely concentrated within the surface 1000 m.

The increase in C\textsubscript{ant} in the southwestern Atlantic has led to acidification of water masses. The calculated C\textsubscript{ant}-driven acidification is greatest in SACW, where a current rate of pH decline of 0.0016 yr\textsuperscript{-1} is found. However, the acidification response per µmol kg\textsuperscript{-1} increase in DIC is greatest in the intermediate and mode waters. We identify SAMW as the water mass with the greatest risk of rapid acidification in the future, due to a combination of its high C\textsubscript{ant} uptake and its
limited buffering capacity. AAIW, on the other hand, is more at risk of aragonite undersaturation due its low $\Delta T$ values and resultant high $\omega_{DIC}$ values. Continued increase in $C_{\text{ant}}$ at the current rate calculated will lead to aragonite undersaturation in the core of AAIW around the year 2100.

Acknowledgements. We thank the captains and crews of RV Pelagia and RRS James Cook. The Earth and Life Sciences division (ALW) of the Netherlands Organisation for Scientific Research (NWO) supported this research under project number 817.01.004. The research leading to these results was supported through the EU FP7 project CARBOCHANGE “Changes in carbon uptake and emissions by oceans in a changing climate”, which received funding from the European Commission’s Seventh Framework Programme under agreement no. 264879. We also thank M. Álvarez and an additional, anonymous referee for their helpful comments and suggestions.
